The most frequently used approach to read out cantilever deflections is optical beam deflection [15.32], because it is a comparatively simple method with an excellent lateral resolution. The schematic is shown in Fig. 15.7e.

The actual cantilever deflection Δx scales with the cantilever dimensions. Therefore, the surface stress $\Delta\sigma$ in N/m is a convenient quantity to measure and compare cantilever responses. It takes into account the cantilever material properties, such as the Poisson ratio ν, the Young's modulus E, and the cantilever thickness t. The radius of curvature R of the cantilever is a measure of bending, see (15.2). As shown in the drawing in Fig. 15.7e, the actual cantilever displacement Δx is transformed into a displacement Δd on the PSD. The position of a light spot on a PSD is determined by measuring the photocurrents from the two facing electrodes. The movement of the light spot on the linear PSD is calculated from the two currents I_1 and I_2 and the size L of the PSD by

$$\Delta d = \frac{I_1 - I_2}{I_1 + I_2}\frac{L}{2} \,. \tag{15.11}$$

As all angles are very small, it can be assumed that the bending angle of the cantilever is equal to half of the angle θ of the deflected laser beam, i. e., $\theta/2$. Therefore, the bending angle of the cantilever can be calculated to be

$$\frac{\theta}{2} = \frac{\Delta d}{2s} \,, \tag{15.12}$$

where s is the distance between the PSD and the cantilever. The actual cantilever deflection Δx is calculated from the cantilever length l and the bending angle $\theta/2$ by

$$\Delta x = \frac{\theta/2}{2} l \,. \tag{15.13}$$

Combination of (15.12) and (15.13) relates the actual cantilever deflection Δx to the PSD signal

$$\Delta x = \frac{l\Delta d}{4s} . \tag{15.14}$$

The relation between the radius of curvature and the deflection angle is

$$\frac{\theta}{2} = \frac{l}{R} , \tag{15.15}$$

and after substitution becomes

$$R = \frac{2ls}{\Delta d} , \tag{15.16}$$

or

$$R^{-1} = \frac{2\Delta x}{l^2} .$$

15.5.3 Miniaturized Piezoresistive Arrays

One of the drawbacks of cantilever array sensors is the bulky size of equipment required for optical cantilever deflection readout. Especially for the development of handheld devices one would prefer a more compact type of measurement electronics. This disadvantage can be overcome by employing another method for deflection detection involving the use of piezoresistor elements to determine bending. Since no alignment optics are required, the complete readout electronics for piezoresistive sensors easily fits in a portable box of typically 10 cm × 10 cm × 16 cm, including data acquisition and gas handling.

15.5.4 Membrane Surface Stress Sensors

Membrane-type surface stress sensors (MSS) were first described by *Yoshikawa* et al. [15.33]. Their application for medical sensing was reported in a publication by *Loizeau* et al. [15.34, 35]. MSS are also arranged in arrays and are mainly used for molecular detection in the gaseous phase. MSS have been microfabricated from silicon-on-insulator substrates and structured by deep reactive ion etching. The sensors consists of a round membrane with a diameter of typically 500 µm and a thickness of 2.5 µm, which serves as a platform for applying the sensing layer (typically a polymer layer similar to that used in cantilever array-based electronic noses). The preferred way of coating the membranes is inkjet spotting of polymer solution, but also spray-coating or spin-coating is applicable. The membrane is suspended by four sensing beams with integrated p-type piezoresistors, representing a full Wheatstone bridge (Fig. 15.8). The four piezoresistor bridges are wired in such a way that their responses add up, increasing the sensitivity by a factor of 4 as compared to piezoresistive cantilevers. Further geometrical enhancements reported by *Yoshikawa* et al. [15.36] allow one to increase the sensitivity of MSS by a factor of 100 compared the previous generation of piezoresistive cantilevers. p-Doped piezoresistors were fabricated using two subsequent doping processes (ion diffusion through Boron Silica Glass and implantation). The latter method features shallow resistors, which are very sensitive to surface stress changes. The measured signal pattern consists of the bending responses of an array of piezoresistive polymer-coated membranes due to exposure to volatile organic compounds (VOCs). Recent applications of MSS are described in [15.37–42].

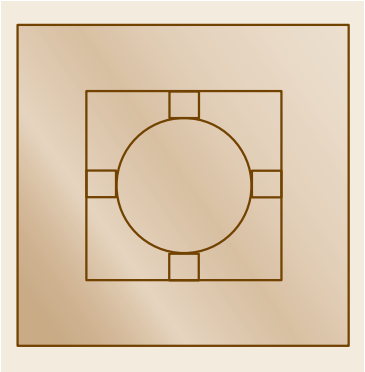

Fig. 15.8 Schematic representation of a membrane-type surface stress sensor (MSS). The actual diameter of the round membrane is 500 µm and its thickness is 2.5 µm. The membrane is suspended by four sensing beams with integrated p-type piezoresistors, representing a full Wheatstone bridge. A solid supporting frame holds the sensor. Several MSS can be arranged in an array

15.6 Functionalization Techniques

15.6.1 General Strategy

To serve as sensors, cantilevers have to be coated with a sensor layer that is either highly specific, i. e., is able to recognize target molecules in a key-lock process, or partially specific, meaning the sensor information from several cantilevers yields a pattern that is characteristic of the target molecules.

To provide a platform for specific functionalization, the upper surface of these cantilevers is typically coated

with 2 nm of titanium and 20 nm of gold, which yields a reflective surface as well as an interface for attaching functional groups of probe molecules, e.g., for anchoring molecules with a thiol group to the gold surface of the cantilever. Such thin metal layers are believed not to contribute significantly to bimetallic bending, particularly because the temperature is kept constant.

15.6.2 Functionalization Methods

There are numerous ways to coat a cantilever with material, both simple and more advanced ones. The method of choice should be fast, reproducible, reliable, and allow one or both of the surfaces of a cantilever to be coated separately.

Simple Methods

Obvious methods to coat a cantilever are thermal or electron beam-assisted evaporation of material, electrospray, or other standard deposition methods. The disadvantage of these methods is that they are only suitable for coating large areas, but not individual cantilevers in an array, unless shadow masks are used. Such masks need to be accurately aligned with the cantilever structures, which is a time-consuming process.

Other methods to coat cantilevers use manual placement of particles onto the cantilever [15.9, 20, 43–45], which requires skillful handling of tiny samples. Cantilevers can also be coated by directly pipetting solutions of the probe molecules onto the cantilevers [15.46] or by employing air-brush spraying and shadow masks to coat the cantilevers individually [15.47]. All these methods have only limited reproducibility and are very time-consuming if a larger number of cantilever arrays has to be coated.

15.6.3 Microfluidics

Microfluidic networks (μFN) [15.48] are structures of channels and wells, etched several tens to hundreds of micrometers deep into silicon wafers or glass. Also polymer replicas, typically from poly(dimethylsiloxane) (PDMS) may be used. The wells can be filled easily using a laboratory pipette, so that the fluid with the probe molecules for coating the cantilever is guided through the channels towards openings at a pitch matched to the distance between individual cantilevers in the array (Fig. 15.9a).

The cantilever array is then introduced into the open channels of the μFN that are filled with a solution of the probe molecules. The incubation of the cantilever array in the channels of the μFN takes from a few seconds (self-assembly of alkanethiol monolayers) to several tens of minutes (coating with protein solutions).

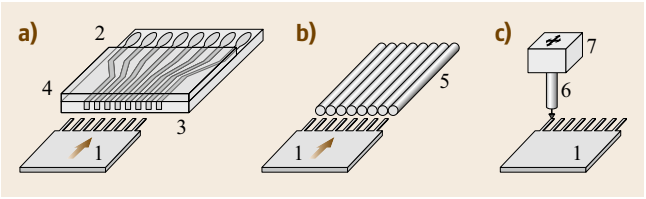

Fig. 15.9 (a) Cantilever functionalization in microfluidic networks. (b) Incubation in dimension-matched microcapillaries. (c) Coating with an inkjet spotter: 1 cantilever array, 2 reservoir wells, 3 microfluidic network with channels, 4 PDMS cover to avoid evaporation, 5 microcapillaries, 6 inkjet nozzle, 7 inkjet *x*-*y*-*z* positioning unit

To prevent evaporation of the solutions, the channels are covered by a slice of PDMS. In addition, the microfluidic network may be placed in an environment filled with saturated vapor of the solvent used for the probe molecules.

15.6.4 Array of Dimension-Matched Capillaries

A similar approach is insertion of the cantilever array into an array of dimension-matched disposable glass capillaries. The outer diameter of the glass capillaries used here is 240 μm so that they can be placed neatly next to each other to accommodate the pitch of the cantilevers in the array (250 μm). Their inner diameter is 150 μm, providing sufficient room to insert the cantilevers (width: 100 μm) safely (Fig. 15.9b). This method has been successfully applied for the deposition of a variety of materials onto cantilevers, such as polymer solutions [15.47], self-assembled monolayers [15.49], thiol-functionalized single-stranded DNA oligonucleotides [15.50], and protein solutions [15.51].

15.6.5 Inkjet Spotting

All of the above techniques require manual alignment of cantilever array and functionalization tool, and are therefore not ideal for coating a large number of cantilever arrays. The inkjet-spotting technique, however, allows rapid and reliable coating of cantilever arrays [15.52, 53]. An *x*-*y*-*z* positioning system allows a fine nozzle (capillary diameter: 70 μm) to be positioned with an accuracy of approx. 10 μm over a cantilever. Individual droplets (diameter: 60–80 μm, volume 0.1–0.3 nl) can be dispensed by means of a piezo-driven ejection system in the inkjet nozzle. When the droplets are spotted with a pitch smaller than 0.1 mm, they merge and form continuous films. By adjusting the number of droplets deposited on cantilevers,

the resulting film thickness can be controlled precisely. The inkjet-spotting technique allows a cantilever to be coated within seconds and yields very homogeneous, reproducibly deposited layers of well-controlled thickness. Successful coating of self-assembled alkanethiol monolayers, polymer solutions, self-assembled DNA single-stranded oligonucleotides [15.53], and protein layers has been demonstrated. In conclusion, inkjet spotting has turned out to be a very efficient and versatile method for functionalization, which can even be used to coat arbitrarily shaped sensors reproducibly and reliably [15.54, 55].

15.7 Applications

15.7.1 Chemical Detection

Hydrogen

Early reports on detection of gases such as hydrogen involved nanomechanical detection of catalytic reactions of bimetallic microcantilevers coated with aluminum and a top layer of platinum in thermal mode [15.9]. The catalytic reaction of oxygen present in a reaction chamber with hydrogen being introduced into the chamber produces oscillatory chemical reactions resulting in mechanical oscillations of the cantilever due to heat formation related to catalytic conversion of H_2 and O_2 to form H_2O. By use of an array of four platinum-coated and four uncoated microcantilevers, a change of the deflection signal due to bending of the platinum-coated cantilever relative to the uncoated cantilevers can be observed upon hydrogen adsorption in the presence of oxygen [15.11]. Similar responses were obtained with Pd-coated glass cantilevers [15.56] and with Pd-coated silicon microcantilevers using dynamic mode [15.57], capacitive readout [15.58] or beam-deflection readout in static mode [15.59].

Water Vapor

The first observation of microcantilever resonance frequency detuning was reported in [15.8]. A dependence on relative humidity of ZFM5 zeolites attached to resonating microcantilevers was observed in [15.60]. Relative humidity was measured with an accuracy of 1% using piezoresistive sensors embedded in polymer [15.61]. A detection limit of 10 ppm was achieved using Al_2O_3-coated microcantilevers [15.62].

Other Vapors

ZFM5 zeolites have been used to detect vapor of *p*-nitroaniline dye in dynamic mode with picogram sensitivity [15.60]. A freon gas sensor using a piezoelectric microcantilever coated with MFI zeolite was described in [15.63]. Ethanol vapor detection in dynamic mode was described in [15.64].

Alkane Thiol Vapors

Surface stress changes and kinetics were measured in situ during the self-assembly of alkanethiols on gold by means of a micromechanical sensor, observing scaling of compressive surface stress with the length of the alkane chain [15.13, 65]. 65 ppb of 2-mercaptoethanol have been measured evaluating the response of gold-coated silicon nitride microcantilevers [15.66]. The mechanism of stress formation upon adsorption of thiol layers has been studied by exposing monolayers of alkanethiols on gold to low-energy Ar ions, resulting in formation of a large tensile stress [15.67]. The influence of surface morphology and thickness of the gold coating of the cantilever was discussed in [15.68, 69]. A multiple-point deflection technique has been used to investigate stress evolution during the adsorption of dodecanethiol on microcantilever sensors, allowing one to assess the cantilever bending profile [15.70]. Using gold-coated, piezoelectric-excited, millimeter-sized cantilevers exposed to 1-hexadecanethiol (HDT) in ethanol, a detection range between 1 fM to 1 mM has been claimed [15.71]. The formation of alkanedithiol (HS-(CH)SH) monolayers on gold in solution has been monitored using microcantilever sensors [15.72]. The nanomechanical bending of microfabricated cantilevers during the immobilization of alkanethiols of different chain lengths has been investigated in the liquid phase [15.73].

Metal Vapors

Detection of mercury vapor was one of the first applications of microcantilever sensors in dynamic mode [15.10]. 20 ppb of Hg vapor was detected using a microcantilever with an integrated piezoelectric film [15.74]. A monolayer of 1,6-hexanedithiol has been identified as an unusually specific recognition agent for CH_3Hg^+ [15.75]. A 15 ppb detection limit for mercury was reported using microcantilevers that were thermally excited at the fundamental and first three higher order modes [15.76, 77]. Cs ion concentrations in the range of 10^{-11}–10^{-7} M were detected using a 1,3-alternate 25,27-bis(11-mercapto-1-undecanoxy)-26,28-calix[4]benzo-crown-6 caesium recognition agent bound to a gold-coated microcantilever [15.78]. The crown cavity is highly selective to Cs, as compared to K or Na. An atomic force microscope cantilever has been used as a bending-beam

sensor to measure surface stress changes which occur during electrochemical processes, such as the formation of a Pb layer on Au [15.79].

HF and HCN

Microcantilevers have been used as a gas sensor to detect hydrofluoric acid (HF) at a threshold of 0.2 ppm [15.80]. Femtomolar HF concentrations, which are also a decomposition component of nerve agents, were detected using an SiO_2 microcantilever. The high sensitivity was considered to be due to the reaction of HF with SiO_2 [15.81]. The etching rate was determined to be 0.05 nm/min for SiO_2 and 0.7 nm/min for Si_3N_4 [15.82]. Sensor responses towards HCN at a concentration of 150 ppm within seconds were reported [15.83].

Ion Sensing

Using microcantilevers coated with a self-assembled monolayer of triethyl-12-mercaptododecylammonium bromide on gold CrO_4^{2-} ions were detected at a concentration of 10^{-9} M. Other anions, such as Cl^-, Br^-, CO_3^{2-}, HCO_3^-, and SO_4^{2-} did not deflect such modified cantilevers significantly [15.84]. Hg^{2+} has been measured down to a concentration of 10^{-11} M using a microcantilever coated with gold. Almost no affinity to other cations exists, such as K^+, Na^+ Pb^{2+}, Zn^{2+}, Ni^{2+}, Cd^{2+}, Cu^{2+}, and Ca^{2+} [15.85]. Adsorption characteristics of Ca^{2+} ions as a function of concentration in aqueous $CaCl_2$ solution were investigated in static and dynamic mode [15.86]. Microcantilevers functionalized with metal-binding protein, AgNt84-6, have been shown to detect heavy metal ions like Hg^{2+} and Zn^{2+}, but were insensitive to Mn^{2+} [15.87]. Hydrogels containing benzo-18-crown-6 have been used to modify microcantilevers for measurements of the concentration of Pb^{2+} in aqueous solutions [15.88]. Using different thiolated ligands as self-assembled monolayers (SAMs) functionalized on silicon microcantilevers (MCs) coated with gold allows one to detect Cs^+, Co^{2+}, and Fe^{3+} [15.89]. A gold-coated microcantilever has been utilized as the working electrode to detect Cr(VI) [15.90]. Others used 11-undecenyltriethylammonium bromide [15.91] or sol-gel layers [15.92] for detection of Cr(VI). On the basis of the EDTA-Cd(II) complex and its binding capability to bovine serum albumine (BSA) an antibody-based Cd(II) sensor using microcantilevers has been presented [15.93].

Volatile Organic Compounds (VOC)

A microcantilever-based alcohol vapor sensor was described in [15.94]. It used the piezoresistive technique and a polymer coating. The authors also presented a simple evaporation model that allowed determination of concentration. The detection limit found was 10 ppm for methanol, ethanol, and 2-propanol. In [15.95], an integrated complementary metal oxide semiconductor (CMOS) chemical microsensor with piezoresistive detection (Wheatstone bridge configuration) using poly(etherurethane) (PEUT) as the sensor layer was presented. The authors were able to reversibly detect volatile organic compounds (VOCs) such as toluene, *n*-octane, ethyl acetate, and ethanol with a sensitivity level down to 200 ppm. An improved version of that device was described in [15.96]. The sensitivity was increased to 5 ppm for *n*-octane. Later, the technique was refined using electromagnetic rather than electrothermal actuation and a transistor-based readout reducing power dissipation on the cantilever [15.97]. Piezoelectric readout in dynamic mode and electromagnetic actuation of cantilevers spray-coated with PEUT was reported in [15.98], which achieved a sensitivity of 14 ppm for ethanol. In [15.99], a study on how to prepare polyethylene glycol (PEG)-coated microcantilever sensors using a microcapillary pipette-assisted method was reported. The PEG coating is suitable for ethanol sensing as ethanol quickly forms hydrogen bonds with the −OH groups of the PEG. Sensor operation was reported to be reversible and reproducible. In [15.100], artificial neural networks were used for analyte species and concentration identification with polymer-coated optically read-out microcantilevers. The analytes detected were carbon dioxide, dichloromethane, diisopropylmethylphosphonate (DIMP), dioxane, ethanol, water, 2-propanol, methanol, trichloroethylene, and trichloromethylene. In [15.101], the chemical sensing performance of a silicon resonant microcantilever sensor was investigated in dependence on the thickness of the sensitive coating. For a coating thickness of 1, 4, and 21 μm of PEUT a limit of detection of 30 ppm was found for ethanol. A new concept of a parylene micromembrane array for chemical sensing was presented in [15.102] using the capacitive method. The parylene membrane was suspended over a metal pad patterned on the substrate. The pad and part of the membrane that was metal-coated served as electrodes for capacitive measurement. The top electrode located on the membrane was chemically modified by application of a gold layer and self-assembled thiol monolayers (−COOH, $-CH_3$ and −OH) for detection of analyte molecules. Successful detection of 2-propanol and toluene was reported. In [15.103], a sensitive self-oscillating cantilever array was described for quantitative and qualitative analysis of organic vapor mixtures. The cantilevers were electromagnetically actuated and the resonance frequency was measured using a frequency counter. Sensor response was reproducible and reversible. Using

a PEUT coating the smallest measured concentration was 400 ppm, but the limit of detection was well below 1 ppm. In [15.104], a combination of gas chromatography with a microcantilever sensor array for enhanced selectivity was reported. Test VOC mixtures composed of acetone, ethanol, and trichloroethylene in pentane, as well as methanol with acetonitrile in pentane were first separated in a gas chromatography column and then detected using microcantilevers coated with responsive phases such as 3-aminopropyltriethoxy silane, copper phtalocyanine, and methyl-β-cyclodextrin. Analytes detected included pentane, methanol, acetonitrile, acetone, ethanol, and trichloroethylene. In [15.105], results were presented on independent component analysis (ICA) of ethanol, propanol, and DIMP using a cantilever coated with molecular recognition phases (MRP), whereby ICA proved its feature extraction ability for components in mixtures.

Toxins

Detection of the organochlorine insecticide compound dichlorodiphenyltrichloroethane (DDT) has been reported using a synthetic hapten of the pesticide as a recognition site conjugated with bovine serum albumin (BSA) covalently immobilized on the gold-coated side of the cantilever by using thiol self-assembled monolayers [15.106].

Explosives, Chemical Warfare, and Biohazards

Security measures require inexpensive, highly selective and very sensitive small sensors that can be mass-produced and microfabricated. Such low-cost sensors could be arranged as a sensor grid for large area coverage of sensitive infrastructure, such as airports, public buildings, or traffic infrastructure. Threats may be of chemical, biological, radioactive, or explosive nature. Microcantilever sensors are reported to offer very high sensitivities for explosives detection. Photomechanical chemical microsensors based on adsorption-induced and photo-induced stress changes due to the presence of diisopropyl methyl phosphonate (DIMP), which is a model compound for phosphorous-containing chemical warfare agents, and trinitrotoluene (TNT), an explosive, were reported [15.107]. Further explosives frequently used include pentaerythritol tetranitrate (PETN) and hexahydro-1,3,5-triazine (RDX), often also with plastic fillers [15.108]. These compounds are very stable, if no detonator is present. Their explosive power, however, is very large, and moreover, the vapor pressures of PETN and RDX are very low, in the range of ppb and ppt. By functionalizing microcantilevers with self-assembled monolayers of 4-mercaptobenzoic acid (4-MBA) PETN was detected at a level of 1400 ppt and RDX at a level of 290 ppt [15.109]. TNT was found to readily stick to Si surfaces, suggesting the use of microcantilevers for TNT detection, taking advantage of the respective adsorption/desorption kinetics [15.110, 111]. Detection of TNT via deflagration on a microcantilever was described by *Pinnaduwage* et al. [15.111]. They used piezoresistive microcantilevers where the cantilever deflection was measured optically via beam deflection. TNT vapor from a generator placed 5 mm away from the microcantilever was observed to adsorb on its surface resulting in a decrease of resonance frequency. Application of an electrical pulse (10 V, 10 ms) to the piezoresistive cantilever resulted in deflagration of the TNT vapor and a bump in the cantilever bending signal. This bump was found to be related to the heat produced during deflagration. The amount of heat released is proportional to the area of the bump in the time versus bending signal diagram of the process. The deflagration was found to be complete, as the same resonance frequency as before the experiment was observed. The amount of TNT mass involved was determined as 50 pg. The technique was later extended to the detection of PETN and RDX, where much slower reaction kinetics was observed [15.109, 112]. Traces of 2,4-dinitrotoluene (DNT) in TNT can also be used for detection of TNT, because it is the major impurity in production-grade TNT. Furthermore, DNT is a decomposition product of TNT. The saturation concentration of DNT in air at 20 °C is 25 times higher than that of TNT. DNT was reported detectable at the 300 ppt level using polysiloxane polymer layers [15.113]. Microfabrication of electrostatically actuated resonant microcantilever beams in CMOS technology for detection of the nerve agent stimulant dimethylmethylphosphonate (DMMP) using polycarbosilane-coated beams [15.114] is an important step towards an integrated platform based on silicon microcantilevers, which besides compactness might also include telemetry [15.115]. Cu^{2+}/l-cysteine bilayer-coated microcantilever demonstrated high sensitivity and selectivity toward organo-phosphorus compounds in aqueous solution. The microcantilever was found to undergo bending upon exposure to nerve agent simulant DMMP at concentrations as low as 10^{-15} M due to the complexation of the phosphonyl group and the Cu^{2+}/l-cysteine bilayer on the microcantilever surface [15.116, 117].

15.7.2 Biochemical Environment

pH

Control of pH is often important in biochemical reactions. Therefore, this section concerns measurement of pH using microcantilevers. The interfacial stress of self-assembled monolayers of mercaptohexadecanoic

acid and hexadecanethiol depends on pH values and ionic strength [15.49]. SiO_2 and silicon nitride microcantilevers were also found to exhibit a deflection dependency with pH when coated with 4-aminobutyltriethoxysilane, 11-mercaptoundecanoic acid and Au/Al-coated over a pH range between 2 and 12. Aminosilane-modified SiO_2/Au cantilevers performed robustly over a pH range between 2 and 8 (49 nm deflection/pH unit), while Si_3N_4/Au cantilevers performed well at a pH between 2 and 6 as well as between 8 and 12 (30 nm deflection/pH unit) [15.118]. Microcantilevers with poly(methacrylic acid) (PMAA) and poly(ethylene glycol) dimethacrylate coating were shown to be sensitive to pH changes [15.119]. Also hydrogel coatings were found to be sensitive to pH [15.120]. The dependence of the micromechanical responses to different ionic strength and ion species present in the aqueous environment was discussed in [15.121], highlighting the critical role of counter- and co-ions on surface stress.

Glucose

Glucose sensing via microcantilevers is achieved by coating the cantilevers with the enzyme glucose oxidase on gold [15.122] or via polyethyleneimine (PEI) conjugation [15.123]. Glucose concentrations between 0.2 and 20 mM could be detected [15.124]. In another study a detection range between 2 and 50 mM was reported for glucose. No signal was observed for fructose, mannose, and galactose [15.125].

Hydrogen Peroxide (H_2O_2)

Hydrogen peroxide is detected at the nM level using multilayer modified microcantilevers functionalized through a layer-by-layer nanoassembly technique via intercalation of the enzyme horseradish peroxidase. The magnitudes of bending were found to be proportional to the concentrations of hydrogen peroxide [15.126].

DNA, RNA

Specific DNA hybridization detection was observed via surface stress changes related to transduction of receptor-ligand binding into a direct nanomechanical response of microfabricated cantilevers without the need for external labeling or amplification. The differential deflection of the cantilevers was found to provide a true molecular recognition signal despite large responses of individual cantilevers. Hybridization of complementary oligonucleotides shows that a single base mismatch between two 12-mer oligonucleotides is clearly detectable [15.17]. The findings were confirmed or modeled by several groups [15.127, 128]. Hybridization in a complex nonspecific background was observed in a complement concentration range between 75 nM and 2 μM [15.50], following Langmuir model kinetics [15.129]. Enzymatic processes were directly performed on a microcantilever functionalized with DNA incorporating a Hind III restriction endonuclease site, followed by digestion with Hind III to produce DNA comprising a single-stranded end on the cantilever surface. Ligase was used to couple a second DNA molecule with a compatible end to the DNA on the cantilever [15.130]. Using gold nanoparticle-labeled DNA, microcantilevers have been used to detect DNA strands with a specific sequence in dynamic mode, whereby a concentration of 23 pM could still be detected, as well as a single base pair mismatch [15.131]. Whereby adsorption of thiol-functionalized single-stranded DNA is easily observed, hybridization cannot be observed if long hydrocarbon spacer molecules between single-strand DNA and the thiol anchor are used [15.132]. DNA hybridization was also observed using piezoresistive cantilevers [15.129, 133]. A different technique to read out the microcantilever deflections in an array was reported in [15.134]. There the optical beam deflection technique was combined with the scanning of a laser beam illuminating the cantilevers of an array sequentially. DNA hybridization has also been reported using polymer SU-8 cantilevers [15.135]. *Mukhopadhyay* et al. reported 20 nM hybridization sensitivity using piezoresistive cantilevers and DNA sequences with an overhang extension distal to the surface [15.136]. A larger array comprising 20 microcantilevers was described in [15.137]. Moreover, the authors presented integration of the array with microfluidics. Surface stress changes in response to thermal dehybridization, or melting, has been reported [15.138]. The dependence of salt concentration and hybridization efficiency was discussed in [15.139]. Two different DNA-binding proteins, the transcription factors SP1 and NF-kappa B were investigated in [15.140]. Phase transition and stability issues of DNA were discussed in [15.141]. Differential gene expression of the gene 1-8U, a potential marker for cancer progression or viral infections, has been observed in a complex background. The measurements provided results within minutes at the picomolar level without target amplification, and were sensitive to base mismatches [15.142].

Proteins and Peptides

Microfabricated cantilevers were utilized to detect adsorption of low-density lipoproteins (LDL) and their oxidized form (oxLDL) on heparin, and to detect adsorption of bovine serum albumine and Immunoglobuline G (IgG) [15.143]. In [15.144] the activity, stability, lifetime, and re-usability of monoclonal antibodies to myoglobin covalently immobilized onto microfabricated cantilever surfaces was investigated. Using

piezoresistive microcantilevers the interaction of anti-bovine serum albumin (a-BSA) with bovine serum albumin (BSA) was studied [15.145]. Continuous label-free detection of two cardiac biomarker proteins (creatin kinase and myoglobin) has been demonstrated using an array of microfabricated cantilevers functionalized with covalently anchored anti-creatin kinase and anti-myoglobin antibodies [15.51]. Label-free protein detection has been reported using a microcantilever functionalized with DNA aptamer receptors for Taq DNA polymerase [15.146]. Label-free detection of C-reactive protein (CRP) using resonant frequency shift in piezoresistive cantilevers was described in [15.147], utilizing the specific binding characteristics of CRP antigen to its antibody, which is immobilized with Calixcrown SAMs on Au. In [15.148], the authors discuss receptors on microcantilevers for serotonin that are insensitive to its biological precursor with a similar tryptophan structure. Using single-chain fragment antibodies instead of complete antibodies allowed the limit of detection to be lowered to concentrations of about 1 nM [15.149]. In [15.150], detection of prostate-specific antigen (PSA) and C-reactive protein was reported. Detection of the human oestrogen receptor in free and oestradiol-bound conformation can be distinguished [15.151]. The Ca^{2+} binding protein calmodulin changes its conformation in presence or absence of Ca^{2+} resulting in a microcantilever deflection change [15.152]. No effect was observed upon exposure to K^{+} and Mg^{2+}. Detection of activated cyclic adenosine monophosphate (cyclic AMP)-dependent protein kinase (PKA) was performed in dynamic mode employing a peptide derived from the heat-stable protein kinase inhibitor (PKI) in [15.153]. Detection of streptavidin at 1−10 nM concentration was reported using biotin-coated cantilevers in [15.154]. Using GST (glutathione-S-transferase) for detection of GST antibodies, a sensitivity of 40 nM was obtained [15.155]. A two-dimensional multiplexed real-time, label-free antibody-antigen binding assay by optically detecting nanoscale motions of two-dimensional arrays of microcantilever beams was presented in [15.156]. Prostate-specific antigen was detected at 1 ng/mL using antibodies covalently bound to one surface of the cantilevers. Conformational changes in membrane protein patches of bacteriorhodopsin proteoliposomes were observed with microcantilevers through prosthetic retinal removal (bleaching) [15.157]. Using an analog of the myc-tag decapeptide, binding of anti-myc-tag antibodies was reported [15.158].

Lipid Bilayers, Liposomes, Cells

Cantilever array sensors can sense the formation by vesicle fusion of supported phospholipid bilayers of 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) on their surface and can monitor changes in mechanical properties of lipid bilayers [15.159]. Liposomes are detected based on their interaction with protein C2A which recognizes the phosphatidylserine (PS) exposed on the surface of the liposome [15.160]. Individual *Escherichia coli* (*E. coli*) O157:H7 cell-antibody binding events using microcantilevers operated in dynamic mode have been reported [15.161]. The contractile force of self-organized cardiomyocytes was measured on biocompatible poly(dimethylsiloxane) cantilevers, representing a microscale cell-driven motor system [15.162]. Resonating cantilevers were used to detect individual phospholipid vesicle adsorption in liquid. A resonance frequency shift corresponding to an added mass of 450 pg has been measured [15.163].

Spores, Bacteria, and Viruses

Micromechanical cantilever arrays have been used for quantitative detection of vital fungal spores of *Aspergillus niger* and *Saccharomyces cerevisiae*. The specific adsorption and growth on concanavalin A, fibronectin, or immunoglobulin G cantilever surfaces was investigated. Maximum spore immobilization, germination, and mycelium growth was observed on the immunoglobulin G-functionalized cantilever surfaces, as measured from shifts in resonance frequency within a few hours, being much faster than with standard petri dish cultivation [15.164]. Short peptide ligands can be used to efficiently capture *Bacillus subtilis* (a simulant of *Bacillus anthracis*) spores in liquids. Fifth-mode resonant frequency measurements were performed before and after dipping microcantilever arrays into a static *B. subtilis* solution showing a substantial decrease in frequency for binding-peptide-coated microcantilevers as compared to that for control peptide cantilevers [15.165].

Medical

A bioassay of prostate-specific antigen (PSA) using microcantilevers has been presented in [15.166], covering a wide range of concentrations from 0.2 ng/ml to 60 µg/ml in a background of human serum albumin (HSA). Detection has been confirmed by another group using microcantilevers in resonant mode [15.167, 168]. The feasibility of detecting severe acute respiratory syndrome-associated coronavirus (SARS-CoV) using microcantilever technology was studied in [15.169] by showing that the feline coronavirus (FIP) type I virus can be detected by a microcantilever modified by feline coronavirus (FIP) type I antiviral antiserum. A method for quantification of a prostate cancer biomarker in urine without sample preparation using monoclonal antibodies was described in [15.170].

15.7.3 Microcantilever Sensors to Measure Physical Properties

Besides chemical and biochemical sensing, microcantilevers can also detect changes in physical properties of surrounding media, such as gas or liquid, or of layers deposited on the cantilever itself.

Density and Viscosity

A piezoelectric unimorph cantilever as a liquid viscosity-and-density sensor was tested using water-glycerol solutions of different compositions, whereby the resonance frequency decreased while the width of the resonance peak increased with increasing glycerol content [15.171]. The viscosity of complex organic liquids with non-Newtonian behavior was studied in [15.172] over a wide range from 10 to 500 mm^2/s. Simultaneous determination of density and viscosity of water-ethanol mixtures based on resonance curves of microcantilevers was reported in [15.173]. A detailed theoretical study of viscoelastic effects on the frequency shift of microcantilever chemical sensors was presented in [15.174]. Microcantilever deflection as a function of flow speed of viscous fluids was investigated in [15.175]. Viscosity of sugar solutions has been tested using microcantilevers [15.176].

Gas and Flow Sensing

Gas sensing not only involves chemical detection, but also pressure and flow sensing. *Brown* et al. [15.177] studied the behavior of magnetically actuated oscillating microcantilevers at large deflections and found hysteresis behavior at resonance. The amplitude at the actuation frequency changes, depending on pressure due to damping. The authors used cantilever-in-cantilever (CIC) structures, and observed changes in deflection as gas pressure was varied. At atmospheric pressure, damping is large and the oscillation amplitude is relative small and hysteresis effects are absent. At lower pressure, abrupt changes in the oscillation amplitude occur with changes in the driving frequency. Since the change of amplitude and driving frequency, at which they occur is pressure dependent, these quantities can be used for accurate determination of gas pressure, demonstrated in the range between 10^{-3} and 10^2 mbar. *Brown* et al. [15.178] emphasized that microelectromechanical system pressure sensors will have a wide range of applications, especially in the automotive industry. Piezoresistive-cantilever-based deflection measurement has major advantages over diaphragms. The pressure range has been extended to 15−1450 mbar by means of design geometry adaptation. *Su* et al. [15.179] presented highly sensitive ultrathin piezoresistive silicon microcantilevers for gas velocity sensing, whereby the deflection increased with airflow distribution in a steel pipe. The detection principle was based on normal pressure drag producing bending of the cantilever. The minimum flow speed measured was 0.07 m/s, which is comparable to classical hot-wire anemometers. *Mertens* et al. [15.180] have investigated the effects of temperature and pressure on microcantilever resonance response in helium and nitrogen. Resonance response as a function of pressure showed three different regimes, which correspond to molecular flow, transition regimes and viscous flow, whereby the frequency variation of the cantilever is mainly due to changes in the mean free path of gas molecules. Effects observed allow measurement of pressures between 10^{-2}−10^6 Pa. *Mortet* et al. [15.181] presented a pressure sensor based on a piezoelectric bimorph microcantilever with a measurement range between 0.1 and 8.5 bar. The resonance frequency shift was constant for pressures below 0.5 bar. For higher pressures the sensitivity was typically a few ppm/mbar, but depended on the mode number. *Sievilä* et al. [15.182] presented a cantilever paddle within a frame that operated like a moving mirror to detect displacements in the oscillating cantilever using a He/Ne laser in a Michelson interferometer configuration, whereby the cantilever acted as a moving mirror element in one path of the interferometer. A fixed mirror served as a reference in the other arm of the interferometer.

Thermal Expansion

The thermal expansion of TaO_xN_y thin films deposited on a microcantilever was measured to examine the residual stress and the thermal expansion coefficient by observing changes in radius of curvature [15.183]. Thermal drift issues of resonating microcantilevers were discussed in detail in [15.184].

Infrared

Microcantilevers can also be used as uncooled, microcantilever-based infrared (IR) imaging devices by monitoring the bending of the microcantilever as a function of the IR radiation intensity incident on the cantilever surface. The infrared (thermal) image of the source is obtained by rastering a single microfabricated cantilever across the image formed at the focal plane of a concave mirror [15.185–187]. The method was later refined such that photons are detected using the stress caused by photoelectrons emitted from a Pt film surface in contact with a semiconductor microstructure, which forms a Schottky barrier. The photo-induced bending of the Schottky barrier microstructure is due to electronic stress produced by photoelectrons diffusing into the microstructure [15.188]. The performance of IR imaging via microcantilevers has been enhanced by one-fold

leg and two-fold leg beam structures with absorber plates [15.189–191].

15.7.4 Recent Developments

More than two decades after the first reports on the use of cantilevers as sensors the field is still active with a substantial number of research groups working and publishing. A new trend is the integration of novel materials as sensing layers or the direct use of them as nanomechanical structures. Mass sensing in ultrahigh vacuum down to the yoctogram (10^{-24} g) range by employing a frequency-modulation mixing technique for the readout of a carbon nanotube resonator has recently been demonstrated by *Chaste* et al. [15.192]. Electrochemistry is reported to be a way to control the surface of a microcantilever biosensor [15.193], as the topography of the functionalized cantilever surface seems to influence the efficiency of detection [15.194]. In biochemical measurements the work by *Mukhopadhyay* et al. [15.195] represents major progress in reliable recognition of DNA by using modified versions of DNA like PNA (peptide nucleic acid) and LNA (locked nuclei acid) having different sugar backbones. Especially for detection of single base mismatches PNA and LNA produce more reliable results [15.196]. The effects of hydration might play an important role in DNA hybridization [15.197]. *Ndieyira* et al. [15.198] report on nanomechanical detection of antibiotic resistance in bacteria by observing antibiotic-mucopeptide binding, even in blood serum [15.199]. Significant progress in high-throughput screening with cantilever sensors combined with a DVD-ROM-based optical readout technique has been reported by the Boisen group [15.200]. Detection of femtomolar concentrations of oligonucleotides in a complex background of total cellular RNA extracts from cell lines without labeling or amplification has been achieved by *Mishra* et al. [15.201] giving the perspective of RNA pharmacokinetics, nucleic acid biomarker assays, and miRNA quantification for disease monitoring and diagnosis. *Huber* et al. [15.202, 203] demonstrated application of cantilever sensor arrays for detection of melanoma, based on the presence of a predominant mutation in the BRAF gene. Detection of this single-point mutation allows one to screen melanoma patients for eligibility for treatment with a specific drug which only works if this point mutation is present. Detection and monitoring of *Aspergillus niger* growth directly on an oscillating cantilever using the first two flexural resonance modes has been observed in [15.204]. Even single spore growth has been observed within 10 h and is reported in [15.205]. A very ingenious way to detect motility of bacteria has been described by *Longo* et al. [15.206]. They show that fluctuations (noise) in the *dc* signal of cantilevers onto which low numbers of bacteria have been attached, characterize their metabolism. The technique quantitatively screens (within minutes) the response of bacteria such as *Escherichia coli* and *Staphylococcus aureus* to antibiotics. Living bacteria produced larger cantilever fluctuations than bacteria exposed to antibiotics [15.207]. A major contribution to the problem of chemical sensitivity of cantilever sensors has been published by the Thundat group. By using photothermal spectroscopy molecules adsorbing on a bimetallic cantilever can be qualitatively identified [15.208]. The technique is even capable of distinguishing both anti and gauche conformers of EtOH based on wavelength-dependent cantilever deflections [15.209]. Deeper theoretical understanding of viscoelastic phenomena in vibrating nanostructures is described in [15.210].

15.8 Conclusions and Outlook

Cantilever-sensor array techniques have turned out to be a very powerful and highly sensitive tool to study physisorption and chemisorption processes, as well as to determine material-specific properties such as heat transfer during phase transitions. Experiments in liquids have provided new insights into such complex biochemical reactions as the hybridization of DNA or molecular recognition in antibody-antigen systems or proteomics.

Future developments must go towards technological applications, in particular to find new ways to characterize real-world samples such as clinical samples. The development of medical diagnosis tools requires an improvement of the sensitivity of a large number of genetic tests to be performed with small amounts of single donor-blood or body-fluid samples at low cost. From a scientific point of view, the challenge lies in optimizing cantilever sensors to improve their sensitivity to the ultimate limit: the detection of individual molecules.

Several fundamentally new concepts in microcantilever sensing are described in the recent literature, and these could help to achieve these goals: the issue of low quality factor of resonating microcantilevers in liquid has been elegantly solved by fabrication of a hollow cantilever that can be filled with biochemical liquids. Confining the fluid to the inside of a hollow cantilever also allows direct integration with conventional microfluidic systems, and significantly increases sensitivity by eliminating high damping and viscous drag

[15.211]. Biochemical selectivity can be enhanced by using enantioselective receptors [15.212]. Other shapes for micromechanical sensors like microspirals could be advantageous for biochemical detection [15.213]. Miniaturization of microcantilevers down to *true* nanometric dimensions, for example by using single-wall carbon nanotubes [15.214] or graphene sheets [15.215] will further increase sensitivity. Reports on optomechanical coupling to graphene-based oscillators via microwaves are already available [15.216]. Single-layer graphene films have also been applied as pressure sensors [15.217].

What is still lacking after two decades of development is the ease of use of cantilever array sensors. Complicated alignment and calibration procedures should be avoided and preparatory steps before measurement should be automatized. Functionalization and measurement protocols must be standardized, so that every user gets the same results when doing the same experiment. Array-to-array variability must be reduced and evaluation of results must be done in a transparent and reproducible way. We should still keep in mind that we are measuring with cantilever sensors an indirect mechanically transduced response and not a primary physical quantity. Nevertheless, nanomechanical cantilever array sensors offer possibilities to monitor molecular processes that are inaccessible or barely measurable using traditional techniques.

Acknowledgments. We thank R. McKendry (University College London, London, U.K.), J. Zhang, A. Bietsch, V. Barwich, M. Ghatkesar, T. Braun, F. Huber, N. Backmann, J.-P. Ramseyer, P. Oliva, H.R. Hidber, E. Meyer, and the late H.-J. Güntherodt (University of Basel, Basel, Switzerland) for valuable contributions and discussions, as well as U. Drechsler, M. Despont, H. Schmid, E. Delamarche, H. Wolf, R. Stutz, R. Allenspach, and P.F. Seidler (IBM Research, Zurich Research Laboratory, Rüschlikon, Switzerland). We are grateful for MSS collaboration with G. Yoshikawa, T. Akiyama, F. Loizeau, S. Gautsch, P. Vettiger, and Nico de Rooij. We acknowledge the continuous technical support from A. Tonin, R. Maffiolini (electronics workshop), H. Breitenstein, S. Martin and his crew (mechanical workshop) in the Department of Physics, University of Basel. We thank the Swiss Nanoscience Institute (SNI), NanoTera Program (projects 853_406, 20NA21_150957 and MSSdevices), the Cleven Foundation, and the Swiss National Science Foundation for financial support.

16. Microfluidic Devices and Their Applications

Aditya Aryasomayajula, Pouriya Bayat, Pouya Rezai, P. Ravi Selvaganapathy

Microfluidics and nanofluidics is a field of science that operates in the micrometer and nanometer scale. A microfluidic–nanofluidic device consists of components such as valves, pumps and mixers for manipulating and transporting the fluid at this scale. In this chapter we review the history, physics, fabrication methods and applications of microfluidics and nanofluidics. This interdisciplinary field has a wide range of application areas including environmental sensing, medical diagnostics, drug discovery, drug delivery, microscale chemical production, combinatorial synthesis and assays, artificial organs, and micropropulsion, microscale energy systems. The global market for microfluidic devices was estimated at around $3.1 billion dollars in 2015 and is expected to rise to $7.5 billion dollars by 2020. In the future, microfluidics and nanofluidics will see miniaturization and development of novel microfabrication techniques along with more sensitive detection methods and diagnosis of diseases in a point-of-care platform. Developments in the fundamental physics of fluid flow and its control, microfabrication methods, microfluidic components, and applications in new and emerging areas are all anticipated.

16.1 Preface

Microfluidics and nanofluidics are fields of study dedicated to the understanding of fluid flow in the micrometer (μm) to nanometer (nm) scales and the development of devices to manipulate liquids or gases in the microliter to femtoliter range. In order to put the dimensions in context, a human hair on average is about 100 μm thick and a strand in our genetic code, deoxyribonucleic acid (DNA) is about 2.5 nm thick. Unlike the macroscale, where inertial (bulk) forces and momentum dominate, fluid flow at the micro- and nanoscale is highly influenced by fluid drag, surface forces and interactions as well as other molecular-level effects [16.1]. The understanding of the fluid flow phenomena at these scale and the ability to fabricate micromechanical struc-

tures can be applied to develop components such as valves, pumps and mixers to handle such small volumes of fluid and process them in a defined sequence. These components can be combined to perform a sequence of unit operations such as filtration, mixing, heating–cooling, dilutions and others required for an assay or chemical production in what is called a micro total analysis system [16.2] (μTAS) or lab-on-chip (LoC) system. A well-known example of such an LoC system is the glucometer. The glucometer performs separation of plasma from whole blood, mixing of the plasma with a dried glucose oxidase enzyme on-chip, reaction of the glucose oxidase enzyme with glucose in the plasma and its subsequent coupling with redox compounds to electrochemically transduce the signal into an electrical current. All of these unit operations are performed in an automated way inside a flow cell coupled with the electrochemical sensing electrode and can analyze a single drop of blood from a patient with a high degree of reliability [16.3].

A more recent example of a nanofluidic device is a DNA analyzer called minION Mkl (Fig. 16.1). This device uses nanopore technology to sequence a single strand of DNA. It consists of a nanopore (≈ 2–20 nm diameter) that is electrically conducting. The presence of the DNA strand inside the nanopores, which can be pulled in by electric field, displaces some of the ions, which reduces the current. Since the pore is small, small stretches of DNA can have a unique modulation of the current through the pore, which can be sensed [16.4].

Apart from these specific examples, microfluidic devices have had significant impact in various bioanalytical and biomedical systems like microarrays, capillary electrophoresis, nucleic acid amplification devices, immunoassays, cell culture, biosorting, hemoanalysis, metabolic analysis, drug discovery assays, *in-vivo* and *in-vitro* drug delivery, artificial organs, medical and environmental sensors, microdispensers and inkjet print heads. The market for microfluidic devices was about $3.1 billion in 2015 and is expected to grow to $7.5 billion by 2020 [16.5].

Fig. 16.1 Oxford Nanopore Technologies Ltd minION Mkl device to sequence the single DNA strand. This device uses a nanopore (≈ 2–20 nm diameter) to measure the current of a single nucleotide for sequencing. (Courtesy of Oxford Nanopore Technologies Ltd)

16.1.1 Why Miniaturize?

There are several important reasons for the drive towards miniaturization of unit operations into a microfluidic format. The foremost among them is that through miniaturization all the unit operations can be packaged into a small form factor that could be completely automated and made portable. Automation can enable the use of these systems by the user without any specific training in the assay, which will then enable a broader and more widespread use. For instance, the Cepheid GeneXpert device [16.6] automates the process of cell lysis, DNA extraction, its amplification and detection so that assays for disease identification can be performed at any location, from hospital laboratories to rural regions and resource-poor settings, with equal ease and without skilled laboratory personnel.

The other main reason is the ability to parallelize many operations on one device thereby expanding the capabilities offered by the device by orders of magnitude. The advent of Affymetrix microarray technology [16.7], which used a photolithographic process employed in the electronic industry to synthesize a large number of unique nucleic acid strands closely spaced to each other in a microarray, has revolutionized biological analysis by analyzing protein compositional signatures of cells and other biological matrices.

Another unique advantage offered by miniaturization is the similar size of sensors and reaction chambers to that of a cell, which makes it possible to manipulate and sense proteins or nucleic acids at single-molecule resolutions. The example of the nanopore sensor [16.4] and its capability in reading a single strand of DNA is illustrative of this reason.

Miniaturized devices also consume significantly lower volumes of reagents, which can reduce the cost of assays and mean they can be manufactured at lower prices. They generally operate in the laminar flow regime, which is more convenient for handling, transporting and aliquoting small volumes of fluids and small objects such as cells. Furthermore, small operating volumes also offer faster processing and analysis times in assays that require heating or cooling such as nucleic acid amplification.

16.1.2 Advantages of Microfluidics and Nanofluidics

The microfluidic technology exploits the physical and chemical properties of fluids at the micrometer scale.

The advantages offered by this technology have led to the development of techniques with improved capabilities compared to the conventional methods. Chemistry and biology are the two primary areas where microfluidics has had a significant impact. Chromatography and electrophoresis were one of the earliest areas of research where microfluidic technology was applied. Microfluidics not only improved the sensitivity of these techniques but also reduced the overall reaction times significantly. This is due to the ability to inject extremely small sample volumes for separation through the tight integration of the sample injector with the separation column, which was not possible earlier. In addition, the low consumption of chemical compounds has reduced the cost of the overall method drastically. In biology, improved control of the microenvironment has made way for studying three-dimensional (3-D) cell culture, which was previously not possible. The operating scale in microfluidic technology makes it particularly suitable for studying cells, organisms, and bacteria. The high throughput and easy handling of microliter volumes has helped researchers to develop alternative methods like polymerase chain reaction (PCR) on a chip, and DNA sequencing and microfluidic sorting methods that are faster, more sensitive and consume fewer reagents when compared to the conventional methods.

One of the unique advantages of micro- and nanofluidic technology is the physical and chemical phenomenon that applies at this microscale. On-chip PCR for DNA amplification exploits the fast diffusion of chemical compounds and transfer of heat at the micrometer level. Microfluidic devices have a high surface area-to-volume ratio because surface tension dominates and reduces inertial and body forces. In digital microfluidic technology, droplets are formed using the surface tension property of liquids and droplet production is precisely manipulated using electric fields. This property is also useful in chip-based electrophoresis devices where Joule heating can be reduced, thereby increasing the performance, sensitivity and resolution of separation of compounds. High viscous forces inside microfluidic channels lead to laminar flow characteristics. This property is exploited to control particle location precisely and for defining electric field strength inside microfluidic channels. Cell sorting and electrotaxis devices are examples that make use of this property. The small size of the devices and channels means lower consumption of reagents, which is particularly useful in drug screening tests as it can lower the overall cost of the experiment. The ability to form thousands and millions of droplets in oil using droplet microfluidics technology where each droplet acts as a separate reaction chamber increases the throughput to a great extent and also makes it possible to carry out single-cell analysis. The rapid prototyping technique using low-cost soft lithography gives a high flexibility in designing devices. The high parallelization or multiplexing is useful for DNA sequencers. Small sample volumes along with high sensitivity enable this technology to detect trace amounts of target species efficiently. Microfluidics also offers the advantage of integrating different technologies onto one platform quickly.

Microfluidics is one of the fastest growing research areas with over 15 300 publications since 2015 (number of publications with the word *microfluidics* searched in Google Scholar). The broad application areas, including physics, chemistry, biology, environmental sciences and engineering, make it a very attractive area to investigate. Microfluidics also fosters a large interdisciplinary community, bringing people in different fields for the first time to interact and carry out research, thereby pushing the frontier of science forward. Microfluidics also has generated a billion-dollar revenue in the area of LoC, diagnostics and the drug screening/pharmaceutical industry, which is likely to grow bigger in the coming years. As is the norm in a fast-growing field, the central challenge in microfluidics is the lack of standardizationof techniques and components due to the diversity of users and applications. In the next sections of this chapter, the history of this field, the physical principles that govern in this technology, different fabrication methodologies, some examples of applications of this area and the outlook and future direction of microfluidics will be presented.

16.2 Historical Developments

Although flows in the micro- and nanoscale have been studied significantly far back in history, such as electroosmosis by *Reuss* in the early 1800s [16.8], they have been investigated as an aggregate phenomenon. The advent of technologies for miniaturization and its application to the fabrication of micromechanical structures such as microchannels kick-started the study of fundamental phenomena of fluid flow in these scales as well as their application in various domains. One of the early works was the application of the emerging silicon microfabrication technology in the early 1970s to fabricate high surface area microchannels for gas chro-

matography applications. *Terry* et al. [16.9] developed a microscale gas chromatography device with an inbuilt sensor, which was sensitive but not specific to gas detection, and used the same principle of a conventional gas chromatographer to separate gaseous hydrocarbon mixtures in less than 10 s. They demonstrated that high surface area columns can be fabricated and extremely long lengths can be fitted into a small form factor on a chip. They also proposed that miniaturization and integration of all the other components including preconcentrators and pump would make the device portable compared to the bulky conventional equipment.

Around the same time, inkjet printers were introduced [16.10] in the market that used microfluidic technology to print ink on paper. The inkjet cartridges have a tiny nozzle ($\approx 30-100\,\mu m$) through which the ink is forced out. The nozzles are fabricated in silicon using photolithographic approaches used in the electronic industry so that up to 600 nozzles can be placed in a single printhead in close proximity to each other, with each one individually connected to the ink reservoir through microfluidic channels. Today the inkjet printing market is worth $\approx$ \$900 million and projected to be over \$1 billion by 2021 [16.11].

Then in the early 1990s, a group of scientists led by *Stephen Fodor* invented the Affymetrix gene chip technology [16.12]. They used semiconductor manufacturing technologies to fabricate DNA microarrays that have millions of unique DNA recognition elements on a single glass chip. These microarrays massively expanded the capability of biologists to analyze gene expression of thousands to millions of proteins in a cell or tissue, a capability that was not available before. This technology is currently used widely and has become a standard in the field. The microarray market is $\approx$ \$1.5 billion in 2015 and is likely to grow to \$2 billion by 2020 [16.13]. Around the same time, *Manz* et al. [16.2] introduced the idea of using miniaturized integrated systems that used electrophoresis or chromatography for separation and integrated sensors for detection of a variety of chemicals and biomolecules. Their pioneering analysis started a new field called micro total analysis systems (μTAS) or lab-on-chip (LoC). They compared the theoretical performance of such a system for flow injection analysis, chromatography, and electrophoresis with the existing chemical sensors and analysis systems and noted that miniaturization made devices separations more efficient and faster with shorter transport times. They also found that μTAS consumed much fewer reagents and had higher sensitivity. Since then research and development in LoC systems for medical, environmental and other biochemical analysis has taken off and excellent review articles on the theory and technology [16.14], applications in chemistry and biology [16.15–17] and miniaturization for POC applications [16.18] are available.

A little later, in 1993, *Northrup* et al. [16.19] developed the first polymerase chain reaction (PCR) chip for DNA amplification and later went on to develop an integrated PCR and electrophoresis system on a single silicon chip [16.20]. The chip was fabricated using a photolithography technique and included a PCR chip to amplify the DNA and later separate the DNA using capillary electrophoresis. Their work opened the field of miniaturization to biological applications. They showed that miniaturization of the PCR analysis reduced the overall amplification time due to faster heating and cooling rates obtained in their device.

One of the first microfluidic fully integrated DNA sample analysis devices was developed by *Burns* et al. [16.21]. The device consisted of microchambers, microchannels, heaters, temperature sensors, and a fluorescence detector all integrated on a single chip. All the components of the system were made from similar materials and fabricated together using photolithography-based microfabrication methods. It was capable of aliquoting sample and reagents, metering them, mixing, performing an amplification reaction, transporting the sample to a separation channel and measuring the sequence of arrival of DNA from the sample on the integrated detector.

Until the late 1990s, researchers mainly used silicon and glass microfabrication technology to develop microfluidic devices. This technology was useful for fabricating microfeatures but was expensive and time consuming. In the late 1990s significant effort was devoted to developing microfabrication methods for LoC devices in plastics and polymers [16.22]. One of the techniques that emerged out of this polymer revolution was a rapid prototyping method known as soft lithography [16.23] where casting of polymers on lithographically fabricated molds was used to fabricate microfluidic devices. The material used was an elastomeric silicone rubber known as polydimethylsiloxane (PDMS), which was capable of replicating mold features down to a few 100 nm and was able to bond with glass or other PDMS substrates using a simple plasma exposure. The material was optically clear, had little autofluorescence, was flexible, had high gas permeability and had excellent elastomeric properties for the fabrication of membranes and diaphragms. The low cost, simple setup and the ability to rapidly prototype made this method popular and accessible to many labs around the world that were interested in developing microfluidic devices. Further development of valving and pumping technology for PDMS-based microfluidic devices using pneumatics by *Quake* et al. in the early 2000s [16.24] and the demonstration of scalability of

this approach and integration of hundreds of valves on a single chip made PDMS and soft lithography well established and the standard method for rapid prototyping in the microfluidic and nanofluidic research community. The PDMS valves that were developed are widely used in many microfluidic systems such as those to study PCR [16.25], protein separations [16.26] and cell sorting [16.27, 28]. Extensive reviews on various aspects of soft lithography including its application in nanofabrication [16.29], microfluidics [16.30], patterning [16.31] and application in the field of biology and biochemistry [16.32] are available.

Towards the middle of the 2000s, a new subfield called droplet-digital microfluidics emerged based on the science of emulsions. This technology exploited the fact that precisely fabricated microscale geometries can be used bring together two or more immiscible phases (such as water and oil) to form tiny droplets (in micrometer scale) precisely. Since then this subfield has grown enormously and large number of studies have been performed to gain deeper understanding of the physics of droplet formation [16.33, 34] and to develop methods for generating droplets [16.35–38] and their manipulation [16.39]. Furthermore, this technology has seen applications in single-cell analysis [16.40], molecular detection [16.41, 42], high-throughput imaging [16.43], drug delivery [16.44, 45] and diagnostics [16.46, 47].

Towards the end of the 2000s, several groups extended the application of microfluidic devices to performing biologically significant assays on small biological organisms in what was termed organism-on-chip. Organisms like *Caenorhabditis elegans*, *Drosophila melanogaster* and zebrafish are biologically important as they are considered to be rudimentary but significant models of human biological systems. In addition, disease models have been developed in these organisms to mimic the physiological characteristics of diseases such as Parkinson's and Alzheimer's. Some of the stages of these organisms, especially the embryo and the larval stages, are at the same size range as microfluidic devices. Several innovative microfluidic devices were developed for *Caenorhabditis elegans* [16.48–50], *Drosophila melanogaster* [16.51–53] and zebrafish [16.54–56] primarily to perform imaging and behavioral studies in these organisms in response to drugs and external stimuli. More recently, microfluidic devices have been used to recreate the biological and functional aspects of human organs for drug testing. These microfluidic chips are engineered to mimic the systems that produce the key functions of a living organ, for example, lungs, kidneys etc. These devices have proven to be more accurate in mimicking the organ functions compared to conventional cell cultures, which has led to an increased interest from the pharmaceutical industry. Recent reviews on organ-on-chip provide a detailed understanding of the state of this research as well as the future prospects [16.57, 58].

Although nanofluidics emerged later than microfluidics, it has made rapid progress in the past decade especially in advancing biological measurements at single-molecule resolution. Use of nanopores [16.59] for DNA sequencing and understanding protein folding are examples of applications where nanofluidic devices are used. Excellent, in-depth reviews on single-molecule detection [16.60] and biological measurement at single-molecule resolution [16.61] have been recently published. Nanopatterned structures have also been developed as artificial sieving matrices to interact with biomolecules at their size range in order to separate them [16.62]. Nanofluidic devices have also been used for improving the performance of microscale polymer electrolyte membrane fuel cells [16.63].

As the historical retrospective shows, micro- and nanofluidic research and technology is driven by exploiting the physics of fluid flow in these scales to perform assays, reactions and analysis faster, at low cost, in parallel but at a single-molecule, -cell and organism resolution. Several of these technologies have also developed large markets and commercially viable products.

16.3 Dominant Phenomenon and Micro–Nanofluidic Design

As an object, structure or device is miniaturized its surface area increases in proportion to its volume, which can be quantified through the surface-to-volume (S/V) ratio. Consider a chamber that is $1\,\mathrm{mm} \times 1\,\mathrm{mm} \times 1\,\mathrm{mm}$ in length, breath and height. The volume of that chamber is $1\,\mathrm{mm}^3$, its surface area is $1\,\mathrm{mm}^2$ and its S/V ratio is $1\,\mathrm{mm}^{-1}$. Now when its size is proportionately reduced to $1\,\mu\mathrm{m} \times 1\,\mu\mathrm{m} \times 1\,\mu\mathrm{m}$ its volume reduces to $10^{-9}\,\mathrm{mm}^3$, its surface area reduces to $10^{-6}\,\mathrm{mm}^2$ but its S/V ratio increases to $10^3\,\mathrm{mm}^{-1}$. This increase in S/V ratio is the reason for all the interesting and dominant phenomena that are observed at the micro- and the nanoscale. Forces that depend on the surface gain in prominence over forces that depend on the volume, which typically tend to dominate at the macroscale. For instance, gravity and inertia, which are dominant in the macroscale, are not significant compared to surface tension in the micro- and nanoscale. The following section

details some of the dominant phenomena observed in micro- and nanofluidics that should be considered in design of devices.

16.3.1 Laminar Flow

One of the consequences of miniaturization and small-sized channels is that the walls of the channels are very close to each other. Since the walls are immobile, they impede the flow of fluid layers adjacent to them thereby reducing the overall velocity of flow in a microfluidic channel. The resistance that the channel provides to fluid flow is dependent on the viscosity of the fluid and channel dimensions. For a high aspect ratio channel ($w \ll h$ or $h \ll w$) the fluid resistance R, is given by

$$R = \frac{12\mu L}{wh^3}\,, \tag{16.1}$$

where μ is the viscosity of the fluid, L is the length of the channel, and w and h are the width and height of the channel respectively. This equation demonstrates the nonlinear effect of miniaturization of the channel on the fluidic resistance and consequently on the flow velocity. Therefore, microfluidic flows are usually laminar in nature. For instance, the Reynolds number (Re), which is a dimensionless parameter that is used to identify the significance of inertial forces in a fluid flow in comparison with the viscous drag forces, is usually below 100 and most often close to 1 or less [16.64]. The Reynolds number can be calculated using the following

$$\mathrm{Re} = \frac{\rho \upsilon D_\mathrm{h}}{\mu}\,, \tag{16.2}$$

where ρ is fluid density, υ is the velocity of the fluid stream, D_h is the hydraulic diameter or cross-sectional diameter of the channel and μ is the viscosity of the fluid. In macroscale flows, when $\mathrm{Re} < 2300$, the flow is considered laminar and as Re approaches 2300 the flow transforms from laminar to turbulent. The Reynolds number has a direct dependence on the dimension of the channel through the hydraulic diameter and an indirect dependence through the velocity of the fluid stream, which is dependent on the dimension due to the drag effect induced by the walls. At high Reynolds numbers, which are normally encountered in macroscale flows, the inertial forces are dominant and this leads to turbulent mixing. However, in the case of microfluidic flows the viscous forces dominate over inertial forces and the layers of fluid that flow adjacent to each other along the axis of the channel do not convectively mix. The only mixing that happens is because of diffusion of molecules in the fluid between the individual layers that are flowing adjacent to each other.

16.3.2 Diffusion in Microfluidics

Diffusion is the process of movement of particles from a higher concentration to a lower concentration due to Brownian motion so that over time the average concentration of the particles in the entire volume is equal. It is a time-dependent process and is characterized by the equation

$$d^2 = 2Dt\,, \tag{16.3}$$

where d is the distance traveled by a particle in time t, and D is the diffusion coefficient of the particle. In the above (16.3), it can be seen that the diffusion varies as a square power of distance, which is very significant in the microscale. To understand the significance of diffusion at the microscale, consider diffusion of hemoglobin (blood) in water. The diffusion coefficient of hemoglobin is $7 \times 10^{-7}\,\mathrm{cm}^2/\mathrm{s}$ [16.65]. Hemoglobin takes 106 s to diffuse into 1 cm of water but only 1 s to diffuse through 10 μm. So diffusion, which is negligible at the macroscale, becomes important at the microscale, especially when convective effects are absent.

Therefore, in the design of micro- and nanofluidic devices, one has to contend with low Reynolds number flows, recognize its consequence on the operation of the devices and potentially take advantage of it. This property of low Reynolds number flow in microfluidics allows one to treat the fluid almost like a solid, where it can be structurally positioned and its flow exquisitely controlled. For instance, laminar flow and the dominance of diffusion has been used in order to make a gradient generator (Fig. 16.2), which has been used to study chemotaxis behavior of cells in different pH zones [16.66]. Others have used this property to separate particles of different size at the microscale [16.67] or immunoassays [16.68] that can detect small molecules in the nanomolar concentration in less than a minute. One should also recognize that if mixing of reagents is required, it may not happen spontaneously and therefore special structures that can introduce chaotic advection should be incorporated [16.69, 70].

16.3.3 Rapid Heating–Cooling

As mentioned earlier, the S/V ratio becomes important at the microscale. This means that the scaling down results in faster heat transfer and better isolation. Thermal time constant is a parameter that is used as a measure of the thermal responsiveness of a system. It can be calculated using the following equation

$$\tau = \frac{\rho C_\mathrm{p} V}{\lambda A} \propto [l^1], \tag{16.4}$$

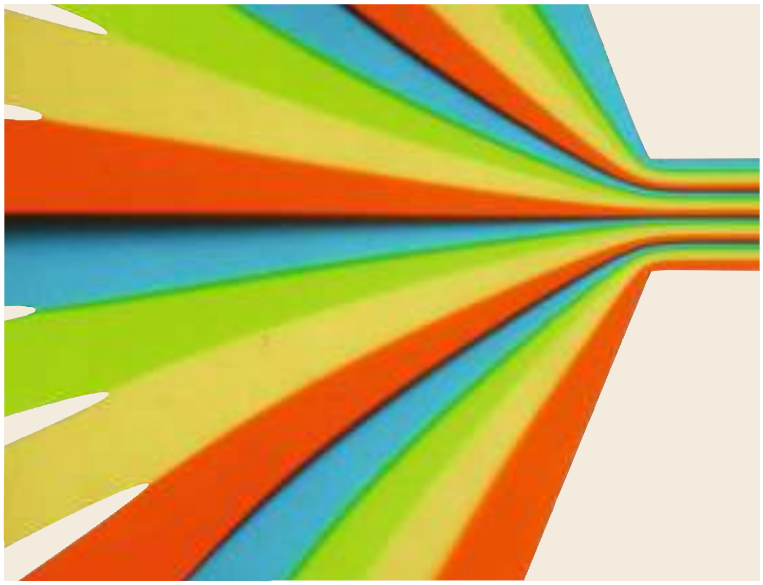

Fig. 16.2 A microfluidic gradient generator. The consequence of laminar flow results in diffusion-based mixing and is a function of time. Each zone can be clearly distinguished, and they do not mix. (Courtesy of Greg Cooksey and Albert Folch)

where τ is the thermal time constant, ρ is the density, C_p is the specific heat, V is the volume, λ is the heat transfer and A is the surface area. From (16.4) we can see that the thermal time constant is directly proportional to the length scale. So in microfluidics, where the length scale is small the thermal time constant is correspondingly smaller and the chambers or channels could be heated or cooled faster. This is particularly advantageous in the case of capillary electrophoresis where the microchannels can quickly remove heat and reduce the detrimental effects of Joule heating on resolution [16.71]. Also the sample volumes are much lower in capillary electrophoresis, which has an added advantage. Similarly, in the case of DNA amplification using a process like polymerase chain reaction (PCR) where the temperature of the chamber has to be rapidly cycled between 55 and 95 °C, the small channels help in faster heating and cooling, which reduces overall time to complete the assay [16.72]. This feature of micro- and nanofluidic devices can be used in the design of devices that require fast heat dissipation or accumulation. For instance, microchannels can be used as reactors to perform flow through exothermic chemical reactions for high-yield specialty chemical production, as the heat generated can be quickly dissipated.

16.3.4 Surface Tension

Another significant force that increases in prominence in micro- and nanofluidics is surface tension. Surface tension is due to the cohesion of fluid molecules at the surface of the liquid and air interface. For example, when a needle is placed gently on the surface of the water it does not sink due to surface tension, even though the density of the needle is much larger than that of water. However, as soon as the needle is pushed down the surface tension is overcome, and the needle immediately sinks. While cohesive forces act on the surface of the fluid, adhesive forces act at the walls, which cause capillary action. The absorption of water into a paper without any external force is due to the capillary action. Surface tension tends to bend the fluidic interface in order to balance the normal pressure difference across it. The relationship between the surface tension and the normal pressure difference across a thin fluid interface is given by the Young–Laplace equation

$$\Delta p = \gamma \left(\frac{1}{R_1} + \frac{1}{R_2} \right), \tag{16.5}$$

where Δp is the pressure difference, γ is the surface tension and R_1 and R_2 are the radii of curvature of the fluidic interface. The equation above (16.5) clearly demonstrates that an interface can sustain high pressure differences across it when the radius of curvature, which is determined by the sizes of the channels, is small such as in the case of micro–nanofluidic devices. Equation (16.5) can be simplified for a circular channel as

$$\Delta p = \frac{2\gamma \cos\theta}{a}, \tag{16.6}$$

where Δp is the pressure difference, γ is the surface tension, θ is the contact angle and a is the radius of curvature of the tubing. For example, a circular glass

capillary with a radius of 100 nm, filled with water ($\gamma = 71.97$ and $\theta = 24°$ [16.73]) has a pressure difference of 13 090 bar. Such high pressures are possible due to the small channel dimensions in microfluidic devices.

Alternatively, molecular interaction between a solid and a liquid can lead to a curved interface due to the preference for adhesive over cohesive forces. The curved interface, once established, leads to a pressure difference across it, which then tends to drive fluid flow in micro- and nanochannels. This property is very useful in the design of microfluidic diagnostic devices for transporting the liquid sample without external forces [16.74].

Another important factor arising because of adhesive and cohesive forces at the liquid–solid interface is called wettability. Wettability is the ability of a fluid to spread on a solid surface. It depends on the adhesive–cohesive force balance at the interface and contact angle measurement is used to measure this force. By changing the surface energy (e.g., by chemical treatment), we can manipulate the contact angle. Figure 16.3 shows the schematics on how to measure the contact angle. If the contact angle is less than 90°, the surface is considered hydrophilic and when greater than 90° is called hydrophobic. The wettability of a surface can be modulated by changing its chemistry, temperature or electrical charge.

A gradient in wettability along a surface can also drive fluid flow. For instance, a droplet on a surface will bead up if the cohesive interactions among its own molecules are preferred over adhesive forces with the surface. However, when presented with a gradient of adhesive interactions with the surface, the droplet will tend to move in the direction of the gradient with stronger adhesive forces in order to spread and minimize its overall energy and achieve the lowest possible energy state. A gradient in surface tension can be introduced using electrical, chemical and thermal means [16.37]. Digital microfluidics technology uses dynamic gradients in surface tension introduced on a surface electrically to control movement of droplets on it.

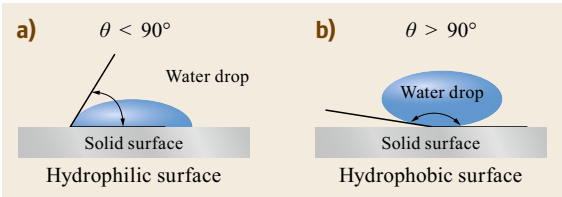

Fig. 16.3a,b Contact angle measurement of a drop. When the angle **(a)** $\theta < 90°$, the surface is hydrophilic and when **(b)** $\theta > 90°$, the surface is hydrophobic

In any microfluidic design, the influence of surface tension forces on the operation and functioning parameters of the device must be considered. For instance, hydrophilic surfaces are suitable for many microfluidic LoC devices to ensure that they fill smoothly and uniformly when samples are loaded. It is also desirable if the operating mechanism of the device exploits this dominant force in its working.

16.3.5 Electrokinetics

An interface such as between a solid and a polarizable fluid such as water develops a separation of charges known as a double layer [16.75]. This charged surface layer is insignificant in determining the properties of the flow in the macroscale. However, it may become a significant determinant of fluid flow in the microscale. Application of a pressure head across a microfluidic channel normally leads to a velocity profile that is a characteristic parabolic flow profile as shown in Fig. 16.4a. However, as discussed earlier, as the channel dimension is reduced, the flow resistance increases nonlinearly and in channels that are smaller than $\approx 1\,\mu$m, pressure-driven flow is not a suitable method. The primary reason for higher flow resistance is due to the walls of the channels that are close together and offer resistance (drag) to movement of the fluid layers adjacent to it.

In this scenario, the surface charging effects can be exploited to reduce the flow resistance. Application of an electric field along the length of the channel provides an electrostatic force on that thin layer of fluid close to the walls and causes *slip*. This phenomenon significantly reduces the drag associated with the walls and also drags the rest of the fluid in the channels as shown in Fig. 16.4b with a velocity that is uniform throughout the cross-section of the channel. This is known as the electrokinetic or electroosmotic flow. *Zeng* et al. [16.76] developed an electroosmotic pump that has no moving parts. They were able to achieve pressures over 20 bar and flow rates of 2.6 µl/min for a 2 kV applied potential. *Paul* et al. [16.77, 78] have generated high pressures using porous microstructures using the electrokinetic principle.

Similar to electroosmotic flow, the movement of particles suspended in a solution instead of the bulk fluid due to an applied electric field is called electrophoresis. Electrophoresis is a standard technique used to separate DNA based on size. By applying an electric field in a gel containing DNA strands (which have a negative charge) of varying size, smaller DNA moves faster and farther than the longer DNA strands and thus can be separated based on the size. Dielectrophoresis is another method used for separating par-

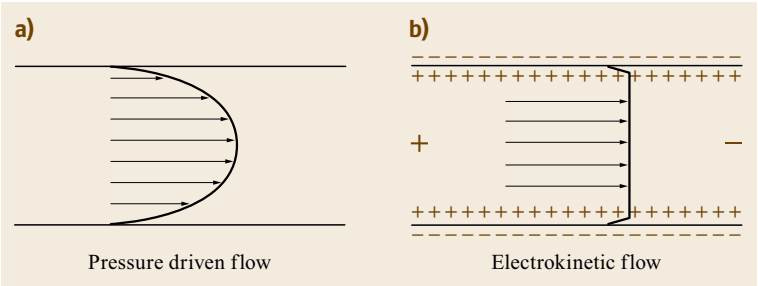

Fig. 16.4a,b Fluid flow profile for **(a)** pressure-driven and **(b)** electrokinetically driven flow

ticles. In dielectrophoresis, a particle with a different dielectric constant as compared to the fluid medium experiences a force when placed in a nonuniform electric field. The force depends on various factors such as medium, particle electrical properties, size, shape and strength of the electric field. Researchers have used this method to separate cells [16.79], particles [16.80] and droplets [16.81].

16.3.6 Geometric Control of Two Phase Flow

Since surface tension dominates in the micro- and the nanoscale, the interaction between two phases (oil and water or gas and a liquid) can be precisely controlled. This property is taken advantage of in droplet microfluidics. Aqueous droplets ($\approx$ 1 nanoliter) can be produced in an oil medium either actively (using valves [16.82] or electric fields [16.83]) or passively (geometry [16.38, 84]). Flow of two immiscible fluids such as oil and water can be brought together at precise angles such as shown in Fig. 16.5a, which leads to the production of uniform-volume droplets of one fluid in the other as the surface tension of the interface holds one fluid until the pressure buildup from the incoming flow overcomes it [16.85]. Similarly, the instabilities introduced in a coaxial flow of two immiscible phases either through a nozzle [16.86, 87] such as in Fig. 16.5b, or those that naturally occur [16.88] such as in Fig. 16.4c, lead to breakup of the coaxial flow into precise and uniform droplets and high rates ($\approx$ kHz).

Various groups have studied droplet manipulation, which includes mixing [16.90], fusion [16.91] and fission [16.39, 92]. Researchers have used these techniques on-chip for applications in sorting [16.93, 94], single-cell analysis [16.95, 96] and drug screening [16.97].

16.3.7 Nanoscale Phenomena

The S/V ratio becomes much larger in the nanoscale and in some cases that leads to breakdown of continuum mechanics in some cases and molecular interactions become dominant. For instance, nanoporous materials have been used to fabricate a Knudsen pump that can create a pressure difference across it due to a thermal gradient and with no mechanical moving parts [16.98]. The more frequent interaction of the air molecules with the walls of the nanopores than with other air molecules leads to this phenomenon.

Nanoscale channels and nanopillar arrays can be made to confine polymers and other long-chain molecules such as nucleic acids. Typically, in free solution these molecules fold themselves into a blob-like structure that is characterized by their persistence length. By forcing them into confined nanochannels, these molecules open up revealing their true linear structure. These nanofluidic channels have been used in a variety of applications including DNA sequencing and single-molecule detection [16.99].

Nanoscale channels also are so small that the double layers created due to the interaction of a polarizable fluid with the surface overlap or form a significant portion of the channel. This effect can lead to surprising phenomena such as exclusion of the co-ion of the type that is present on the walls of the channels [16.100, 101]. These devices can potentially be applied to fluidic electronics and other such applications [16.102, 103].

16.4 Fabrication of Micro–Nanofluidic Devices

Microfabrication technology was initially developed in the electronics industry in the 1950s and 1960s and has since been applied to construct micromechanical systems and micro–nanofluidic devices. The philosophy behind integrated circuit fabrication, which is to use common materials and fabrication methods to build multiple components so that they can be fabricated in parallel and tightly integrated, has been adopted to fabricate microchannels, microvalves, pumps, mixers, separation columns, amplification chambers and sensors, and to integrate them into lab-on-chip (LoC) and micro total analysis systems (μTAS). These systems can perform the entire sample processing and detection on a small form factor in a automated manner with high efficiency, increased throughput, lower cost, small reagent consumption, shorter analysis time and high sensitivity. Initially, silicon and glass were the main materials that were used for microfabricating these devices primarily because they had well-developed and mature microfabrication processes. However, unique requirements for biological assays such as disposability, need for surface functionalization and the need for inertness and biocompatibility provided impetus for the development of microfabrication methods in polymeric materials. Since the mid-1990s, fabrication methods have been developed for a range of elastomers, thermoplastics and thermosetting materials. More recently, the demand for devices that could be operated by minimally trained personnel for diagnosis purposes in resource-poor settings led to the development of fabrication methods to build microfluidic devices utilizing paper and more recently threads. Widespread availability of these materials, their low cost and simplicity of their fabrication methods and ability to transport fluids without any external power sources has led to rapid growth of this research field and a large number of functionalized paper- and thread-based microchips for detection and analysis of a variety of analytes have been reported during the past ten years. Microfabrication methods for hydrogels have been developed more recently due to interest in building cell culture scaffolds for tissue engineering applications The following sections describe the most extensively used materials in microfluidics along with their fabrication and integration methods as well as applications in biological investigations. Readers are encouraged to refer to the cited literature and subject-specific review papers for more detailed explanations of each process.

16.4.1 Silicon and Glass

Silicon was the first material adopted in microfluidics owing to the origin of microfluidics, which was the semiconductor industry that relied extensively on silicon as the main material abundantly available in the Earth's crust. Several techniques such as bulk micromachining, surface micromachining and buried channel methods have been developed for fabrication of silicon-based microfluidic devices [16.9, 104, 105].

In bulk micromachining, a photolithographic process is employed to pattern desired microfeatures on a substrate (typically silicon). Two different etching methods based on the etchant phase, i. e., wet (liquid) and dry (gas), have been used to remove silicon from the wafer and shape the microstructures. After etching, another substrate such as glass or silicon is bonded to the patterned piece to from enclosed channels, chambers and other features [16.106]. Alternatively, in surface micromachining, a thin film of a sacrificial material is deposited and patterned on the substrate to form the scaffold of the microfluidic structure. The structural layer is deposited next forming the side walls and the top surface of the microchannel or microfluidic chambers. Next, the reservoir areas are etched in the sacrificial layer to expose the underlying sacrificial material. Then the sacrificial layer is etched away to form the designed channel on the base substrate [16.107]. The sequential deposition of sacrificial and structural materials and their patterning can be continued to form multilayer microfluidic structures. SiO_2 and Si_3N_4 are the two most commonly used sacrificial materials while polysilicon (poly-Si) is mostly used to form the structural layer. Another process used in silicon micromachining that combines the bulk and surface micromachining is the buried channel technique. It is a multistep, bonding-free approach that involves patterning a thin narrow line on the substrates corresponding to the region where the microfluidic channel or structure is to be formed. This pattern is used to anisotropically etch a narrow trench. Subsequently, the thin nitride layer is deposited conformally to cover the side walls and the bottom of the trench and then etched anisotropically so that the nitride at the bottom of the trench is removed while that at the side walls form a protective coating. Next, the exposed bottom is etched isotropically producing a enlarged cavity buried into the substrate, which can form the channel structure. Finally, the nitride is stripped and sealing is achieved by deposition of another layer of a suitable material (poly-Si, SiO_2, Si_xN_y) conformally to a thickness that is more than half of the original trench width, which will enclose the channel. This method also enables the construction of channels at different depths by adjusting the depth of the trench [16.108–110].

Well-established fabrication techniques, the ability to obtain smooth sidewalls and anisotropic etches and the availability of several methods for surface modification were the main reason for the initial extensive use of silicon as the substrate material in microfluidics [16.111]. Silicon-based devices have been used in a wide range of applications from micropumps [16.112] and valves [16.113] to microreactors [16.114] and cell growth chambers [16.115]. Nevertheless, cost of the material and its opacity made it not ideal for biomedical and lab-on-chip applications [16.116, 117]. Moreover, high electrical and thermal conductivities of silicon necessitate employing electrical and thermal insulation layers in some applications, which increases the cost of fabrication [16.118]. These factors led to the development of microfabrication methods for more suitable substrates such as glass [16.119].

Glass is an amorphous silicon compound that can be used in microfabrication. Glass compared to silicon offers superior optical transparency and electrical insulation properties. Additionally, it is chemically inert, shows low fluorescence emissivity and is compatible with biological samples [16.111] as many of the biochemical assays and processes have been developed on Petri dishes and glass containers in the macroscale. Hence, it became the material of choice after the initial interest in silicon devices. The most widely used glass is 7740 Corning Pyrex due to its high thermal compatibility with silicon that results in smaller bending mismatches when high temperature is required for bonding [16.120, 121]. Soda lime glass and FOTURAN are two other types of glass that have proven to be useful in fabricating microfluidic devices.

Methods of fabricating glass microchannels are not as diverse and advanced as silicon [16.111]. Glass microchannels were mostly fabricated by mechanical, wet or dry etching approaches. The mechanical technique is similar to traditional drilling and often produces rougher surface finish [16.122]. Among the chemical methods, wet etching is the most common and can be used to fabricate isotropic structures [16.105]. It involves removing glass from the substrate by masking and submerging it in a selective liquid etchant like hydrofluoric acid, potassium hydroxide and tetramethylammonium hydroxide [16.123, 124]. The etchant used in this method and the glass type are two parameters that determine the etch rate. Adding some chemicals such as hydrochloric acid and HNO_3 can also be effective in tuning the etch rate [16.125]. The desired depth can be achieved by adjusting the etch rate and the duration of etching. Due to its isotropic nature, the aspect ratios obtained with this method is ≈ 1 or less. In dry etching, it is the momentum of ion species with the help of a masking process that removes the maskless glass. Alternatively, etchants can be introduced in the gas phase, ionized and provided momentum through an electric field in order to provide directionality to the etch and increase anisotropy. Dry etching has a significantly slower etch rate compared to wet etching [16.105]. After etching and definition of the microfluidic features using bulk micromachining, the substrate is bonded to another glass or silicon substrate using a variety of methods including fusion bonding, adhesive bonding and anodic bonding, which have been developed for bonding glass to glass and glass to silicon wafers [16.126, 127].

The intrinsic properties of glass make it a suitable choice for biomedical and biological fields. Its transparency also facilitates optical bioanalytical assays [16.128]. Therefore, glass microchannels have been extensively used for electrophoresis [16.129], polymerase chain reactions [16.72], and gas chromatography [16.130]. However, several shortcomings, such as relatively high cost of fabrication and lack of an easy technique for bonding glass to another substrate, limit its applications as the main material for microfabrication of microfluidic devices. Additionally, glass is not permeable to gases and cannot be used in more complex applications of microfluidics such as analysis of cells in which permeability to gases is vital [16.131]. Consequently, new materials needed to be explored to conduct more elaborate research experiments in microfluidics.

Although silicon and glass were the first materials that were used for microfluidic devices, they are now replaced by polymers to a great extent due to higher biocompatibility, easier fabrication process, lower fabrication cost, flexibility, permeability to gas, and good optical transparency of polymers [16.132]. However, silicon and glass are still important in applications where thermal, chemical and mechanical stability is required. For instance, rigid walls that are needed in nanoscale channels can be constructed by silicon or glass due to their high mechanical stability [16.131, 133].

16.4.2 Polymers

Drawbacks of silicon- and glass-based microfabrication such as relatively high cost of fabrication, complex and cumbersome fabrication procedure and silicon being optically opaque [16.22, 134], drove researchers towards seeking new materials. Polymers are among the most suitable for use in microfluidic devices, especially in biomedical applications. They offer desirable properties such as modifiable thermal, electrical and surface characteristic properties as well as low cost, chemical inertness, biocompatibility, and transparency that make them a proper choice for disposable bioassay devices [16.118]. Over the last decade,

polydimethylsiloxane (PDMS) has been the dominant polymer used in prototyping of microfluidics and LoC devices [16.135, 136]. Nevertheless other thermoplastic and thermosetting materials such as polycarbonate (PC), polystyrene (PS), cyclic olefin copolymer (COC), poly(methyl methacrylate) (PMMA) and polyimide (PI) [16.137, 138] have been used in commercial microfluidic devices due to their chemical inertness, minimal adsorption and ease of fabrication especially using standard processes like injection molding and hot embossing.

The advent of polymer casting methods (e.g., soft lithography) was an important step towards widespread prototyping and experimentation of LoCs [16.139, 140]. PDMS is the most extensively used polymer in soft lithography (Fig. 16.6) for fabrication of microfluidic devices [16.141, 142]. It is among the low-cost polymers that are transparent and permeable to gases, and its intrinsic mechanical properties render it the first choice for many microfluidic applications. Another advantage of this material is that it can replicate features in molds that are a few tens of nanometers in dimension [16.136]. This elastomeric polymer is commercially available in a kit that contains the base polymer and a curing agent, which is used to crosslink the polymer. The amount of the curing agent in PDMS defines the hardness of the final product. A larger ratio of the curing agent to base polymer results in a harder material. In the soft lithography method, photolithography or chemical etching of substrate is used to develop a negative replica of a desirable design called a master mold. PDMS base to curing agent mixture (typically 10 : 1 ratio) is then cast over the master followed by curing at 65 °C for 1–4 h to allow crosslinking of the prepolymer. Due to the low surface energy of PDMS, it can be peeled off from the master mold with ease. The cured PDMS needs to be bonded to another surface to form an enclosed channel. Various methods such as plasma treatment (most common) [16.144, 145], mechanical bonding [16.146] and chemical treatment [16.147] can be used depending on the application of the device and working pressures. The plasma bonding method includes exposure of surfaces to oxygen or other gases' plasma to generate free radicals on surfaces for bonding of PDMS with a variety of materials including PDMS, glass, parylene, silicon, silicon oxide, quartz, silicon nitride, polyethylene, polystyrene, and glassy carbon [16.139, 148].

Polymers in microfluidics are not limited to elastomers and thermoplastics are also commonly used. PMMA, as a low-cost polymer with superior mechanical strength, electrical insulation and transparency, can be a representative of this type of polymer. PMMA also shows high biocompatibility and is used in dental fillings [16.149], contact lenses [16.150] and bone cements [16.151]. Therefore, it is a suitable candidate for biomedical and disposable devices [16.152]. Microfluidic chips that exploit PMMA as their main manufacturing material are typically fabricated using a hot embossing technique [16.153] and based on their desired application can be used as the master molds for the subsequent soft lithographic process or as the microchannel itself [16.154, 155]. In the hot embossing method, a mold containing the features to be embedded into the plastic in negative is heated above the glass transition temperature of the plastic and pressed against a thin sheet with a significant pressure. The mold transfers heat to the plastic, which upon reaching temperatures above its glass transition temperature, flows to conform to the mold's topography. Subsequently, the mold and the plastic is cooled and the plastic removed to emboss the features permanently. Mass production of PMMA devices can be achieved via a microinjection molding method that facilitates shorter fabrication cycle times [16.156]. A variety of techniques can be found in the literature for bonding and integration of PMMA. Thermal bonding requires heating the PMMA channel layer up to glass transition temperature and pressing it over a cover plate [16.157]. In solvent bonding, which is conducted at room temperature, a solvent (plasma-enhanced ethanol [16.158], low azeotropic solvent [16.159], 2,4-pentadione [16.160]) is applied at the interfaces to produce a strong bond [16.161]. Although PMMA as a material presents several favorable proper-

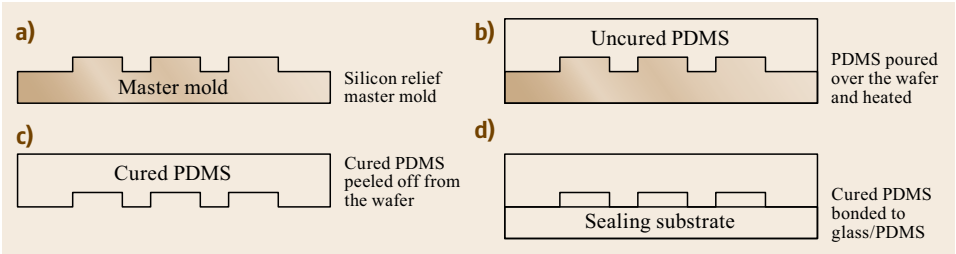

Fig. 16.6a–d Soft lithography method for replicating PDMS over a master mold. Uncured PDMS is poured over the mold and heated followed by bonding to another substrate to make closed microchannels (after [16.143])

ties that are ideal for biomicrofluidics, it is hydrophobic and presents a challenge in its use in devices that rely on capillary flow for sample transport. This shortcoming has been overcome by adding ionic charged surfactants or dynamic modification to form amine-terminated surfaces or by bulk copolymerization that results in modification of PMMA during the manufacturing process [16.162–164].

Polyimide (PI) is a thermosetting polymer that was initially introduced into microfluidics as a membrane for micropumps and microvalves [16.165, 166]. PI possesses high tensile strength, superior chemical stability and low water absorption. Its high resistance to chemicals along with high dielectric constant and excellent biocompatibility make it more suitable than other polymers for biomolecular applications [16.167, 168]. Fabrication methods used for making microfluidic structures include thermal injection molding [16.165] and, in the case of photosensitive PI, photolithography [16.167, 168]. Several methods can be employed for bonding PI to another substrate, which is commonly glass or PI. *Glasgow* et al. [16.169] reported solvent bonding as a technique for enclosing PI-based open channels. This method can exert a significant amount of stress on the device because of solvent evaporation. In another study, *Bayrashev* and *Ziaie* [16.170] used radio-frequency dielectric heating to achieve PI-PI bonding that led to bond strength of 1.5 MPa. *Min* and *Kim* [16.171] proposed thermomechanical bonding by pressing a three-dimensional PI-based device between two glass slides at 300 °C and 10 kPa for 1 h to achieve pressure tolerance of 70 bar. PIs are ideal in applications in which mechanical and electrical properties are important, such as electrophoresis and cell sorting and separation [16.172–174] where PI composites have been used to enhance its properties. The use of PI in microfluidics is still nascent but is likely to emerge as an important material with the advent of new additive manufacturing methods.

The broad spectrum of applications for polymers, the increasing demand for materials with specific properties that suit various research topics, and the compatibility of polymers with specific manufacturing processes have encouraged researchers to explore newer polymers that could be integrated in microfluidics devices. For instance, polystyrene (PS) is a synthetic thermoplastic polymer that is optically transparent and chemically inert. It has been used widely in conventional cell culture and the majority of cell culture and coculture protocols have been developed on this substrate. Recently, hot embossing-based microfabrication techniques have been developed for PS so that microfluidic devices can be used to perform cell-based assays and molecular biology studies [16.175, 176] using the same protocols as in macroscale Petri dishes. Despite its advantages, PS has low melting temperature and is attacked by organic solvents and aromatic hydrocarbons and hence not suitable for other chemical assays or microreactors. Polycarbonate (PC) is another polymer that has been used in microfluidic devices. It is preferred over PMMA in applications where high tolerance of operating temperatures is required and is commonly used in bioanalyses that include polymerase chain reactions [16.177, 178]. More recently, thermoplastic materials such as cyclic olefin copolymer (COC) have been introduced into microfluidics. COC has high moisture barrier properties and excellent optical properties that make it suitable for applications where fluorescence-based detection is required. Their glass transition temperatures also exceed 200 °C and therefore they can be used in assays that require heating and are compatible with autoclaving. These characteristics make it an appropriate choice for biodetector LoCs that utilize integrated circuits [16.179, 180]. Nevertheless, it cannot be used for pharmaceutical studies due to its hydrophobic surface that increases protein adsorption and cell adhesion [16.181].

16.4.3 Paper

Paper has been widely used as a material to develop diagnostic tools such as dipsticks and pregnancy tests [16.182, 183]. In 2007, Martinez et al. used a photolithographic approach to define hydrophobic barriers in paper to direct fluid flow and transport samples passively using capillary forces. They developed various bioassays using this format and called it microfluidic paper-based analytical devices (μPADs, Fig. 16.7a) [16.143]. The primary objective of μPADs is to offer easy-to-use, portable, and affordable devices that can be used for multi-analyte semiquantitative analyses [16.187, 188]. Ubiquity and low cost of paper along with its easy adaptability with chemical and medical applications make it suitable for portable and low-cost microfluidic systems [16.188]. Despite these advantages, μPADs suffer from risk of handling contamination [16.189] and long analysis times due to the slow capillary-based transportation of fluids [16.190], which can lead to evaporation of solvents and chemical instabilities.

Over time, a wide variety of methods have been used for fabrication of μPADs including wax printing [16.184, 191] (Fig. 16.7b), flexographic printing [16.185] (Fig. 16.7c), inkjet printing [16.192, 193], screen-printing [16.194], wax screen-printing [16.195], paper cutting [16.196, 197], photolithography [16.143, 198], laser treatment [16.199, 200], and plasma treatment [16.201]. Most of these techniques, except paper

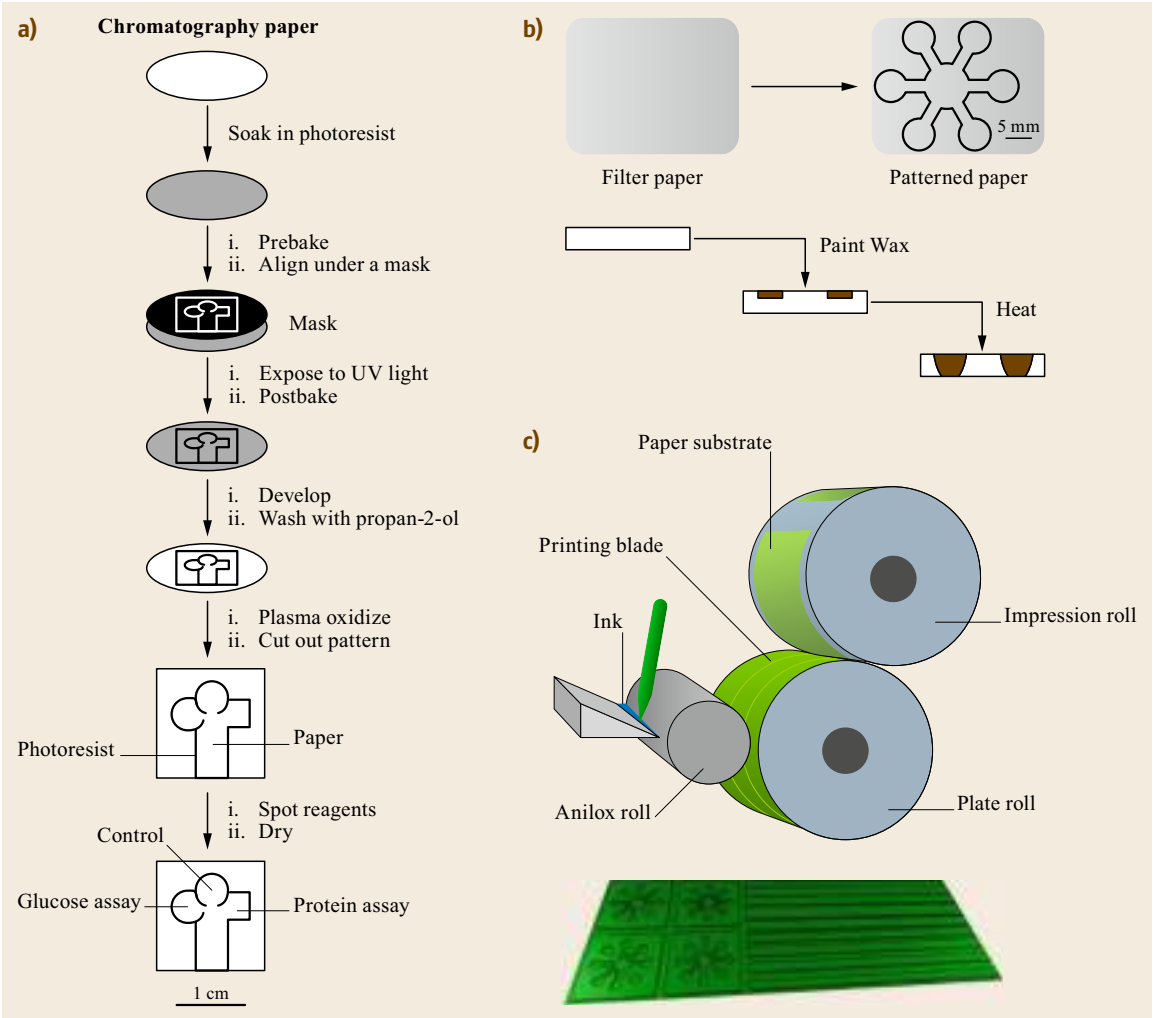

Fig. 16.7 **(a)** Paper-based microfluidics was first proposed by *Martinez* et al. [16.143]. They used a chromatography papers soaked in photoresist to be exposed under ultraviolet (UV) light to form the hydrophobic barrier required for fluid transport (after [16.184]). **(b)** In th wax printing method, wax needs to be printed on a hydrophilic paper followed by heating that helps the wax to penetrate into the paper and make the boundaries of the channel (after [16.185]). **(c)** A Flexographic unit that enables large-scale fabrication of μPADs. Rotation of impression role on which the paper substrate is fixed against the plate role that contains the pattern transfers the desired pattern onto the paper. Penetration depth is controlled by the pressure between impression and plate roles (after [16.186])

cutting, rely on patterning paper with hydrophobic materials to define the microchannel boundaries and confine the fluid flow. Early devices were made using photoresist as the hydrophobic barrier. However, higher cost of the photoresist ($\approx \$0.1$ for $100\,cm^2$) [16.202] compared to other materials made it unsuitable for μPADs that were meant to be low cost. Thus, new materials such as wax ($\approx \$0.01$ for $100\,cm^2$) [16.203] started to be used as the hydrophobic barrier. Lower-cost methods included inkjet printing of alkyl ketene dimer (AKD) ($\approx \$0.00001$ for $100\,cm^2$) [16.193] onto paper followed by polymerization by heating. Readers are encouraged to review the papers by *Xia* et al. [16.187] and *Yetisen* et al. [16.204] for further details about other paper microfluidic fabrication methods.

Paper-based microfluidic devices have been widely used in biomedical, environmental and food contamination applications. Detection in μPADs is based on the reaction between specific reagents functionalized on paper and target analytes, which produces a signal. The output signal can be detected by colorimet-

ric [16.205], electrochemical [16.206], chemiluminescent [16.207], electrochemiluminescent [16.208], fluorescent or photo-electrochemical [16.209] readouts. These methods differ in fabrication techniques, time and limit of detection, cost, and range of application. Colorimetric detection is more commonly compared to other methods, because it depends on visual or imaging-based readouts of the change in color intensity of a detection spot due to presence of target analytes and their concentration. Other detection techniques are more accurate and sensitive, but they require access to signal detection equipment such as electrochemical analyzers or fluorescent microscopes.

μPADs have also been used in environmental applications where precise detection of contaminants in surface water, soil or air is needed. For instance, *Mentele* et al. [16.210] developed a device that could simultaneously detect Fe, Ni and Cu in combustion ash. Many other strategies for detection of metals in water, soil and aerosol using μPADs have been proposed by other research groups [16.211–215].

The food industry has benefited from μPADs designed for detection of foodborne contamination. Detection methods in this area mostly rely on immunoassays or enzymatic reactions that occur in the detection zone. Using swab sampling followed by culturing in the appropriate media, *Jokerst* et al. [16.216] could detect *Listeria monocytogenes*, *E. coli O157:H7*, and *Salmonella typhimurium* in meat. Detection of Pb and Cd in beverages, dichlorvos (DDV) from vegetable skin and *E. coli* in ground beef and cucumber are other successful examples that show the capability of using paper-based microfluidics for affordable detection of contaminants in the food industry [16.217–219].

Although paper-based microfluidics is still in its early stages, its advantages such as being low cost and lightweight make it an appropriate choice for fabrication of diagnostic devices in less industrialized countries. Challenges that need to be immediately addressed are evaporation of reagents and precise control of flow along the porous media that can set the stage for development of the next generation of complex and efficient μPADs [16.220].

16.4.4 Threads

One of the important goals of microfluidics technology is to design low-cost, easy-to-fabricate, portable and disposable chips for bioassays and diagnosis applications. This has resulted in utilization of a few accessible materials such as paper and threads in microfluidic devices. Passive fluid transport along a thread is achieved by dominant capillary forces inside the pores of the fabric and along the interfiber cavities [16.221, 222]. Major advantages of thread over paper are the ability to develop 3-D devices, no need for micropatterning to produce fluidic paths, and availability of various type of threads with different wicking rates. However, lack of uniformity in the interfiber gaps and heterogeneities on the surface can cause limitations in the operation of the device and result in wicking rate inconsistencies [16.223–225].

It is essential to be able to predict the operation of the device and the fluid behavior in order to design efficient chips. One of the determinative elements in designing thread-based microfluidics is wicking rate. Modeling the wicking rate phenomenon in threads is a highly complex task that requires consideration of various parameters such as the size of the interfiber gaps, hydrophobicity and hydrophilicity, contact angle, viscosity, and tortuosity. However, it is believed that the Lucas–Washburn equation can be used to develop mathematical models to estimate the wicking rate [16.226]. Wicking rate has been comprehensively studied by *Wang* et al. [16.227] using a capillary rise method. They used the Hagen–Poiseuille equation and considered the effect of gravity to arrive at the following formula

$$\frac{\mathrm{d}h}{\mathrm{d}t} = \frac{R_\mathrm{D}^2}{8\eta h}\left(\frac{2\gamma\cos\theta}{R_\mathrm{S}} - \rho g h\right), \tag{16.7}$$

where γ, η, ρ and g denote surface tension, viscosity, density and gravity acceleration respectively while θ is the advancing contact angle, R_S shows mean static radius of the pores and R_D represents mean hydrodynamic radius. Similar equations can be found in the work of *Ballerini* et al. [16.228]. *Bhandari* et al. [16.229] showed that twist frequency and weaving coverage area of the yarn can be changed in order to adjust the desired wicking rate. *Safavieh* et al. [16.230] assumed that only 30% of the yarn was satiated with fluid and could propose a simple formula for the flow rate in hydrophilic yarns that obey Washburn's equation. They also showed that by increasing the wetting length, evaporation becomes important and proposed an equation for the volumetric flow rate of water, considering the saturation temperature, dew point and latent heat of water. Further details on models for prediction of wicking rates are reported by [16.231–234].

Natural threads are mostly coated with wax to increase their strength but this makes them unsuitable for microfluidic applications [16.230] since the presence of wax on the surface decreases the hydrophilicity of the material thus resulting in wicking rate reduction. Therefore, wet and dry methods are used to increase the wettability and hydrophilicity of the threads. Dry

methods are mostly based on plasma treatment while wet approaches hinge on mercerization.

Li et al. [16.225] performed a series of experiments to investigate the effect of plasma treatment as a dry method on wettability. Samples were analyzed with x-ray photoelectron spectroscopy (XPS) and it was shown that surfaces were highly oxidized and polarized, resulting in hydrophilization of the thread. *Rahel* et al. [16.235] used two alumina plates with discharge and induction electrodes on upper and lower plates and N_2, air, CO_2 and Ar as plasma gases in a surface dielectric barrier discharge system to hydrophilize polypropylene nonwoven fabric (PPNF). The authors concluded that N_2 was the most suitable gas to hydrophilize the fabric. Plasma treatment is reported by several other groups as a successful method for increasing the wicking rate [16.228, 236, 237].

Nilghaz et al. [16.238] utilized a wet method to increase wettability of unmercerized cotton cloth as their basic material by performing scouring treatment with NaOH and Na_2CO_3 (known as soda ash) to remove noncellulosic contamination. Briefly, the process included boiling the cotton for 5 min in the solutions followed by recovering the pH of the cotton by washing it with water and drying for 2 h. XPS, scanning electron microscopy (SEM), energy-dispersive x-ray spectroscopy (EDS) and light optical microscopy tests were carried out to compare the wicking rates of treated cottons and raw, untreated ones. Na_2CO_3 treatment was shown to give higher wicking rates. *Bhandari* et al. [16.229] investigated the effect of boiling tabby, crape and silk fabric in blocking solutions and demonstrated that the treated fabrics are capable of wicking colored dye solutions. Scouring treatment with a variety of solutions is also reported by other research teams to be a low-cost method for dewaxing and increasing the wicking rate [16.229, 232, 239].

Passive thread-based splitters and mixers were presented in the work of *Safavieh* et al. [16.230]. Mixing and splitting were attained by making handmade knots. Mixing ratios were analyzed quantitatively and it was demonstrated that different ratios of mixing can be achieved by using different knots.

Several scholars have tried to use various forms of textile-based microfluidics as chemiluminescence and electrochemiluminescence detectors [16.240, 241], electrochemical sensors [16.242], immunochromatographic assessment tools [16.243] and means of energy harvesting [16.231]. Thread-based microfluidic chips have also shown promising results in biomedical assays. *Agustini* et al. [16.244] showed the capability of a cotton thread-based microfluidic device for determination of acetaminophen and diclofenac in phosphate-buffered saline by a multiple pulse amperometry method. They used cylindrical graphite (used in mechanical pencils) with 0.5 mm diameter as working and reference electrodes and 0.7 mm-diameter graphite as a counter electrode. The cylindrical graphites were simply bonded to the device using a double-sided tape with a hydrophilic gauze deposited on top of the electrodes. *Nilghaz* et al. [16.245] introduced a device with a polyester substrate that could be used for blood typing by a chromatographic separation of blood. The authors immersed the threads in the antibody and dried them followed by addition of blood. Red blood cells then agglutinated and blood phases were separated resulting in creation of a band that could be easily visualized by the user. This method was reported to be a rapid method (< 1 min) that can be used in impoverished regions of the world. In this approach, shortcomings of paper-based methods such as higher blood volume consumption and substrate absorbency are resolved.

As a demonstration of the capability of performing electrochemical detection and separation by electrophoresis, *Wei* et al. [16.246], inspired by a dulcimer (a musical instrument), designed a chip to perform electrophoresis and electrodetection of $K_3Fe(CN)_6$ solution (Fig. 16.8). Their device consisted of polyester threads that acted as a route to transport the fluid while electric contacts were placed on protruding nuts as detector elements. The authors also showed that electrical current can be ten times higher in plasma-treated threads compared to nontreated threads.

All these methods display the capability of textile microfluidics as affordable platforms for diagnostics applications. However, we are still at the early stage of this technology and there remains further investigations to observe the capacity of using these devices in wearable clothing [16.223].

16.4.5 Hydrogels

The importance of using engineered materials that resemble characteristics of tissue environments for applications such as synthesizing extracellular matrices (ECM) brought up the idea of integrating hydrogels in microfluidics [16.247, 248]. Hydrogels are crosslinked polymers that are shaped from hydrophilic homopolymers, copolymers or macromers [16.249]. Heating, exposure to UV light and using chemical chelators are common methods to have the hydrogel chains crosslinked to form desired networks [16.247, 249]. Hydrogels have been used in many applications such as cell-to-cell interaction, drug delivery, artificial tissue constructs, and regenerative medicine [16.248–255]. Natural (collagen, agarose, alginate, chitosan, and gelatin) and synthetic (poly(acrylic acid), poly(ethylene oxide)) hydrogels, being optically transparent, can fa-

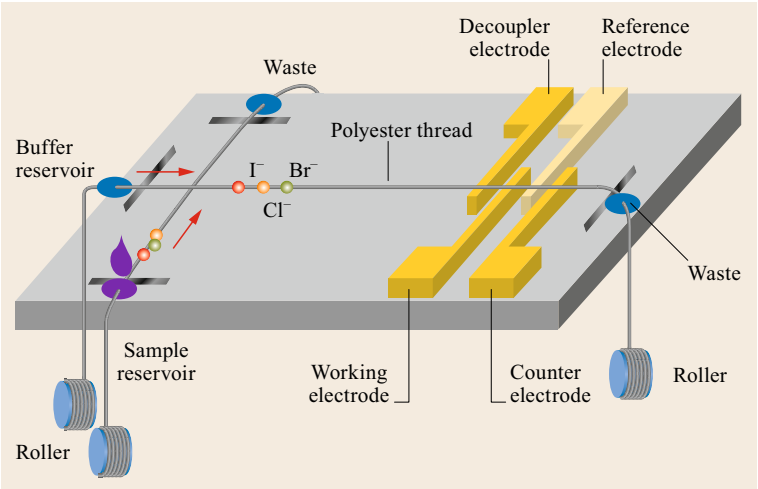

Fig. 16.8 Polyester thread-based device similar to the concept of a dulcimer designed for electrophoresis separation and electrochemical detection of ion samples and biological samples. Polyester threads act as conveyors of the solution to the detection zone where electrodes transmit signals associated with the detected sample (after [16.246])

cilitate free diffusion of molecules due to the presence of water-filled spaces between the polymeric chains [16.256–258]. Hydrogels are also nontoxic and can be accurately size calibrated [16.247]. In order to choose the appropriate hydrogel for a specific design, various properties of the gel such as swelling, porosity, diffusive characteristics, elasticity, and viscosity can be determinative [16.259–261].

Several methods are used for the integration of gels in microfluidics including a soft lithography-based approach with sacrificial or reusable templates, photopolymerization, and local integration. Briefly, soft lithography with reusable templates is very similar to conventional soft lithographic methods explained in the polymers section. Liquid hydrogels can be poured over a designed mold and solidified to from two-dimensional (2-D) or quasi-2-D structures in the gel [16.262, 263]. Although this method is straightforward and can be simply carried out for microfabrication, sealing and enclosing the channel is still a challenge in this approach. Therefore, sacrificial templates, that do not need sealing, can be used to form 3-D architectures in gels. A 3-D degradable template needs to be covered with the desired hydrogel to construct the replica of the template. The template can then be sacrificed to obtain the final device [16.186, 264–266]. This approach is typically followed when precise dimensions are not required such as studies of vascular systems (Fig. 16.9a). Another fabrication method is the local integration approach in which researchers take advantage of the laminar nature of flow in microfluidic systems. Various gels are co-introduced in a microchannel and due to the low Reynolds number, these flows form a laminated structure (Fig. 16.9b). Hence, the microchannel is subdivided into multiple layers separated by microslabs of hydrogels. The process is followed by solidification of the hydrogel using aforementioned methods [16.267, 268]. In the photopolymerization technique, for integrating microstructures into the microsystem, a UV light is employed to construct gel structures with high spatial resolution. Three types of photopolymerization are commonly used to form the structured gel components in a device: uniform exposure, printing with a mask and directed writing. High spatial resolution and high aspect ratio features are achievable using this method [16.248, 269–272].

Hydrogel technology is mainly applied to biological studies. Hydrogels have been very successful in tissue engineering as a means of mimicking native tissue architectures. *Miller* et al. [16.186] used a cytocompatible sacrificial template to construct a 3-D vascular network that could be lined with endothelial cells. *In-vitro* cell cultures that can be related to animal studies, in situ cardiac microtissues with real-time stress measurement, and bone-mimicking structures to study tumor cell migration are other examples that represent the capability of hydrogels in cell and tissue engineering studies [16.253, 273, 274].

Hydrogels are also being increasingly explored in organ-on-chips that are *in-vitro* devices in which microfabrication technologies are employed to develop microenvironments for coculturing of tissue- and organ-specific cells to mimic *in-vivo* physiology. Hydrogels could facilitate fabrication of 3-D cell cultures to perform more complex organ-on-chip studies in tissue microenvironments [16.57]. In one study, *Li* et al. [16.276] made a hepatic microtissue using PEG hydrogel that exhibited hepatocellular activities. These microtissues were then introduced in a microchannel for drug screening and could prove the capability of using hepatic microtissues for detection of hepatotoxicity and drug-drug interaction. Cell–cell interactions between human

mesenchymal and endothelial cells utilizing fibrin hydrogel, analysis of cytotoxicity of anticancer drugs in 3-D structures in which cells were cultured in hydrogels to simulate liver, tumor and marrow, are other examples that show the potential of incorporating hydrogels in organ-on-chip studies [16.277, 278]. Further details on methods of integration of hydrogels in organ-on-chips can be found in more specific review papers [16.279].

16.5 Applications

The principles of micro–nanofluidics have been applied in a wide variety of areas including environmental sensing [16.280], medical diagnostics [16.281], drug discovery [16.282], drug delivery [16.283], microscale chemical production [16.284], combinatorial synthesis and assays [16.285], artificial organs [16.57] and micropropulsion, microscale energy systems [16.286]. The applications can be broadly classified into those that have been commercialized and others that are in the research phase.

16.5.1 Commercial Applications and Their Working Mechanism

The need to control fluid flow at the micro- and nanoscale is applicable in a wide variety of application areas. Some of these areas have become multimillion dollar revenue-generating markets in themselves. In this section, some of the commercial microfluidic devices are discussed.

Inkjets

Microfluidic nozzles for inkjet printers were one of the early commercial successes of microfluidic technology in the 1980s. Inkjets replaced the dot-matrix printing technology, which was slower and more expensive. In inkjet printing, tiny droplets of ink are sequentially placed on paper in a controlled way to form an image pattern. Today the inkjet printing market is worth $900 million and expected to reach $1 billion [16.11]. The inkjet technology has expanded to other areas such as bio-ink printing [16.287], printing

plastics and conductive materials [16.288] and carbon nanotubes [16.289]. The print head consists of hundreds of micronozzles that were machined using laser micromachining. The nozzles were integrated with microfluidic channels that connect all the nozzles to a central ink reservoir and microfabricated actuators that can be individually controlled to precisely dispense the ink only from the selected nozzles. There are two types of inkjet printers depending on their mechanism of actuation. One method was known as bubble jet where tiny resistors were used to heat and vaporize the ink to form bubbles locally underneath the nozzles ($\approx 30-100\,\mu m$). The expansion of the bubble pushes the confined ink out between the bubble and the nozzle forming a drop. Removal of heating collapses the bubble and creates a vacuum that pulls in more ink from the cartridge through the microfluidic channel. The bubble jet technology was pioneered by companies like Canon and Hewlett Packard and relied on the small thermal time constants associated with the microfluidic channels and devices to form and collapse the bubble within $80-200\,\mu s$ [16.290]. There can be up to 600 nozzles that can produce tiny droplets either in a sequence or simultaneously. Another technology patented by Epson uses a piezoelectric crystal, which is placed behind the nozzle as the actuation method to produce tiny droplets. The charging of the piezoelectric crystal makes it vibrate towards the nozzle and pushes a small amount of ink through a nozzle, and when discharged, it vibrates away from the nozzle and it sucks in a tiny amount of ink from the reservoir to repeat the process (Fig. 16.10). The inkjet printers can produce 6000 drops per seconds and are capable of printing six pages per second at the highest resolution [16.290].

Microvalves

Microvalves are used for controlling the fluid volume inside a channel. They are critical for manipulating fluid flow inside microfluidic devices. Based on the type of actuation microvalves can be classified as passive and active. *Au* et al. [16.291], *Oh* and *Ahn* [16.113], *Laser* and *Santiago* [16.112] and *Ashraf* et al. [16.292] have reviewed the different kinds of microvalve in detail. The global market value for microdispensing devices was estimated as \$5.5 billion and is estimated to increase to \$7 billion by 2020 [16.293]. The primary advantage of the microvalves over their macroscale counterparts is the significantly reduced dead volume, which is useful in many applications that require precise flow control at small flow rates. Examples include microdispensing of drugs, gas flow in vacuum systems and microreaction engineering.

Passive Valves. Passive valves were among the first microfluidic valves developed and use only their structural design to allow flow in one direction while offering a high fluidic resistance in the opposite direction. They do not have any external actuation mechanism and usually rely on the input pressure level to open a valve that is closed. Check valves and capillary valves are two well known types of passive valves. They are generally incorporated at the inlets and outlets of reciprocal displacement pumps. Passive valves only open when a forward pressure is applied and thus behave like a diode.

Check Valves. Check valves use a mechanical structure that is compliant to fluid flow in one direction while becoming rigid in the opposite direction. In the case of microvalves, these mechanical structures have often been cantilevers [16.275], membranes [16.294] or flexible structures [16.295]. For instance, *Tiren* et al. [16.275] fabricated a check valve using silicon microfabrication technology as shown in Fig. 16.11. The maximum pressure that the valve could sustain was calculated as 1000 bar and the maximum cantilever deflec-

tion was found to be 10 μm. *Hasselbrink* et al. [16.295] developed a passive valve by selectively polymerizing an ultraviolet-sensitive photopolymer in etched channels of glass substrate. The polymerized conformal plug could be moved in the valve chamber under the flow itself to provide a diode-like function, blocking the flow when its direction is from the outlet to the inlet while allowing it in the opposite direction. They showed that their passive valves could seal a pressure greater than 300 bar with actuation times less than 33 ms.

Capillary Valves. Capillary valves use the dominance of surface tension in microfluidics to perform valving action. They can be designed based on geometry [16.296] or surface property (hydrophilic or hydrophobic) [16.297]. For instance, *Yamada* and *Seki* [16.296] developed a microdispenser array made of PDMS in which nanoliter-sized droplets could be accurately dispensed. In their system, the hydrophobic and narrow channels acted as valves and were used to manipulate and transport fluid. Their geometry included a larger microchannel abruptly narrowing into a smaller channel. The pressure required to overcome the surface tension in the larger channel is much lower than that required to overcome it in the smaller channel as shown by the Young–Laplace equation. Therefore, this geometry creates a unidirection passive valve allowing liquid from the smaller to larger channel to flow freely while preventing the flow from the larger to smaller channel. Once the liquid is valved, pneumatic pressure can be further increased above the threshold required to force the fluid into the narrower channel. In this study the pressure threshold to perfuse the liquid in the larger (100 μm) and smaller (5 μm) channels was 0.001 to 0.197 bar respectively. Similarly, *Andersson* et al. [16.297] used octafluorocyclobutane (C_4F_8) patches as hydrophobic valves. They deposited the fluoropolymer (C_4F_8) lithographically in deep reactive ion etched silicon channels. The change in surface property changes the surface tension, which results in a high critical threshold of pressure required to perfuse the channel. The valve showed good sealing for water (up to 5 h) and a pressure of 0.0076 bar was required to break the seal.

Active Valves. Active valves require an external force of field for actuation. This force/field can be magnetic [16.298–300], electric [16.166, 301], piezoelectric [16.302], thermal [16.303–305], pneumatic [16.24, 272] or of other types [16.306].

Magnetically Actuated Valves. Magnetically actuated valves are usually diaphragm-based, where a large rigid structure attached to a membrane diaphragm is actuated by an external magnetic field to move it closer to the inlet or the outlet of the valve chamber and close it tightly. These valves usually have a ferromagnetic material such as nickel-iron alloy (NiFe) integrated into the boss or the diaphragm structure. Since the ferromagnetic material is strongly attracted to the magnetic field, it can be actuated by controlling a magnetic field external to the device. For instance, *Yanagisawa* et al. [16.298] developed an electromagnetically driven microvalve fabricated photolithographically. The valve consists of a magnetically suspended spring with a valve cap made of NiFe and an external coil for driving the valve cap. When a magnetic force is applied, the valve cap is pushed down closing the outlet forming a tight seal. They were able to control the valve's flow rate between 66 and 51401/min and an input pressure of 3×10^{-12} kPa. Similarly, *Byunghoon* et al. [16.299] designed a microvalve with a permanent magnet attached to a membrane actuated with an external solenoid for a glaucoma implant. The membrane was deflected using a current pulse and a pressure of 2.3 kPa was obtained for a 60 mA pulse. *Oh* et al. [16.300] fabricated a pinch-type valve for lab-on-chip application. The valve consisted of a solenoid actuator with a pinch-type plunger attached to a biomedical grade silicon tubing. Their pinch valve showed no leakage up to 200 kPa and zero dead volume.

Electrostatic Actuated Valves. Electrostatically actuated valves are also usually diaphragm based. Unlike the magnetic valves, the electrostatic ones have electrodes embedded into the membrane diaphragm and another rigid one placed close to it with the electrodes separated by a dielectric. Application of a high potential between the electrodes leads to electrostatic

attraction between the electrodes, which pulls the flexible diaphragm closer to the rigid electrode. As an example, *Goll* et al. [16.166] fabricated a microvalve consisting of three membrane layers. Two insulating layers sandwiched a gold layer of 3 μm thick and was controlled by electrostatic force by using electrodes in the upper and lower chamber separated by 25 μm. A voltage range between 60 and 150 V was required to close the valve compactly and at a pressure of 110 kPa nitrogen gas flow rate was measured as 12 ml/min. *Schaible* et al. [16.301] micromachined a silicon plate and a membrane to regulate pressure up to 1600 kPa and a response time of 1 ms. They used a miniaturized voltage amplifier with inputs between 3 and 12 V to actuate the valve.

Piezoelectrically Actuated Valves. Similar to the magnetic actuation, piezoelectric crystals that produce a mechanical stress when an electric field is applied can be embedded onto diaphragms of valves for valve actuation. These crystals are capable of producing large bending force with small displacements. Application of a potential to these crystals produces a mechanical displacement, which then moves the diaphragm and the structures connected to it against the inlet or outlet of the valve chamber to close it. As an example, *Rogge* et al. [16.302] designed a microvalve for gases and liquids that was piezoelectrically actuated. They achieved 25-fold hydraulic amplification with a stroke volume of 50 μm. Voltages up to 300 V were possible at a response time of 2 ms. The leakage flow rate was measured as 30 μl/min at a pressure of 200 kPa for nitrogen and 0.013 μl/min for water at a pressure of 100 kPa.

Thermally and Thermopneumatically Actuated Valves. Thermally actuated valves can be classified into bimetallic [16.303], thermopnuematic [16.304] and shape memory alloy [16.305] actuation. The bimetallic actuation utilizes the differential thermal expansions of different materials in a bilayer to introduce a bending moment that can actuate a boss attached to it to close the inlet or outlet in the valve chamber. Microheaters are typically embedded with the bimetallic elements to introduce local control of actuation. As an example, *Barth* [16.303] deposited 30 μm Ni film on a silicon membrane to fabricate a bimetallic valve. This microvalve functioned at 1035 kPa and had a flow rate of 1 l/min of air with an actuation time of 0.2 s. Another thermal actuation method is the use of phase change to generate a pressure in a confined chamber that can then deflect a membrane, which can seal the inlet or outlet of the valve. *Rich* and *Wise* [16.304] demonstrated such a microvalve having a cavity sealed with volatile fluid below a membrane. The cavities were partially filled with pentane to improve thermal efficiency and polysilicon heaters were placed 9 μm above the cavities. The microvalve used 500 mW to generate a pressure of 16 Pa. The leakage flow rates were measured as 1 μl/min. An alternative to bimetallic actuators is the use of shape memory alloys. *Kohl* et al. [16.305] developed microvalves based on shape memory alloy (SMA) thin films. The microvalve is in a normally open position. NiTiPd thin film coating was used as SMA (Fig. 16.12) and sustained pressure up to 250 kPa for a gas flow rate of 360 ml/min. A 110 mW power was required for NiTiPd microvalves. Figure 16.12 shows the open (a) and closed (b) positions of the SMA microvalve.

Phase change valves comprise of hydrogel valves [16.272] and paraffin microvalves [16.307]. Smart hydrogels can change their state reversibly with some external stimuli. *Beebe* et al. [16.272] developed a smart hydrogel-based microvalve that can be actuated pH. The hydrogels were photopolymerized in liquid phase directly inside the channels. A flexible PDMS membrane was coupled with the pH-sensitive

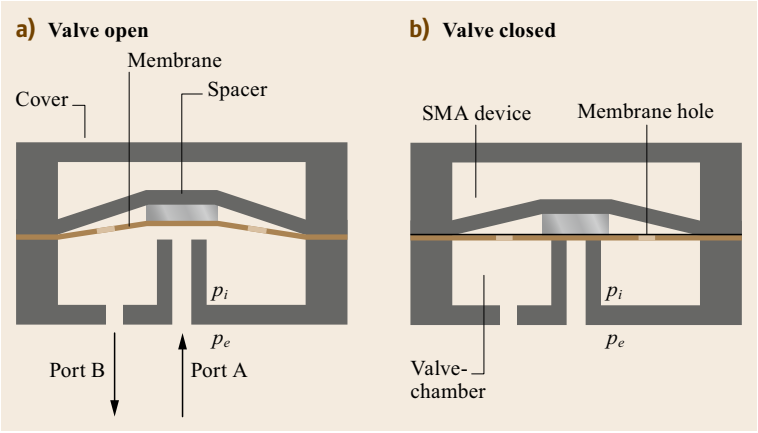

Fig. 16.12a,b Smart material alloy (NiTiPd) microvalves: **(a)** normally open position. **(b)** closed position after actuation (after [16.305])

hydrogel to expand as the pH of the solution changed to 11, sealing the channel completely. The hydrogel expansion generated an internal pressure of 184 kPa with a maximum displacement of up to 185 μm. The membrane completely shut off the channel in 19 s. *Liu* et al. [16.307] heated paraffin wax to change the phase to open and close channels. A paraffin plug was heated so that it changed phase from solid to liquid and by using external pneumatic pressure the plug was moved inside a microchannel. Upon cooling, the paraffin plug changed to solid phase, sealing the entire channel. No leakage was detected over a period of 15 min for a pressure of 1725 kPa. The time response for paraffin-based microvalves was around 2–10 s.

Pneumatic Actuated Valves. In pneumatic actuated valves a positive pressure is applied to expand a flexible membrane to compress a channel thereby sealing it. Pneumatic valves include in-plane [16.129] and inline [16.24] actuation. As an example, *Lagally* et al. [16.129] used a latex membrane for in-plane actuating pneumatic valves to develop a fully integrated PCR-capillary electrophoresis (PCR-CE) system on a glass chip. Two aluminum manifolds were used as hydrophobic vents and a vacuum was used to clamp the latex membrane and inlet ports in place. The manifolds were connected to external solenoid valves for pneumatic actuation. A vacuum was used to load the sample and transport it to the PCR chamber. The latex membrane was pressurized to 89 kPa to seal the PCR sample. *Unger* et al. [16.24] developed multilayer soft lithographically fabricated microvalves. The inline microvalve consists of two PDMS blocks with channels. The two PDMS blocks are then bonded to each other such that they form a cross structure (Fig. 16.13). The upper PDMS channel is pneumatically pressurized and it selectively closes off the bottom channel at the intersections. The channels were 100 μm wide and 10 μm in height. A pressure of 60 kPa was used to close the valve within few milliseconds.

Other Actuation Valves. Several other methods have also been used to actuate microvalves including electrokinetic and electrochemical techniques. *Neagu*

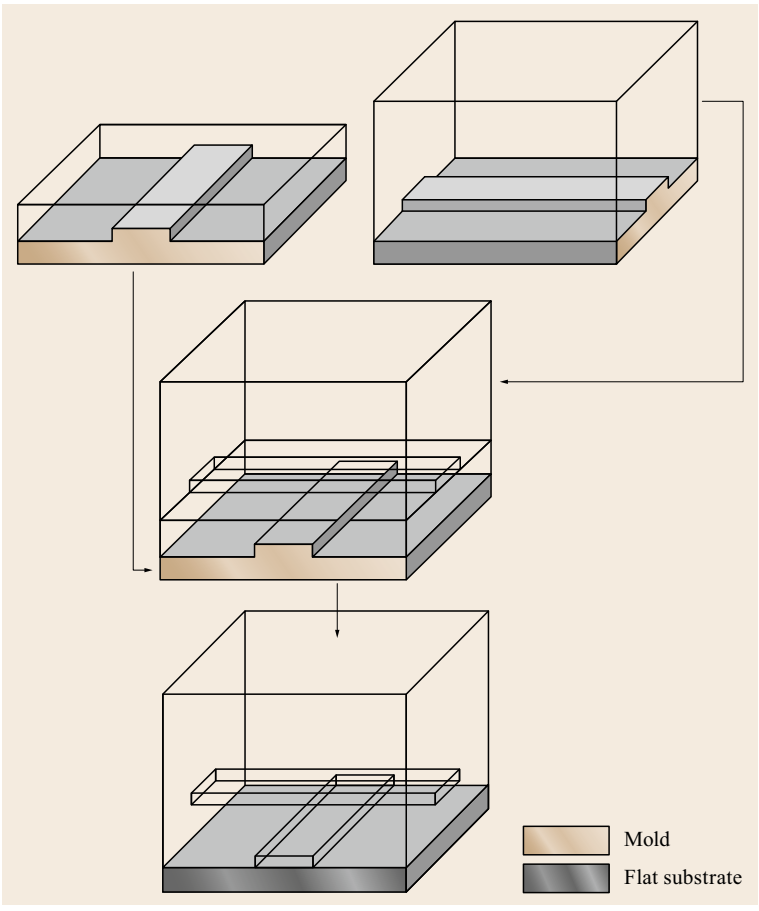

Fig. 16.13 Schematics of the Quake valve setup showing overlapping of the control channels and the fluid channel

et al. [16.306] developed an electrochemical-based microvalve. They utilize the pressure generated due to production of oxygen by electrolysis to deflect a membrane. By supplying 1.6 V and 50 μA, the membrane was deflected by 30–70 μm and generated a pressure of 200 kPa in a few seconds.

Valves were also actuated electrokinetically as demonstrated by *Kirby* et al. [16.308]. Here a potential applied to a fluid generates electrokinetic force that produces a substantial pneumatic pressure in a microchannel. This pressure was used to move a porous polymer plug to seal off a secondary valve chamber and prevent flow between its inlet and outlet. They generated plugs that were 60 μm long by photopatterning of polymer monoliths inside microchannels, which were electrokinetically operated by creating pressure gradients. The valves had a working pressure of 350 bar. They showed a voltage addressable electrokinetic valve useful for liquid chromatography.

Micropumps

Transport of fluid is one of the important aspects of microfluidic devices. Micropumps have been developed using several principles and actuation mechanisms. They can be broadly classified as mechanical [16.309], nonmechanical (electrokinetic and magnetokinetic [16.310], phase change [16.311]) and other novel technologies [16.312]. *Au* et al. [16.291], *Laser* and *Santiago* [16.112] and *Ashraf* et al. [16.292] have reviewed the micropumps in detail. Micropumps can be broadly classified into mechanical and nonmechanical pumps.

Mechanical Micropumps. Mechanical micropumps are characterized by the presence of moving parts in their actuation mechanism. They can be further classified by different actuating mechanisms into rotary displacement pumps [16.309] and vibrating diaphragm pumps [16.310–320].

Rotary Pumps. Rotary pumps typically have a rotor that is positioned such that it sweeps a defined volume of fluid from the inlet to the outlet of the pump. The mechanical action and the direction of motion determine pressure generated. As an example, *Döpper* et al. [16.309] fabricated gear pumps using microfabricated gear wheels. Gear wheels with diameters of 592 and 1192 μm and a height of 500 μm were realized using a combination of lithography, electroplating and molding (LIGA) and precision engineering. They used oil as the pumping medium to achieve a back pressure of more than 1200 kPa and flow rates up to 1 ml/min. They were able to control the amount of oil displaced precisely using this pump and also pump viscous fluids easily because of the good back pressure obtained in their gear pump.

Vibrating Diaphragm Pumps. A vibrating diaphragm pump also known as a membrane pump combines the reciprocating action of the diaphragm or membrane and valves on either side of the flexible diaphragm/membrane to pump fluid. The diaphragm sits atop the pump chamber and vibrates back and forth upon actuation. The motion of the diaphragm displaces the fluid in the chamber in all directions. However, two check valves placed at the inlet and the outlet rectify the flow and cause a net displacement of the fluid over a cycle. These positive displacement pumps can be used to pump any fluid or gas. Vibrating diaphragm pumps can be further classified according to actuation mechanism as electrostatic, electromagnetic, piezoelectric and thermopneumatic pumps. As an example, *Zengerle* et al. [16.310] have developed a flexible diaphragm pump that can be actuated electrostatically with two passive check valves. The unique function of their pump is that it can be run bidirectionally depending on the frequency and pressure. They designed a flap valve that works in the forward direction at low frequency (0.1–800 Hz) and reverses the direction at high frequency (2–6 kHz). They achieved a maximum flow rate of 850 μl/min in the forward direction and 200 μl/min in the reverse direction. The pump had a maximum back pressure of 31 kPa (water) in the forward and 0.7 kPa in the reverse direction.

Dario et al. [16.311] designed and fabricated a microanalyzer for detecting heavy metals in water. Their device consisted of a micropump with a built-in passive valve and an active valve fabricated by a thermoplastic molding process. They actuated the diaphragm using electromagnetic force. Their pump produced a head pressure of 5.5 kPa with a maximum flow rate of 13 ml/s. *Andersson* et al. [16.312] have developed a valveless diffuser micropump for microfluidic analytical systems using peizoelectric actuation. The pump was fabricated on a silicon glass stack (Fig. 16.14) with three subsequent deep ion reactive etching steps. The diaphragm was moved using a piezoactuator placed adjacent to it. They achieved a maximum pump rate of 0.3 μl/min for glycerol and 2.3 μl/min for water.

Piezoelectric actuated pumps are the most researched and have found commercial applications. Several groups including *van Lintel* et al. [16.313], *Stemme* and *Stemme* [16.314], *Forster* et al. [16.315], *Gerlach* and *Wurmus* [16.316], *Koch* [16.317], *Olsson* et al. [16.318] and many more have developed pumps based on piezoelectric actuation. Piezoelectric actuated micropumps are available from companies like ThinXXS2000 [16.319] and Debiotech S.A. [16.320].

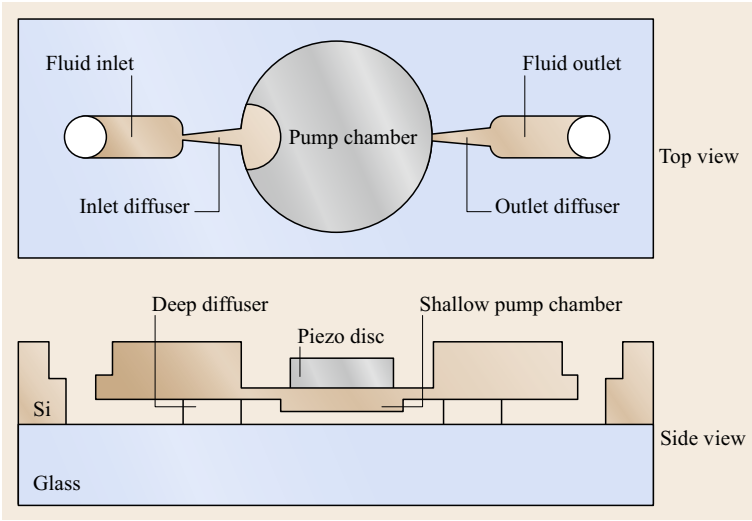

Fig. 16.14 Piezoelectrically actuated micropump fabricated using deep ion reactive etching process (after [16.297])

Phase Change Micropumps. Phase change pumps are a subset of reciprocating pumps where a change in phase (liquid to gas), usually induced by a microheater underneath, generates a pressure that drives the fluid forward. Bubble pumps and electrochemical pumps are types of phase change micropumps.

Bubble Pumps. Bubble pumps expand and collapse a bubble periodically to generate a pressure difference to move the fluid forward. Liquid is heated to expand and its phase change pushes the rest of the fluid in a microchannel. Heating is controlled by applying a voltage. *Tsai* and *Lin* [16.321] reported a bubble pump that was fabricated from two material layers. They pumped isopropyl alcohol at a flow rate of 45 µl/min at a maximum pressure of 400 Pa operating at 20 V.

Electrochemical Pumps. Electrochemical pumps use bubbles generated from electrochemical reactions as the phase change mechanism to generate the pressure to move the fluid forward. *Böhm* et al. [16.322] reported an electrochemical pump to dispense volumes of five nanoliter range. They used electrolysis of water to generate bubbles to drive the fluid forward.

Nonmechanical Pumps. Nonmechanical pumps do not use moving parts as a component of their mechanism but directly convert nonmechanical energy (electrical, magnetic, chemical) into mechanical kinetic energy to pump the fluid in microchannels. They can be categorized as electrohydrodynamic [16.323], magnetohydrodynamic [16.324] and electroosmotic [16.76, 325] micropumps.

Electrohydrodynamic Pumps. Electrohydrodynamic (EHD) pumps move dielectric liquids using electrostatic forces. Application of an electric field between two electrodes placed in a dielectric field leads to some induced charges. The electric field acts on those induced charges producing an electrostatic force that then drags the surrounding fluid along with it. As an example, *Fuhr* et al. [16.323] fabricated an EHD pump where traveling waves were applied to arrays of electrodes. They used dielectric force to transport the fluid by applying an electric field to a fluid having a permittivity gradient. Their pump operated at a maximum voltage of 40 V and generated a maximum flow rate of 2 µl/min.

Magnetohydrodynamic Pumps. Magnetohydrodynamic (MHD) pumps use Lorentz force to induce a body force on the fluid by subjecting the current-carrying ions in an aqueous liquid to a magnetic field. Usually the electrodes are placed in the fluid in such a way that the direction of the current and the magnetic field lines are orthogonal. This produces a body force in the mutually perpendicular direction. As an example, *Jang* and *Lee* [16.324] reported a MHD where they were able to pump fluid through a 40 nm-long microchannel with a hydraulic diameter of 1 mm. The permanent magnets used in their pumps had a magnetic flux density of 0.44 T and generated a maximum flow rate of 63 µl/min with a maximum pressure of 170 Pa.

Electroosmotic Pumps. Electroosmotic pumps use the surface charge created by the electric double layer when a liquid comes into contact with the walls of the microchannel [16.326]. Electric field applied along

the axis of the microchannel tends to impose a body force on the charged layer of fluid adjacent to the walls, which subsequently drags the bulk of the fluid along with it. As an example, *Zeng* et al. [16.76] developed an electroosmotic pump using capillaries packed with silica particles. Their capillaries had large diameters (500–700 μm) and the pump generated a maximum flow rate of 1 μl/min and a pressure of 1 kPa. *Debesset* et al. [16.325] report an electroosmotic pump with flow rates as high as 50 μl/s using an alternating current (AC) electric field to pairs of unequal width electrodes (Fig. 16.15). They developed this pump for chromatography. The electrodes were placed in a circular array and the fluid was pumped in a closed-loop channel.

Other/Novel Micropumps. New technologies like flexural plate waves [16.327], electrowetting [16.328] and acoustic streaming [16.329] have been used to pump fluids.

Flexural Plate Wave Devices. A micropump based on flexural plate waves was developed by *Luginbuhl* et al. [16.327]. In flexural plate wave devices, acoustic waves propagate through a membrane fabricated using thin-film technology to transport fluid. Their device consisted of dual interdigitated transducers fabricated on a thin film membrane made of silicon nitride, platinum and sol-gel-derived piezoelectric ceramic. The device operated at a frequency between 2–3 MHz and actuated a 2×8 mm thin-film membrane. They reported a flow rate of 255 nl/min.

Electrowetting Micropumps. A change in wettability due to applied electric potential moves the fluid. Surface tension is the main reason for transport of fluid in electrowetting micropumps. When a voltage is applied to a dielectric layer, the interfacial energy decreases for the solid–liquid interface causing the fluid to move. *Yun* et al. [16.328] report a surface tension-driven pump by continuous electrowetting. They used the surface tension-induced motion of a mercury drop to transport fluid inside the microchannel. The micropump has a three-layer stack of silicon wafers bonded together. The mercury drop is inserted into a SU-8 channel fabricated on the bottom silicon wafer. When the mercury drop moves it drags an electrolyte solution that deflects the membrane on the second silicon wafer. The third layer consists of passive check valve forming the inlet and outlet of the pump. They achieved a flow rate of 70 μl/min at a voltage of 2.3 V with a maximum pump pressure of 800 Pa.

Acoustic Streaming. Surface waves were used by *Wang* et al. [16.327] to transport fluid inside a microchannel. Interdigital transducers were fabricated to generate surface waves, which propagated towards the microchannel and interacted with the liquid. The compressional component of the wave would be diffracted at the Rayleigh angle into the liquid. The surface waves transfer heat to the substrate and liquid, which increases the saturation pressure of water vapor and will increase the evaporation rate, pushing the liquid forward. Piezoelectric actuators operated at 2–3 MHz to generate a flow rate of 255 nl/min.

Micromixers

Micromixers are important components of lab-on-chip devices for applications in drug delivery, sequencing, amplification and biochemical reactions. *Hessel* et al. [16.69] and *Nguyen* and *Wu* [16.70] have contributed detailed reviews on micromixers. Based on the actuation method, micromixers can be broadly classified as passive and active.

Passive Mixers. Passive mixers do not require external energy and depend solely on diffusion and chaotic advection processes for mixing. The microfabricated structure forces the two combining fluids into shapes

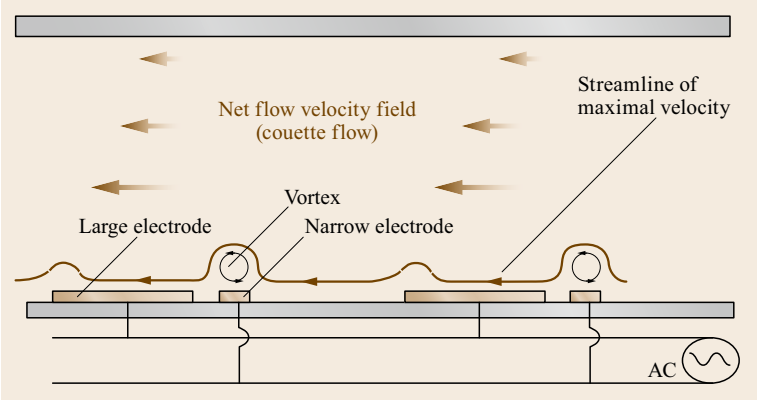

Fig. 16.15 Electroosmotic flow generated using AC voltage applied to pairs of asymmetric electrodes (after [16.325])

and forms that increases the effective surface area between the two fluids and enhance diffusional transport between them. Different types of passive mixers include lamination, injection, chaotic advection and droplet-based mixers.

Lamination. In lamination micromixers, the inlet stream is split into substreams and then the streams are joined again to form a laminate. Diffusional mixing in microfluidic channels can be enhanced by increasing the surface area of contact and reducing the diffusion length. The lamination micromixers generally consist of two inlets connected to a long microchannel. They are also called T-mixers or Y-mixers [16.330, 331] because of the design (Fig. 16.16). The long microchannel provides good contact area for diffusion and the width of the microchannel is small enough for fast diffusion process.

Wong et al. [16.332] reported a T-mixer manufactured on a silicon substrate and bonded it to glass. They applied different pressures to study the effects on mixing. They observed best mixing performance between Reynolds numbers of 400 and 500. They report for a T-mixer 67 μm in hydraulic channel diameter, an applied pressure of 5.5 bar is sufficient to generate complete mixing in less than a millisecond after the two fluids are in contact. *Yi* and *Bau* [16.333] studied the effect of rectangular cross-sections aligned at 90° on steady laminar flows. The bend in their design (Fig. 16.17b) helped in inducing vortices to stir the fluid and this improved mixing. They observed that the vortices disappear quickly at low Reynolds numbers and as a result they had to introduce a number of bends to achieve the desired effect. Using this design they were able to achieve a Reynolds number of 30 where mixing happened right after the bend. *Bessoth* et al. [16.334] used parallel flow lamination design to develop a micromixer. They fabricated a device with structures from a glass/silicon/glass sandwich (Fig. 16.17c), which had a total volume of ≈ 600 nl. They report flow rates between 1–200 ml/min to achieve 95% mixing in 15 ms. *Knight* et al. [16.335] report a continuous flow focusing mixer for fast mixing in microchannels. They showed mix times of less than 10 μs for a sample flow rate of nl/s. They adjusted the flow rates between the sample and sheath flow to achieve this fast mixing. They also reported a Reynolds number of 0.5 for their mixer.

Injection. In an injection mixer, the solute flow is split into many streams and then injected back into the solvent flow at multiple locations. An array of nozzles create microplumes on top of the stream creating a shorter path and increasing the contact area to accelerate diffusion. *Miyake* et al. [16.336] have developed an injection mixer to increase the mixing efficiency in microchannels. They report a homogeneous mixing of 0.5 μl volume in 1.2 s at a flow rate of 0.75 μl/s and a Reynolds number of 0.018.

Chaotic Advection. Chaotic advection is another process by which mixing can occur passively at low Reynolds numbers besides diffusion. Chaotic advection can be generated by special geometries incorporated in the microchannels or by external force. The shape of the channel is altered for splitting, folding, stretching or breaking the flow of fluid. The Reynolds number in such devices can vary anywhere between 10 and 100.

Lin et al. [16.337] developed a mixer that operated at Reynolds numbers ranging between 200 to 2000 and was able to mix 450 pl volume in 50 μs. They introduced vertical pillars (10 μm diameter) in a staggered fashion perpendicular to the direction of flow to achieve turbulent mixing.

Hong et al. [16.338] developed a 2-D micromixer with a modified Tesla valve-type structure. It generated a Coanda effect that caused chaotic advection

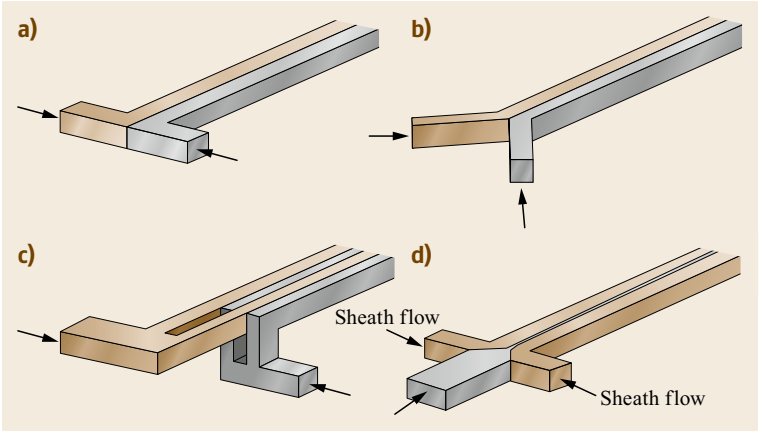

Fig. 16.16a–d Micromixing in microchannels. **(a)** T-mixer **(b)** Y-mixer **(c)** parallel lamination mixer **(d)** continuous flow focusing mixer

and improved mixing. The mixer was fabricated using cyclic olefin copolymer by both thermal bonding and hot embossing techniques. The mixer operated well at Reynolds numbers of 5 and above.

Stroock et al. [16.339] investigated the staggered herringbone structures for mixing. Their mixer operated in low Reynolds numbers ranging between 1 and 100. They fabricated channels 200 μm wide and 70 μm high in PDMS.

Droplet Mixing. Diffusion path can also be reduced by mixing inside droplets. The mixing happens inside the droplet due to its movement, which causes an internal flow field. This technique was used by *Hosokawa* et al. [16.340]. They fabricated a droplet micromixer in PDMS and sealed the channels using a PMMA sheet. A hydrophobic capillary vent was used to fuse two droplets. They showed mixing of two 5 nl droplets pneumatically inside a microchannel.

Active Mixers. In active mixers, an external perturbation is required for actuation. The various perturbations that have been used include pressure disturbance, and electrohydrodynamic, dielectrophretic, electrokinetic, magnetohydrodynamic, acoustic and thermal pulses.

Pressure Disturbance. *Deshmukh* et al. [16.341] used micropumps to achieve pulsatile flow in a continuous flow microfluidic mixer. They fabricated a T-mixer (Fig. 16.17b) within which the micropumps attached to the two inlet arms alternatively drive and stop the flow inside the channel to create a segmented flow. Their micromixer was integrated into a microfluidic device and was fabricated using deep reactive-ion etching (DRIE). Their mixer operated at a low Reynolds number of 0.01.

Electrohydrodynamic Mixing. In electrohydrodynamic mixing, the two fluids that merge into a central flow in a T-channel mixer subjected to anytime varying electric field generate an electrohydrodynamic force (Fig. 16.17d). The superimposition of the time-varying EHD body force over the constant pressure-driven flow causes the advection process and mixing. *Moctar* et al. [16.342] fabricated electrodes such that they were perpendicular to the interface between the two fluids, creating a transversal flow. They used a flow rate of 0.26 μl/s, which corresponded to a Reynolds number of 0.0174. By optimizing the voltage and frequency they observed time for good mixing took 0.1 s over a very short distance (≈ 250 μm).

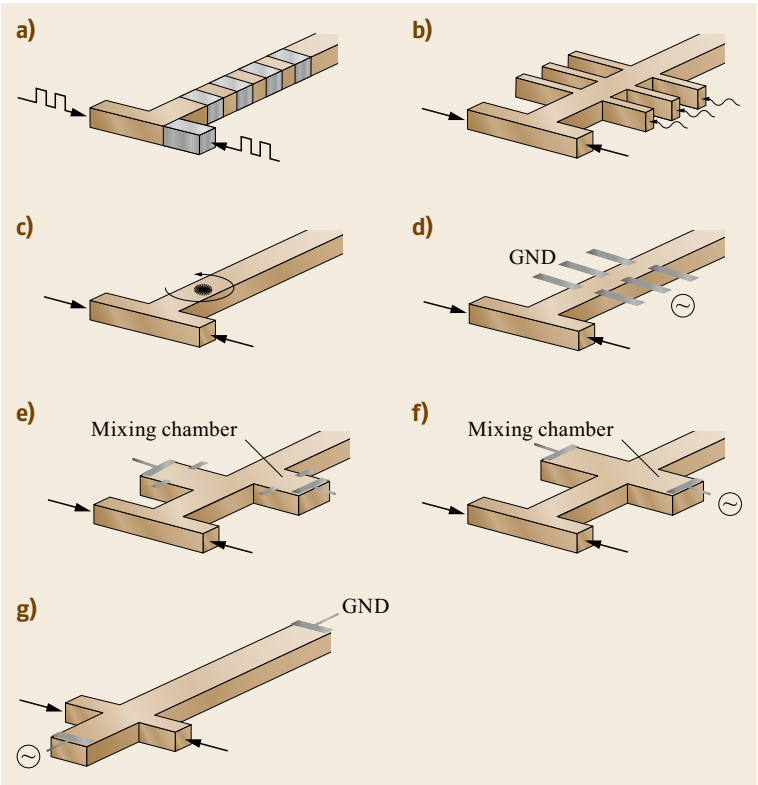

Fig. 16.17a–g Schematics of different types of active mixers

Dielectrophoresis. Dielectrophoresis is the the force acting on a particle when it is subjected to nonuniform electric field. This effect can be used to move a particle towards or away from an electrode (Fig. 16.17e). *Deval* et al. [16.343] reported a dielectrophoretic mixer that used electrical fields as well as geometry to produce chaotic advection. The micromixer operated at 0.02 Reynolds number. The micromixer was integrated into microchannels fabricated using a photolithography technique on silicon and glass.

Electrokinetic Mixing. Similar to pressure disturbance in microchannels for mixing, electrokinetic perturbation can be used to generate segmented flow (Fig. 16.17f). *Tang* et al. [16.344] used periodic application of an electric field to induce electrokinetic flow superimposed on the pressure drive flow to generate alternating segments of the two fluids for mixing. They fabricated the micromixer chamber in PDMS material. Their micromixer operated at 0.04 Reynolds number and they found that the mixing in channels is highly dependent on applied frequency.

Magnetohydrodynamic Mixing. In the presence of a magnetic field orthogonal to an applied direct current (DC, voltage on the electrodes would generate Lorentz force, which can be used for mixing. *Bau* et al. [16.345] developed a micromixer using the magnetohydrodynamic force. The mixer was made from ceramic tapes and a gold paste was used for printing the electrode.

Acoustic Mixer. Acoustic wave energy can also be used to mix fluids inside microfluidic chambers. *Vivek* and *Kim* [16.346] developed an acoustic wave mixer in fabricated silicon. Acoustic waves were produced using a zinc oxide membrane located under the mixing chamber. The vibration was controlled by changing the frequency and voltage of the signal.

Thermal Mixing. Thermal energy was used for mixing fluids. Since diffusion coefficient is dependent on temperature, mixing can be accelerated by increasing the temperature of the chamber. *Tsai* and *Lin* [16.347] developed a thermal mixer based on advection created due to thermal bubble generation. They used a thermal bubble actuated micropump to oscillate the flow creating disturbance inside the mixing chamber. They found that 200 Hz was the optimized frequency for fast mixing in a channel 200 μm wide and 50 μm deep.

Microreactor

Micro–nanofluidic devices can be fabricated in which channels and chambers have extremely small volumes (pl–μl). If these chambers are used as reactors, then reactants can be combined in a precise way and allowed to react for a controlled duration of time. The ability to precisely control the residence time of the reaction allows microfluidic reactors to achieve reaction chemistries that are not possible in large-batch-type reactors. For instance, reactions that produce the desired compound as an intermediate can be performed in the microreactor where the reaction stream is quenched before the intermediate is converted to the final product. The large surface-to-volume ratio of the microreactor also allows highly exothermic reactions to be performed, which may not be possible in a large-batch reactor. Furthermore, microreactors can be parallelized for batch production with higher yields. Reviews regarding chemical synthesis [16.348], novel chemical compounds [16.349], and photocatalytic reactions [16.350] using microfluidic microreactors and production process [16.351] are available.

The microreactor technology has seen much interest from industry. For instance, Lonza has developed a Flowplate lab microfluidic reactor designed for laboratory research for process development. This platform technology was developed to enable easy transfer of technology for commercialization. A production-scale Flowplate A6 microreactor has also been developed that can synthesize products in the kilogram range [16.352]. Other companies such as Little Things Factory GmbH have also developed microreactors on silicon and glass substrates [16.353]. They also supply starter kits for training purposes through SigmaAldrich Inc. and are also capable of developing customized solutions for specific reactions. Researchers at Hitachi Plant Technologies Ltd. [16.351] carried out three reactions (bromination, nitration and ester reduction) in microreactors and compared the yield to conventional batch processes. They reported a 40% increase in yield for the bromination reaction by using microreactor technology. Microreactor technology has been used for studying emulsification processes and nanoparticle generation [16.351]. *Lee* et al. [16.354] have used the microfluidic microreactor technology to synthesize radiolabeled chemical for injection into mice. A micro-computer tomography (micro-CT) image showed the accumulation of the radiolabeled chemical *in-vivo* in mice. Microreactors optimize reaction parameters. In such a study [16.355] the Paal–Knorr reaction product was continuously monitored using infrared analysis for reaction optimization using several multitrajectory strategies.

Lab-on-Chip Systems

Many processes in biochemical analysis, especially those associated with molecular assays, have a number of unit operations that have to be sequentially

performed in order to identify a particular molecular species from the sample. Starting in the 1990s, microfluidic device were designed to miniaturize, integrate and automate many of the unit operations so that these assays could be performed in a wide variety of settings from the bedside and in the field without any particular user expertise. These devices came to be known as lab-on-chip as they performed all the operations that happen in a laboratory effectively on a microfabricated chip.

Microamplification Devices. DNA amplification is one of the most important processes in molecular biology and was one of the earliest process implemented in microfluidic devices. Polymerase chain reaction (PCR) was the first amplification method that was developed in the early 1980s to copy a defined stretch of DNA a million times to enable its detection. It uses a temperature cycle from 55 to 95 °C to perform the biochemical operations of denaturing the DNA, attaching markers known as primers and initiating the polymerase enzyme to copy the strand between the primers. Repetition of this temperature cycle, a process that takes several hours, leads to an exponential increase in the number of copies producing a million copies in 30 cycles. Based on the cycling temperatures, PCR can be broadly classified as temperature-cycling PCR and loop-mediated isothermal amplification (LAMP). LAMP is an isothermal process where the amplification takes place at a constant temperature (typically 65 °C). The cycling-temperature PCR process was miniaturized first in 1995 by *Northrup* et al. [16.19], which led to faster amplification. Since then a large number of amplification devices have been developed that can be categorized based on types of heating and materials [16.356, 357] and method of amplification (chamber [16.358], continuous [16.357] and droplets [16.359]).

Heating Methods for Amplification. Various heating methods (contact and noncontact) have been developed for carrying out PCR reactions in microfluidic chips. Contact methods include thin-film heating elements [16.360], metal or heating blocks [16.361] and other methods [16.362]. *Daniel* et al. [16.360] fabricated a PCR device in silicon by micromachining using an anisotropic wet etching process. They used thin-film platinum metal for heating the chamber. *Khandurina* et al. [16.361] developed an integrated system for rapid PCR analysis on a microfluidic chip. They utilized dual Peltier thermoelectric elements for heating the samples. Other technologies like commercial thin-film resistance heaters [16.362] have been used for PCR. The authors carried out PCR in a plastic microfluidic chip for bacterial detection. Graphite ink electrodes were used as heaters for heating 29 nl volume samples.

Noncontact methods of heating for PCR include hot air cycling [16.363], infrared light irradiation [16.364], laser-mediated heating [16.365] and other methods [16.366]. *Wittwer* et al. [16.363] report a thermal cycler for PCR based on heat transfer with air in a sealed capillary tube. They control the air temperature using a thermocouple and heating coil. *Oda* et al. [16.364] developed a noncontact heating method for PCR in glass chips. They used a tungsten lamp as a heating source and cooled it by natural air convection. *Tanaka* et al. [16.365] used a diode laser to carry out photothermal temperature control of enzyme-catalyzed reaction in a microchip. Other noncontact heating methods include microwave-assisted heating demonstrated by *Fermér* et al. [16.366].

Fluid Handling Methods for Amplification. PCR has been performed in a single chamber, as a continuous phase and in an emulsion (droplets). In single-chamber PCR, the sample is injected into the chamber and the whole chip is heated and cooled through required PCR temperatures. *Belgrader* et al. [16.367] report a PCR device microfabricated in silicon microchambers with integrated optics. They were able to achieve fast cycle times (17 s) because of efficient heating and cooling of the reactions inside the chambers. Instead of heating the fluid in chambers a new method known as continuous flow PCR has been developed where the fluid is cycled between three regions that are maintained at constant but different temperatures [16.368]. Continuous flow-based PCR devices can further be classified into closed-loop devices [16.369], oscillatory device [16.369] and fixed-loop devices [16.72]. In oscillatory PCR devices the sample is moved back and forth between chambers in an oscillating motion to perform PCR. The thermosiphonic effect was used to transport the sample in a fixed circuit in both closed-loop and fixed-loop devices. The only difference being the number of cycles in a fixed loop is predetermined before the fabrication of the device. *Liu* et al. [16.368] have shown closed-loop PCR on microfluidic chips using a 12 nl volume sample. *Bu* et al. [16.369] fabricated a microfluidic chip with an integrated microperistaltic pump and chambers for carrying out PCR. They had three different chambers maintained at three different temperatures for PCR reactions. The sample is pumped back and forth (oscillatory motion) in the chamber to carry out the reactions. *Kopp* et al. [16.72] developed continuous flow micro-PCR chips that use fixed-loop amplification to amplify 176 base pair DNA. The amplification was carried out in less than 20 min, which compared to conventional PCR was much faster, show-

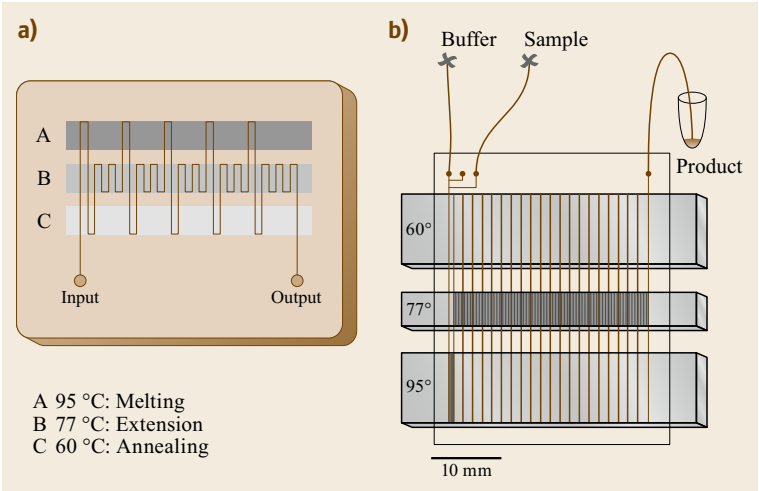

Fig. 16.18a,b Schematics of a continuous flow micro-PCR device. **(a)** Channel design and different heating zones. **(b)** Device layout consists of three inlets and one outlet. The sample and buffer are injected in the two inlets

ing the capabilities of microfluidics as a versatile and useful technology for amplification (Fig. 16.18). PCR in droplets has been reported by various groups [16.370–372] and is primarily used to segment the sample into a number of parallel reactors so that multiple amplifications can be performed. Such segmentation is useful in amplifying DNA that occurs at low concentration in a background of DNA at high concentration. Droplets of PCR mixture are cycled through specific PCR cycle temperatures to perform the PCR reaction within the droplets. *Leman* et al. [16.373] have developed a PCR in droplets technique using droplet microfluidic technology. They report PCR reactions in 20 femtoliter droplets produced at high frequency (3 kHz). The current PCR market size is around $3.28 billion and is estimated to rise to $4.94 billion by 2021 [16.374]. Companies that have commercialized microfluidic PCR platforms include Thermo Fisher Scientific Inc., Bio-Rad Laboratories Inc., F. Hoffmann-La Roche Ltd, Qiagen N.V., Agilent Technologies Inc., Fluidigm Corporation, Takara Bio Inc. and Affymetrix Inc.

Sequencing and Separation. Every living cell carries a genetic code that is required for major functions like protein synthesis, proliferation and apoptosis. Instructions to cells are embedded as codes in the DNA for every function the cell performs starting from a stem cell and differentiating into the specialized cell form. Understanding how this code works is crucial for understanding the genetic, developmental and biological behavior of all living cells. It also helps in deciphering complex processes like cell signaling and mutation. Finally, the cure for cancer and other genetic diseases lies in understanding how the genetic code interacts with the outside environment. A number of microfluidic devices have been developed that aim at low-cost, fast and portable identification of the DNA sequence present in medical, biological or environmental samples. Reviews on microfluidic DNA sequencing technology [16.375–377], emerging technologies [16.378], next generation [16.379–384] and DNA microarrays [16.385].

Sanger Sequencing. One of the earliest methods for sequencing DNA was developed by *Sanger* and is considered as the gold standard for comparison with other methods [16.386]. In Sanger sequencing, a primer, DNA polymerase along with a deoxynucleotide triphosphate (e.g., deoxyadenosine triphosphate (dATP), deoxyguanosine triphosphate (dGTP), deoxycytidine triphosphate (dCTP) and deoxythymidine triphosphate (dTTP)) are added to four tubes containing the target sequence. Next, a chain terminating dideoxynucleotide triphosphate (ddNTP, e.g., ddGTP, ddATP, ddTTP and ddCTP) are added one in each tube at a low concentration. Amplification of the DNA leads to random insertions of the chain-terminating nucleotide into the growing chain, producing extended chains of varying lengths corresponding to where that nucleotide was present in the original sequence. After the polymerization reaction, all the extended sequences in each tube are loaded on a gel in different lanes and separated to arrive at the sequence of DNA in the sample. This sequence of steps is ideal for automation using microfluidic technology.

Microfluidic Sanger Sequencing Devices. Many researchers have developed microfluidic devices to carry out DNA sequencing. *Effenhauser* et al. [16.387] developed a micromachined device to sequence DNA using the capillary electrophoresis principle to separate out short DNA sequences 10–25 base pairs in length. They were able to separate the DNA strands in 45 s. *Woolley*

and *Mathies* [16.388] sequenced DNA using microfabricated capillary electrophoresis. The DNA fragments were fluorescently labeled and were separated to 433 bases in about 10 min. *Burns* et al. [16.21] reported an integrated device that uses microfabricated microfluidic channels, heaters and fluorescence detectors to analyze nanoliter-size DNA samples. They were able to show separation for a 50 base pair DNA sample in 30 s. *Blazei* et al. [16.389] developed a microfluidic platform to perform the Sanger sequencing. They incorporated DNA purification and PCR steps into their microfluidic design. Caliper Life Sciences Inc. [16.390] commercialized the technology for DNA sequencing using electrophoresis.

Next-Generation Sequencing. The Sanger sequencing was time consuming and expensive. In order to sequence DNA strands in parallel so that it is quick and cost effective, next-generation sequencing technologies have been developed over the past 15 yr. Many of these next-generation technologies rely on micro–nanofabricated structures and microfluidics for their operation. Some of the well known next-generation sequencing platforms include Illumina sequencing [16.391], Ion Torrent semiconductor sequencing [16.392, 393], single-molecule real-time sequencing [16.394] and nanopore DNA sequencing [16.395].

Illumina Sequencing Technology. Illumina sequencing [16.391] is one of the most popular types of next-generation sequencing because of the cost effectiveness of the process. In this method, the DNA to be sequenced is first sheared by the shotgun method and then amplified. Next, adapters are prepared and added to the target DNA sequence. A flow cell containing oligonucleotides (oligos) with complementary adapters is used for binding the DNA strands. Once the DNA has attached to the oligos they are amplified by the bridge amplification technique. The DNA strands are then denatured and amplified again to form linear arrays of clusters in the flow cell. For sequencing, nucleotides tagged with fluorophores are added, which compete for polymerization and are simultaneously read using a laser in a high-throughput way. The patterned flow cell device used for Illumina sequencing increases the throughput dramatically. Millions of nanowells ($\approx$ 500 nm) are patterned into glass substrate where the DNA primers are deposited [16.392].

Ion Torrent Semiconductor Sequencing. Ion Torrent Inc. developed a sequencing technology based on sequencing chemistry using a semiconductor technology detection system. In this technology, first the DNA is broken down into millions of smaller pieces and each piece is attached to a bead coated with a specific sequence. They are then amplified to cover the entire bead and made to flow over a flow cell with millions of microwells such that each microwell is occupied by only one bead. Then the chip is flooded with one of the four nucleotides. Whenever a nucleotide is incorporated into a single strand of DNA a hydrogen ion is released. The hydrogen ion changes the pH in the solution, which is measured by an ion-sensitive sensor fabricated beneath the well. The change in pH is converted to voltage and a change in voltage is measured to indicate a nucleotide was incorporated in the sequence. This process is repeated every 15 s with a new nucleotide washing over the chip to continue sequencing. Also if two nucleotides are incorporated consecutively, the voltage value doubles indicating a double nucleotide polymerization [16.393]. This process is carried out simultaneously in millions of wells to obtain a high-throughput sequencing technology.

Single-Molecule Real-Time Sequencing. Single-molecule real-time sequencing (SMRT) is based on sequencing by synthesis. It uses a SMRT cell chip consisting of zero-mode waveguides (ZMWs). ZMW is a nanophotonic visualization chamber ($\approx$ 70 nm in diameter) that can analyze volumes as low as 20 zeptoliters (10^{-21} l). It enables detection of individual molecules against the required background of nucleotides. The ZMWs are illuminated from the bottom and the wavelength of light is too large for it to pass through the waveguide because only the lower 20–30 nm of each ZMW is penetrated by excited light. For sequencing, a DNA template polymerase is immobilized at the bottom of the ZMW and phospholinked nucleotides (each labeled with a different color) are added to the ZMWs chamber. As the nucleotide is incorporated into the sequence, the DNA polymerase cleaves the fluorescent label, which is detected by a sensor. The signal-to-noise ratio is greatly improved due to the low volume of the sample [16.394]. This process occurs in thousands of ZMWs, increasing the throughput of the technology.

Nanopore Sequencing. Nanopore sequencing [16.395] sequences DNA using a method called strand sequencing. The strand sequencing is carried out by a protein nanopore ($\approx$ 2–5 nm diameter), which is inserted into a membrane made of synthetic polymer. A current is applied across the membrane such that it flows only through the aperture of the nanopore due to high resistance of the membrane. When a single molecule flows through the nanopore it causes characteristic disruption in the current, which is measured to identify the molecule. In strand sequencing, a DNA

enzyme complex attaches itself to the nanopore and pushes one nucleotide at a time into the nanopore. The enzyme unzips the double-stranded DNA and feeds the single-strand DNA into the nanopores one base at a time and the characteristic disruption in current is created by a particular combination of bases in a specific part of the nanopores. Because these disruptions in currents are specific to the combination of nucleotides the order of the bases can be determined. This process can be multiplexed to create an array of nanopores for high-throughput sequencing.

Emerging Technologies. Recently, *Macosko* et al. were able to use microfluidic droplet technology to sequence thousands of cells individually and in a high-throughput manner [16.396]. They use a technology called Drop-Seq, where thousands of individual cells are encapsulated into nanoliter droplets with a unique barcode to identify the cells and sequence them together. Figure 16.19 shows the schematics of the experiment. In this study, they analyzed 44 808 mouse retinal cells and were able to identify 39 different subpopulations in retina cells.

Hybridization. Hybridization, which is the process of binding two complementary single strands of DNA to make a double strand, is one of the oldest techniques for DNA recognition. With the advent of the technology to synthesize DNA artificially in the early 1950s, single-stranded DNA could be synthesized with various unique sequences and assembled into an array (known as DNA microarray) that could be used to probe the presence of thousands of nucleic acid sequences in a sample all at the same time. The method to assemble unique sequences of DNA into microarrays started in the early 1990s and three main methods were developed, namely: Oxford Gene Technology [16.397], Affymetrix GeneChip [16.398] and DNA microarray technology [16.399]. Oxford Gene Technology's microarrays rely on immobilization of the molecular probes on a solid surface and detect the complementary sequence by hybridization [16.397]. Affymetrix GeneChips work on a similar principle. Sequence information is used to directly design arrays of synthetic oligonucleotides. These thousands of arrays of nucleotides are spatially patterned on a glass chip using a photolithography technique [16.398]. These chips can be used for obtaining information on gene expression levels. When the target sequence hybridizes with the synthesized oligonucleotide, a fluorescent signal is generated, which is read optically. Another high-throughput method to monitor gene expression levels was reported by *Schena* et al. [16.399]. Microarrays of complementary DNA strands were fabricated using a high-speed robotic printing technology on glass substrate. Differential expressions were measured using a two-color fluorescence hybridization technique. Reviews on application [16.400] and recent progress in DNA microarrays can be found in the literature [16.401, 402]. There has been considerable interest in using mi-

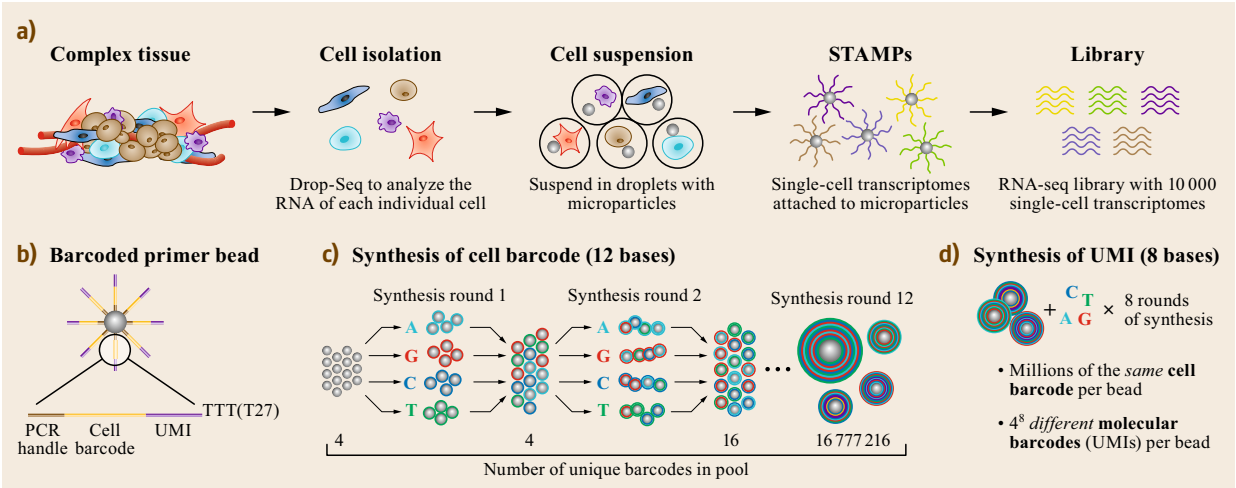

Fig. 16.19a–d Drop-Seq technology. **(a)** Encapsulation of a cell in a nanoliter droplet along with barcoded primer beads suspended in a buffer solution. After lysing the cell and hybridization of messenger RNA (mRNA), the droplets are broken and microparticles collected and washed. The mRNA strands are reverse transcribed to find the complementary DNA (cDNA) sequence. **(b)** The microfluidic device to encapsulate cell and a bead coated with barcoded primer. **(c)** The molecular element of a Drop-Seq library. **(d)** Reconstruction of thousands of single-cell transcriptomes. crofluidic technology for DNA microarrays [16.385, 403]. The high surface area-to-volume ratio in microfluidic channels increases the sensitivity of the DNA hybridization making microfluidics a suitable platform for the DNA microarray technology. *Liu* et al. [16.404] developed a complete microfluidic device to carry out DNA hybridization. Their device consisted of 12 000 microarrays with integrated pumps, valves, mixers for fluid handling and storage to carry out the DNA hybridization in an automated fashion. They were able to detect sample RNA concentrations as low as 0.375 pM. The global market for DNA microarrays was $3.93 billion (2016) and is expected to rise to $5.3 billion by 2020 [16.405].

16.5.2 Research Applications

In addition to applications described previously, which have been widely adopted and have found commercial success, there have been a large number of recent application areas that are still in the research and development phase. This section of the chapter describes some of the more promising application areas that are likely to find widespread usage.

Organ-on-Chip

Microfabrication and microfluidic technology has been applied to create continuously perfused channels containing living cells to simulate tissue- and organ-like functionality. By mimicking the physiology, biophysical and biochemical environments including gas exchange, these devices replicate *in-vivo* conditions closely, which is not possible in a conventional cell culture. High-resolution live imaging and drug testing for pharmacological studies are possible using such microfluidic devices. Understanding specific organ disease models, drug and toxicity testing and biomarker identifications are some major application areas. Reviews on perspective of this field [16.57] and applications [16.58] are available for further reading. Based on the application, organ-on-chips can be classified as microphysiological organ models [16.406], target identification and validation [16.407], drug screening [16.408], pharmacokinetics and body-on-chip systems [16.409] and other applications [16.410].

Organ Models. *Hu* et al. [16.406] developed a lung-on-chip, which mimics the functionality of an *in-vivo* lung. They cultured epithelial, alveolar epithelial and immune cells on an elastic membrane. Their device consisted of a main cell culture channel with two side channels to allow gas exchange, which replicates the inhaling and exhaling of the lungs. The central channel has a lower channel, which has a culture medium continuously flowing to simulate the blood flow. Their nanotoxicology studies using this device revealed that cyclic mechanical strain elevates toxic and inflammatory responses of a lung to silica nanoparticles.

Target Identification and Validation. *Song* et al. [16.407] developed a device where they could microengineer a model for chemokine-mediated interactions between breast cancer cells and microvascular endothelium. They fabricated a microfluidic device comprising of two PDMS layers sandwiching a thin, porous polyester membrane (400 nm pore size). The channel (800 μm wide and 60 μm high) in the top layer intersects the regionally distinct and perpendicularly oriented bottom PDMS layer. Human dermal microvascular endothelial cells were cultured in the top channel. The device reproduced serial interactions of tumor cells with endothelia by activating endothelia over specific regions where both the channels intersect. By producing defined flow rates within the range of physiological effects and site-specific interactions of tumor cells with endothelia they were able to mimic the natural setting. Their system revealed that endothelial recruitment of breast cancer cells induced a chemokine involved in cancer metastasis.

Drug Screening. *Aref* et al. [16.408] used an organ-on-chip system to test drug efficacy. They microengineered a 3-D assay of epithelial and mesenchymal transition (EMT) during cancer progression. The microfluidic tissue culture device used in this study consisted of a main central channel containing extracellular gel matrix and two media channels running parallel on either side of it. All the channels were fabricated using PDMS soft lithography. They were able to recreate the EMT-induced tumor dispersion and phenotypic changes in cancer cells by culturing lung cancer cells next to an endothelial cell cultured microchannel. Twelve drugs were tested of which some were approved by the US Food and Drug Administration (FDA). The drugs were injected in the vascular channel and their ability to inhibit the EMT was studied. They report a three orders of magnitude difference in concentrations between their method and conventional 2-D assays.

Pharmacokinetics and Body-on-Chip Systems. *Kim* et al. [16.409] developed a gut-on-chip using a 3-D microfluidic system. Soft lithography was used to fabricate the gut-on-chip device using PDMS as the material. A PDMS membrane (30 μm thick) with 10 μm holes patterned in it was sandwiched between upper and lower microchannels (1000 μm wide and 150 μm high). A silicon wafer with circular pillars deposited photolithographically 10 μm was used as a mold for

making the membrane with pores. The membrane was lined with Caco-2 cells, which separated two cell culture chambers. They mimicked the cyclic deformation of the Caco-2 monolayer by applying cyclic suction to a tubing connected to vacuum chamber and monitored using a feedback loop from the computer. Their mass spectroscopy results generated results consistent with the previous finding.

Other Applications. *Kim* et al. [16.410] used the organ-on-chip platform to test nanomedicine. They used a blood-vessel-on-chip to study the translocation of nanoparticles in an endothelium-coated microfluidic channel. The device consisted of two channels (upper and lower). The upper channel (200 μm wide and 200 μm tall) and lower channel (400 μm wide and 200 μm tall) were fabricated using soft lithography in PDMS. Electrodes were installed in the upper channel before bonding with a microporous polyester membrane. They were able to validate their data by comparing it with animal studies conducted on a rabbit model of atherosclerosis.

High-Throughput Screening (HTS)

High-throughput screening is widely used in drug discovery in order to test the effect of drug candidates on specific proteins, ligands, biomolecules or cells associated with a disease process in order to determine the few that affect the biochemical pathways that determine the outcome of a disease. Currently, HTS assays are performed on microwell plates using robotic instrumentation for fluid handling, which make them expensive. Micro- and nanofluidic devices have been increasingly investigated in order to increase the throughput while lowering the cost and yet providing the same level of automation as conventional plate-based assays. The devices for HTS can be classified as cell-based assays [16.411], binding assays [16.412] and whole-organism assays [16.413].

Cell-Based Assay. Cell-based assays use cells of the organ type involved in the disease to perform high-content screening of the effect of drug candidates on the target protein of interest. Conventionally, they are performed on multiwall plates where cells seeded in the wells can be exposed to different drug candidates and its effects observed on the whole-cell basis. Researchers have used microfluidics in cell-based assays. *Barbulovic-Nad* and *Wheeler* [16.414] have reviewed microfluidic cell-based assays. *Chin* et al. [16.415] report a microfluidic cell-based assay consisting of 10 000 microwells. The micrsowells were microfabricated on a glass cover slip. The dimension of the wells were tunable according to the application ranging from 20–500 μm in diameter and 10–500 μm in height. Rat neural cells were cultured in the microwells and were enclosed in a microfluidic system such that all the cells received the same media including any chemicals secreted by the cells. Proliferation of over 3000 single cells was analyzed over a period of a few days. They also propose that this platform can be extended to monitor cells in a high-throughput way.

Binding Assay. *Delamarche* et al. [16.416] developed a binding assays for HTS application. They patterned the surface of a microchannel with antigens by using the capillary forces generated because of the small dimensions of the channel. Bovine serum albumin was used as a blocking agent and they were able to pattern antigens in narrow stripes on the surface. By using each line to detect a specific analyte from the sample solution this process can be highly parallelized. They propose that such an assay can reduce the analysis time ten-fold and reduce the sample and reagent volume by 100-fold compared to conventional well-plate techniques.

Whole-Organism Assays. Microfluidics has been used to perform high-throughput behavioral and imaging assays. Recently, *Ghaemi* and *Selvaganapathy* [16.413] developed a microfluidic high-throughput assay to study the effects of drugs on *Drosophila*. They also developed a high-throughput method to load the *Drosophila* in microfluidic devices in an automated way [16.417]. *Rezai* et al. [16.418] studied the biology of human diseases by testing different drugs on *C. elegans* using a whole-organism assay. The electrotaxis property was used to sort *C. elegans* in a whole organism assay in a fast and automated method [16.419].

Bioprinting

Additive manufacturing methods such as 3-D printing have become popular in the construction of 3-D constructs in thermoplastic polymers and metals. Recently, the same technology is being increasingly applied to build tissue-like constructs for biomedical applications such as drug discovery, toxicology and potentially organ replacement. One particular challenge in artificial tissue construction is the need to integrate microscale vascular networks inside the 3-D structures. Still in its early stage, bioprinting has been applied in regenerative medicine to generate transplantable tissues including liver, bone, skin and cartilage. The current bioprinting technology still needs to solve problems like high-resolution cell depositing, controlled cell patterning and integration within complex 3-D tissues. *Mandrycky* et al. [16.420] have a review of this topic. A combination of advances in stem cell biology and bioprinting technology could enable a platform for high-throughput

printing of organs and drug screening methods in the future.

Micro Fuel Cells and Energy Devices

One of the main requirement for microsystems, portable devices and POC applications is a reliable means of power generation. Microfluidic fuel cells can offer portable and fully integrated energy sources. *Safdar* et al. [16.421] have recently reviewed microfluidic technology for energy generation. Some examples of microfluidic fuel cells include microfluidic biofuel cells [16.422], microfluidic photocatalytic fuel cells [16.423] and microfluidic electrochemical fuel cells [16.424]. The microfluidic electrochemical fuel cells use carbon electrodes, metals or metal alloys as catalysts to carry out a redox reaction for generating energy. *Esquivel* et al. [16.424] have developed a paper-based microfluidic electrochemical fuel cell. The fuel cell is capable of producing current densities between $1-5\,\mathrm{mW/cm^2}$. A conjugated pad was used to store the electrolyte solution and a fuel on the device with integrated electrodes. The fuel cell functions by soaking the pad in water. The diluted fuel was oxidized underwater at the platinum-ruthenium electrode to generate current. In the future, a need for microfluidic fuel cells to generate higher power densities with minimal operation and fabrication cost will drive this field forward.

16.6 Outlook and Future Directions

Microfluidics and nanofluidics are enabling technologies that utilize the unique features of the fluid flow at these scale to perform operations with some advantage over its macroscale equivalents. Over the past 20 years the microfabrication technology required to make micro- and nanofluidic devices has developed significantly. Currently, devices in a wide range of materials from metals, inorganic materials such as silicon and glass, polymeric materials such as PMMA, PDMS, PC, PS, PI, COC and COP using a variety of manufacturing processes to achieve resolutions and feature sizes in the micro- and nanoscale have been well developed. Similarly, devices have been designed for a wide variety of applications such as precise fluid dispensing, medical and environmental diagnosis, analytical process such as chromatography, sorting and electrophoresis, microscale chemical production and synthesis, combinatorial screening and others. Some of these applications areas have found significant commercial markets and have generated hundreds of millions of dollars in revenue per year. The future evolution of this field is likely to focus on two aspects, namely new materials and fabrication processes and new applications. Some of the potential emerging innovations in this field are listed below.

16.6.1 Additive Manufacturing

The revolution in additive manufacturing of materials will have a significant impact in the way that micro- and nanofluidic devices are made. Already 3-D printers using fused deposition modeling (FDM) have been developed and commercialized for common thermoplastic polymers that are used in microfluidic devices. In the near future, additive manufacturing methods will be developed for other polymer systems such as thermosets or elastomers. Methods for the combination of elastomers with thermoplastic polymers will also be developed to integrate multiple materials in the same device. Simultaneously, 3-D printing methods for gels and other soft materials will also be extensively developed, catering to the tissue engineering applications. Finally, additive manufacturing methods other than FDM, such as layer object manufacturing, will be investigated for micromanufacturing.

16.6.2 Artificial Organs

The development of microfabrication methods for shaping gels, extracellular matrices and cells is in its early stages currently. With the development of increasingly sophisticated techniques to assemble these materials, they will be used to fabricate tissue-like constructs and subsequently artificial organs that combine multiple cell types, ECMs, and inorganic materials in the 3-D complexity present in human organs. These artificially constructed organs can be used in drug discovery applications, as *in-vivo* bioreactors or as true fully functional organs with multifunctional capacity.

16.6.3 Biopharmaceutical Production

The ability of the microfluidic devices to precisely control the residence time in a microreactor and its modular nature are of importance in cost-effective production of specialty chemicals. Increasingly these same characteristics will be of importance in production of biopharmaceuticals such as proteins and cells. For instance, PEGylation of proteins is an important process in biopharmaceutical production. Microfluidic reactors

can optimize the residence time such that the desired mono-PEGylated product is produced over the undesired di- and tri-PEGlayted ones. Similarly, the ability to fabricate parallel culture chambers will be important in the production of stem cells and immunotherapy cells for treatment of diseases such as cancer. Microscale culture chambers integrated with microfluidic channels to perfuse and maintain nutrients, pH and other culture parameters as well as sensors to measure them will be important in growing cell-based biopharmaceuticals under controlled and documented conditions required for medical products.

16.6.4 Droplets in Food and Cosmetics

Methods for monodisperse droplet formation and the ability to form single, double and triple emulsions have also been demonstrated. Recently, some efforts have been made to identify scalable methods of droplet production. In the near future, more research will be conducted on the development of scalable high-throughput and high-volume production of droplets. Simultaneously, the application areas will spread from medicine and biology, where the sample sizes are small, to more mainstream applications like in food and cosmetics where the batch sizes are extremely large. For instance, the development of scalable high-throughput and cheap techniques to produce microdroplets or gels loaded with specific flavor, odorant and other sensory chemicals can be used for programmed release that will make the eating experience more pleasurable.

16.6.5 Continuous Health Monitoring

Many of the microfluidic and nanofluidic devices that are made currently are designed for single use and are disposable in nature. These are suitable for applications such as disease diagnosis and biochemical assays in the field or hospital settings. Lately, there has been considerable interest in wearable sensors and in the use of physical sensors for continuous monitoring of parameters related to health. In the near future, methods to extend such monitoring using chemical and biochemical sensors will be actively investigated. Such sensors will require microfluidic technology that can clean, compensate and calibrate even with multiple use. These will require incorporation of new materials that are self cleaning, with active cleaning technologies, microfluidic components that are not prone to contamination and retention, as well as components that are reliable and have the same performance characteristics on extended usage. The development of these technologies will enable on-body or in-home continuous biochemical health monitoring of individuals that could serve as a sentinel to identify and detect onset of disease conditions early.

In summary, the outlook for micro- and nanofluidics is bright and the field is extending into a number of significant and interesting avenues that will make it the enabling technology of the future. Developments in the fundamental physics of fluid flow and its control, microfabrication methods, microfluidic components, and applications in new and emerging areas are all anticipated.

17. Microfluidic Micro/Nano Droplets

Gopakumar Kamalakshakurup, Derek Vallejo, Abraham Lee

Microfluidic droplet technology has evolved rapidly since the first microfluidic droplet generator was reported over a decade ago. It has subsequently branched out and emerged as a practical solution to enhance the capabilities of many other fields, including, but not limited to: high-throughput screening, biosensing, drug delivery and synthetic biology. In this chapter, we will report on recent advancements in droplet microfluidic technologies that have emerged since *Teh* et al.'s comprehensive 2007 review. We begin with a brief history of droplet microfluidics and introduce methods of droplet production, manipulation, and sensing methodologies. The remainder of the chapter is dedicated to design considerations for various droplet production configurations, concluding with a discussion on applications, trends and the general direction that the field is headed.

17.1 Introduction to Micro/Nano Droplet Microfluidic Technologies

High-throughput screening (HTS) is a scientific method to conduct millions of chemical and biological reactions. A typical example of HTS is the discovery of drugs in the pharmaceutical industry, where millions of drug compounds are tested against the target samples to analyze the activity. Since early 1960s, screening has been performed using microplate technology and it is still a convenient platform used by many HTS industries. If we take an example of drug screening in pharmaceutical industry, the process flow occurs in three steps as shown in Fig. 17.1:

1. Biological target samples are pipetted into the well plates
2. Drug compounds are added to the wells
3. The fluorescent activity is captured using a detector that scans the wells.

The limitations of this technology includes:

1. Reagent and sample consumption. Each well consumes milliliter volumes of reagents, which increases the cost of screening. To reduce the reagent consumption, attempts have made to incorporate a higher number of miniaturized wells (Moore's law of miniaturization). In general, 96 well plates are considered standard, but companies like DuPont have come up with 9600 well plates. This leads to another limitation of liquid handling.
2. Using 96 well plates, one can use pipettes to manually load the samples, but 9600 well plates require robotic pipetting, which again increases the cost of screening.
3. Evaporation and contamination. Reagents/samples can evaporate from the wells and can also cause contamination issues.
4. Low throughput. To perform millions of reactions, the microplate platform takes several days. These limitations forced the scientific community to come up with an alternate solution to microplate technology.

Advancements in microfabrication technology revolutionized the process of sensing and detection of chemical and biological samples [17.1]. The samples

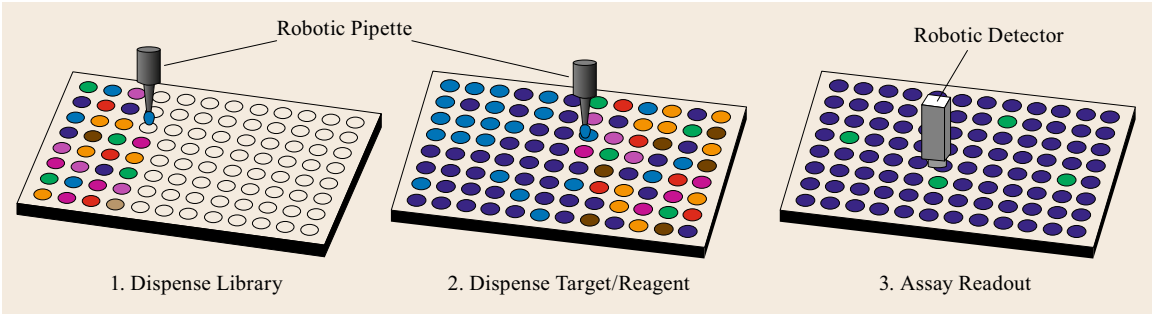

Fig. 17.1 Drug screening process in microplate format: 1. Biological sample is pipetted into the wells 2. The reagent or drug compound is dispensed into the wells. 3. The aftereffect of the reaction is detected using a robotic scanner

are manipulated and analyzed in miniaturized microfluidic chips often referred to as *lab on chip* devices. Depending on the liquid manipulation methodology, we can classify microfluidics into two groups: single-phase (or continuous) microfluidics and multiphase (or droplet) microfluidics. Single-phase microfluidics deals with manipulation of miscible liquids inside a microfluidic chip. Using single-phase technology, numerous chemical or biological reactions can be performed by integrating thousands of micromechanical valves and control components [17.2] (Fig. 17.2). These systems are referred to as microfluidic large scale integration [17.3]. However, single-phase microfluidics has limitations:

1. Samples directly interact with the channel walls and cause cross-contamination of fluid constituents
2. Scaling-up of the screening process require additional chambers and valves, leading to an increase in overall chip size
3. Reagent consumption, though microliters (μL) in volume, could become significant in large-scale screening.

Attempts to overcome the limitations of single-phase microfluidics led to the evolution of the second category of microfluidics referred to as multiphase microfluidics. The most popular form of multiphase microfluidics is droplet microfluidics. Droplet microfluidics deals with the manipulation of nanoliter (nl) to femtoliter (fl) droplets inside microfluidic channels [17.4]. Each droplet can act as an isolated reaction container for biochemical assays while offering several advantages over conventional single-phase methods:

1. Droplets can have volumes as little as femtoliters, leading to a reduction in reagent consumption and therefore the cost of biological screening.
2. The thin layer of carrier phase around the droplet prevents evaporation or contamination; droplets can be generated and detected with ultrafast assay throughputs (rates up to 10 KHz).
3. In droplet format, we can perform millions of chemical or biological reactions in minutes. One of the most important advantages is that droplet microfluidic technology can perform operations that can emulate laboratory benchtop processes, such as fluid dispensing, mixing, aliquot and sorting/separation.
4. Fluid dispensing is analogous to droplet generation; mixing, aliquot and separation is equivalent to droplet merging, droplet splitting and droplet sorting, respectively.

These unit operations make the droplet technology feasible for HTS of chemical or biological assays. Here we describe and discuss the droplet unit operations in detail.

17.1.1 Droplet Generation

One critical aspect of droplet microfluidics is the ability to generate stable, uniformly sized droplets. Precise control over the parameters, including channel geometry, the flowrate of two phases (shear force), the viscosity of the phases and the interfacial tension between the phases, are critical to achieve reliable droplet production. The two basic (and most commonly adopted) device configurations to generate droplets are T-junction and flow-focusing geometries.

T-Junction Configuration

In this configuration, the dispersed phase and the continuous stream intersect perpendicular to each other [17.5]. The continuous phase exerts unidirectional shear on the dispersed phase (Fig. 17.3). As the dispersed phase gradually fills the main channel, it im-

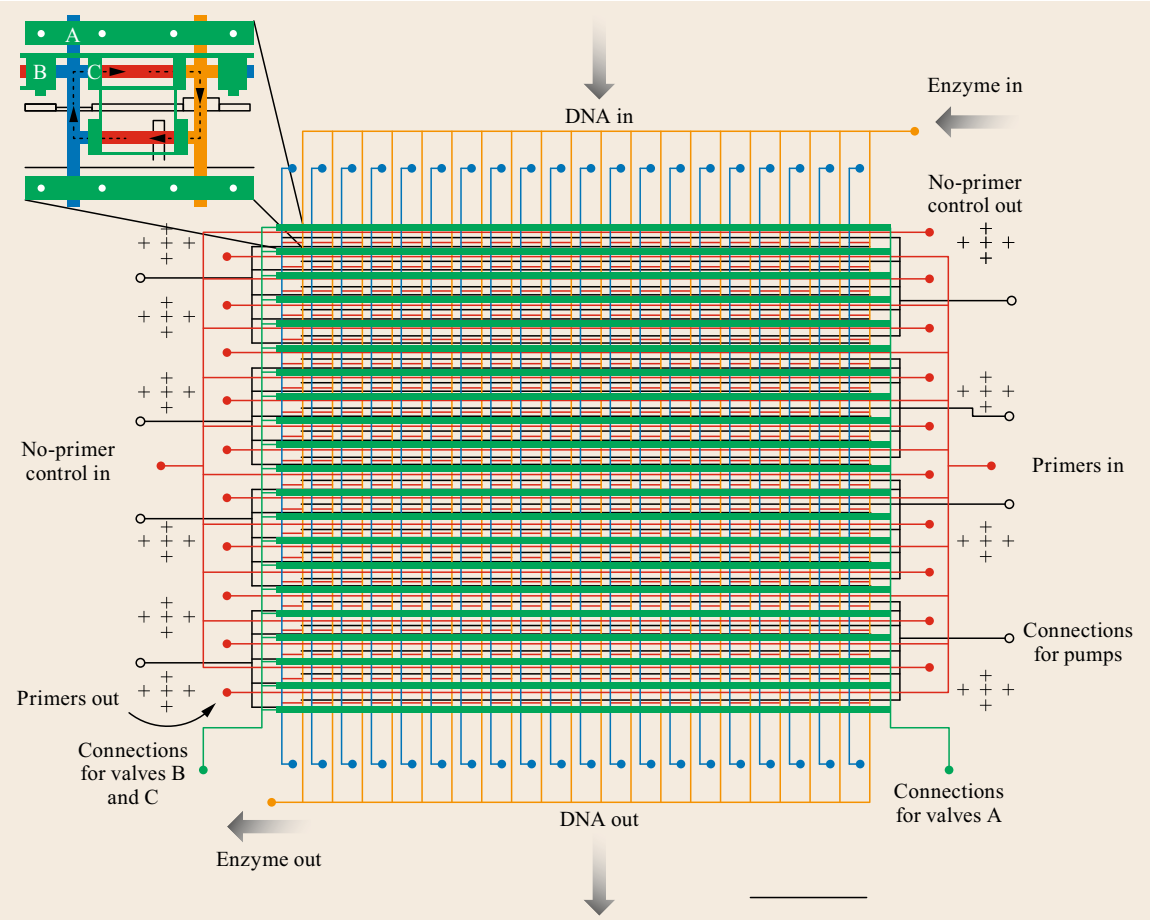

Fig. 17.2 Schematic of a microfluidic large-scale integration device. It consists of 25×40 chambers and each chamber can hold 250 picoliters of sample volume (after [17.3])

pedes the continuous phase flow, resulting in a pressure buildup in the main channel and leading to the droplet pinch-off. To perform more sophisticated assays, alternate droplet generators are implemented with multiple T-junctions enabling simultaneous introduction of multiple reagents and sample solutions (Fig. 17.4) [17.6].

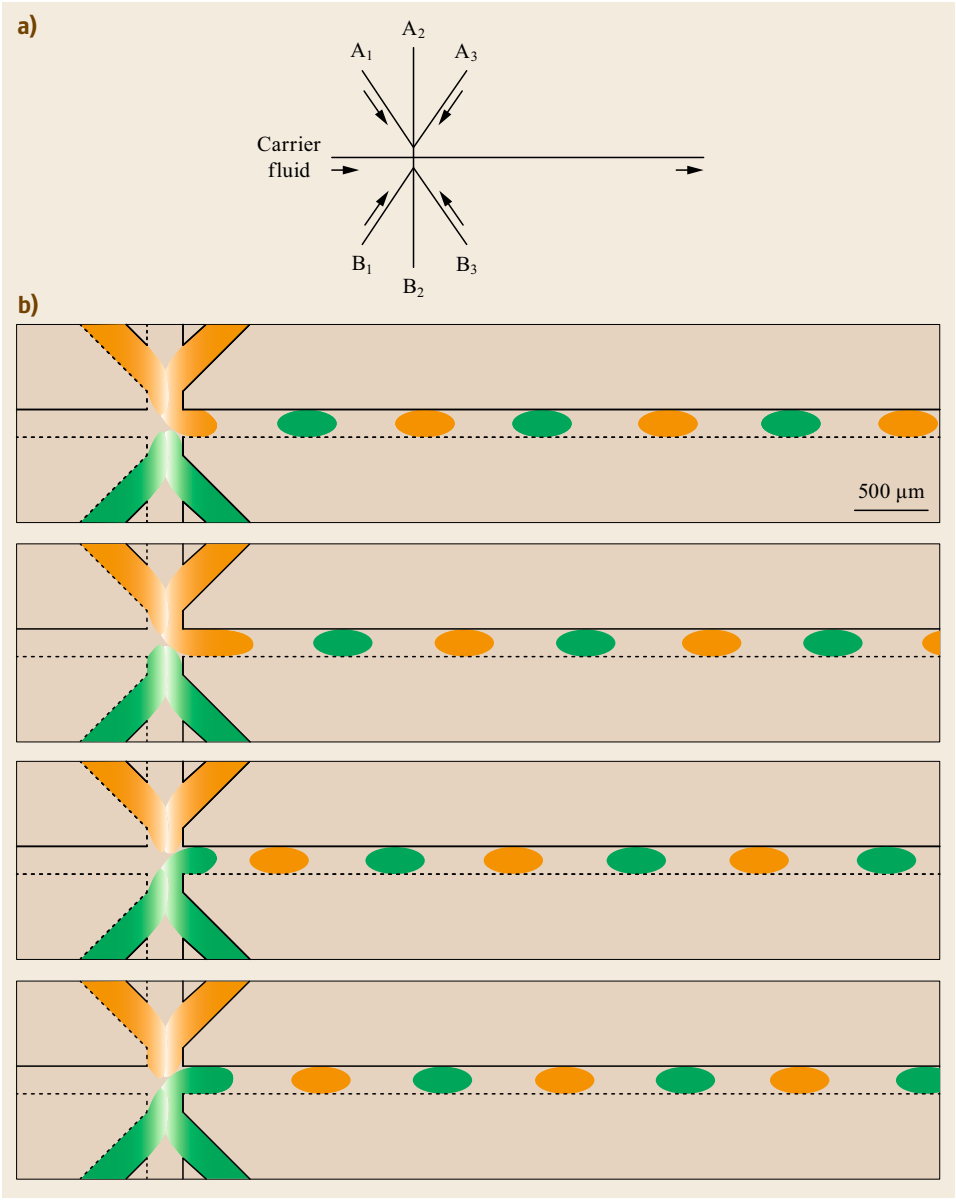

Fig. 17.4a,b Alternating T-junction droplet generator. **(a)** Schematic of the microfluidic chip **(b)** Sequential images illustrating the detailed process of alternate droplet generation

Flow-Focusing Configuration

In this configuration, both the dispersed and continuous phases are forced to pass through a narrow orifice in the microfluidic device in a sheath flow fashion (dispersed phase sandwiched by two continuous phase streams) (Fig. 17.5 and 17.6) [17.7]. The flow-focusing droplet generation can be explained by a simplified model. When the dispersed phase enters the junction, it blocks the flow of continuous phase resulting in a pressure buildup in the continuous phase inlets. The subsequent shear, as a result of the pressure buildup, pinches off the dispersed phase to form droplets. This process of droplet breakup is valid only for geometry-controlled regime, and not applicable for all droplet generation regimes. The physical principles of droplet generation and techniques are described in Sect. 17.3. Recently, it was reported that 10–50 fl droplets can be generated at frequencies ranging from 200 to 1.3 MHz, enabling droplet technology as an ultrahigh-throughput screening platform [17.8]. Parallel droplet generation is an alternative method to increase the throughput by interconnecting networks of individual droplet generators. This can achieve ultrahigh throughput albeit the complexity of the system increases with multiplexing.

An example of parallelization is a three-dimensional monolithic elastomer device with an array of 20×50 flow-focusing generators capable of generating droplets at 8.7 MHz, the highest droplet generation rate reported to date (Fig. 17.7) [17.9]. In most cases, the microfluidic devices are manufactured using polydimethyl siloxane (PDMS), which is an inexpensive, flexible and transparent elastomeric polymer [17.10].

17.1.2 Droplet Merging

Automated droplet fusion is also a critical unit operation, where the independently generated droplets of reagents and samples are subjected to controlled merging and the activity of the merged droplets is monitored using droplet detection technologies.

Passive Merging

Passive techniques utilize microfluidic channel designs to ensure controlled merging. There are several ways to perform passive droplet fusion. However, the two eminent techniques are based on channel expansion [17.11] and pillar designs [17.12]. When a droplet encounters a channel expansion, the decrease in velocity slows down the droplet ensuring merging with the preceding droplet (Fig. 17.8). In the pillar-induced technique, the continuous phase near the droplet drains through the gap between the pillars. This slows down the droplet and eventually enables merging with the successive droplets until the hydrostatic pressure exceeds the capillary pressure, pushing the merged droplet out of the chamber (Fig. 17.9). The process of droplet merging depends on the pillar geometry, interfacial tension, flowrate ratio and viscosity of the continuous and dispersed streams.

Active Merging

Active methods employ on-chip structures and control electronics to achieve droplet merging. It includes electrical, thermal and optical methods. Electrical-based methods include dielectrophoresis (DEP) [17.13] and electrowetting-on-dielectric (EWOD) [17.14] force fields where the actuation of electrodes induces the merging. Droplets are stacked up one by one over a series of electrodes and the controlled actuation of a pair of adjacent electrodes coalesce the packed droplets (Fig. 17.10). It is also possible to actuate the adjacent electrodes to move the droplets to the desired location and fuse them. Digital microfluidics is a field that controls droplet transport by the EWOD principle. Droplet merging can also be initiated by temperature. Temperature changes correlate to changes in the viscosity and drainage rate of the continuous phase resulting in droplet fusion [17.15]. Optical droplet merging techniques rely on the principle of optical tweezers but it is less attractive because of the lower throughput and lower actuation force [17.16].

Droplet Splitting

Droplet splitting is a process of breaking the parent droplet into two daughter droplets. It is an important

operation unit that increases throughput by parallelization. Droplet splitting is achieved using both passive and active methods. Passive techniques split the parent drop into two daughter droplets by shear force induced at the channel bifurcation point [17.11, 17, 18]. Given a constant flowrate, the size of the daughter droplet is determined by the hydraulic resistance of the channels (Fig. 17.11). Bifurcating channels with the same hydraulic resistances results in same shear forces on either half of the droplets, leading to symmetric splitting of the parent droplet (Fig. 17.12). Unequal channel resistances result in uneven droplet splitting such that the daughter droplet in the low-resistance channel is relatively larger than the one in the high resistance channel. Active splitting primarily uses electrical methods to perform droplet splitting. The EWOD technique can be used for active fission in digital microfluidics. The two electrodes on either end of the droplet are actuated while the center electrode is grounded. The electrodes on front and rear end of the droplet pulls the droplet in opposite directions in reference to the ground electrode, resulting in droplet splitting [17.19].

Assay Readout/Droplet Detection Technique

Sensing and detecting droplets is a critical operation unit in HTS of chemical or biological assays. It identifies the positive droplets from the population prior to droplet sorting for postprocessing. Light-induced fluorescent (LIF) detection via chemical labeling of biomolecules is a widely adopted detection technique [17.20]. In LIF, the excitation light source with a suitable wavelength is focused into the microfluidic chip. The excitation light can be either scattered or absorbed by particles, cells or biomolecules. If any of the molecules are stained by fluorophores, the resulting emission wavelength is captured by a detector, which can be a high-speed camera, confocal microscope, complementary metal-oxide-semiconductor (CMOS) sensors, or photomultiplier tubes (PMT). Recently, a combination of microlens array, reflective channel surface and high-speed camera was used for high-speed detection of droplets. This setup can screen droplets at a rate of 2 kHz per microlens [17.21]. Another detection technique relies on a CMOS sensor that can detect 40 pl droplets at 254 kHz [17.22] in the microfluidic chip. An integrated comprehensive droplet digital detection (IC3D) technique was reported in 2014, which can detect one positive droplet from 40 million droplets with 77% confidence [17.23]. Using

this technique, the droplets collected in a glass cuvette are subjected to vertical and rotational translation and are detected by confocal microscopy (Fig. 17.13). In addition to LIF detection, there are other techniques such as electrochemical detection [17.24], mass spectroscopy [17.25], high-pressure liquid chromatography (HPLC) [17.26], surface enhanced Raman spectroscopy or the combinations of the above-mentioned methods [17.27].

Droplet Sorting

Droplet sorting enables the separation of individual droplets from a population as a function of its size or chemical payload. Droplet sorting can be grouped into two categories: passive and active.

Passive Sorting. As the name suggests, passive sorting techniques do not require any active components such as on-chip electrodes or additional instrumentation. Passive techniques are used to sort the droplets

based on their size. In 2007, *Tan* et al. demonstrated a hydrodynamic droplet sorting technique that utilized the channel geometry to alter the flow velocity that resulted in sorting [17.28]. Different sized droplets were successfully sorted into the respective outlets determined by the shear force ratio, which depends on the area of projection and shear rate imposed across the droplet (Fig. 17.14). In 2008, *Chabert* et al. presented a hydrodynamic technique for cell encapsulation and subsequent sorting of the droplets at the channel bifurcation [17.29]. The cell-encapsulated droplets are larger than the empty droplets and thus gets sorted into the *left* outlet by the combined effect of lateral shear induced drift generated by the asymmetric oil flowrates and the steric interactions between the droplets at the bifurcation. In 2011, *Joensson* et al. demonstrated a deterministic lateral displacement (DLD) pillar array that could successfully sort 11 µm droplets from the 30 µm droplets at a frequency of 12 000 droplets/s [17.30]. In 2013, *Hatch* et al. reported a passive hydrodynamic droplet sorting technique by tuning the viscosity ratio (γ), which is defined as the ratio of the viscosity of the dispersed phase to the continuous phase [17.31]. If γ is between 0.5–10, the droplet migrates toward the region of high shear gradient (channel wall). For all other values of γ, the droplet migrates toward the low shear region (channel center).

Active Sorting. Active sorting techniques can sort droplets by their size and chemical contents, but require labeling and on-chip electrodes. In fluorescence-activated droplet sorting (FADS) [17.32] the fluorescent actuation of the on-chip electrodes redirects the droplets at the channel bifurcation via DEP forces [17.33]. This is an efficient technique capable of performing selective sorting of droplets based on their chemical contents (Fig. 17.15). Some of the other active techniques include piezoelectric actuated surface acoustic waves (SAW) [17.34], electrically actuated membrane valves [17.35], which hydrodynamically sort droplets, or laser-induced thermocapillary valves, which can

17.2 Overview of Current Trends in Droplet Microfluidic Technologies

The field of microfluidics originally emerged as an alternative to traditional, expensive, and bulky laboratory techniques. Costly reagents could be used in even smaller quantities, meaning that reaction time were shortened, translating to comparatively high resolution and sensitive detection. Microfluidic unit operations can emulate most basic laboratory operations, such as fluid dispensing, sample aliquot, sample mixing, and assay readout, at a fraction of the cost and time required with traditional methods. This enabled droplet microfluidic technology to rapidly emerge as a powerful platform to perform numerous applications in chemistry and biology. Academic interest in microfluidic technology first grew tremendously in the 1990s when the U.S. Department of Defense saw an opportunity for microfluidic systems to serve as portable detection units for biological and chemical threats, and in turn, developed a series of programs to stimulate microfluidic research in academic institutions.

The first microfluidic droplet generator was reported in 2001 by *Thorsen* et al. [17.5]. Since then, the technological developments in chemistry, biology and medicine have garnered substantial interest in applications enabled by droplet microfluidics. Further advancements in the microfabrication technologies using various substrate materials (e.g., glass, polymer) has led to the realization of many microfluidic droplet generator designs for control of droplet size, generation rate, and chemical composition [17.38]. The droplet based biomolecular assay was the first commercial success story of droplet technology. Bio-Rad Laboratories and Rain Dance Technologies successfully commercialized the droplet digital polymerase chain reaction (ddPCR) system in 2012 [17.39]. However, the droplet generation, thermocycling, and droplet readout are performed in three different instruments and the assay kit is still very expensive (> $ 75 000). Several startups including Intuitive Biosciences (Madison, WI) are working on ways to overcome the limitations and reduce costs. A droplet-based, fully integrated next-generation sequencing platform by GnuBIO Technologies is currently in the development stage [17.40]. The manufacturer claims that this instrument can perform scalable and accurate DNA sequencing that includes the additional steps of target enrichment and DNA amplification. If successful, this will be the first example of a commercial droplet-sequencing platform.

Another highly pursued and top-priority application in the field of droplet microfluidics is single-cell analysis [17.41]. Since the droplet microfluidic technology can easily generate cell-sized aqueous compartments, large populations of cells can be compartmentalized into independent monodisperse droplets. This enables the researchers to query the heterogeneity in cell populations at the single-cell level by performing sequencing or gene expression profiling in droplets, or to screen prospective drug variants against the target sample for cancer therapeutics [17.42, 43]. Droplet microfluidics has also emerged as a powerful tool for applications in directed evolution and synthetic biology. To engineer proteins and enzymes with novel activity, millions of genetic variants can be tested in individual microenvironments, evaluated, and isolated with high-throughput optical sorting methods [17.44].

Even with the tremendous progress of droplet microfluidics in recent years, there are still many technical challenges that researchers are working on to advance the field. One of the primary challenges pertains to high-throughput, sensitive detection and sorting of droplets. At present, there exists many efficient detection technologies, such as fluorescence detection, surface enhanced Raman spectroscopy, electrochemical detection, mass spectroscopy, HPLC and capillary elec-

trophoresis, but how well can these techniques work for high- throughput sensing and detection? Can we extract complete information from the picoliter volume reactors? As the miniaturization effort is still ongoing, droplet microfluidics will require further future dimensional scale-down in terms of the device size, droplet size and reagent volume, which would seriously challenge existing detection systems that have been designed for cell-sized structures.

Another area that requires improvement is the material used in the fabrication of microfluidic devices. In most research applications, polydimethylsiloxane (PDMS) is used to make the microfluidic chips. PDMS is transparent, flexible, biocompatible and permeable to gases; features that are suitable for culturing biomolecules and cells, but PDMS is also auto-fluorescent. If the signal-to-noise ratio is too low, fluorescent measurements can be compromised. PDMS also has low thermal conductivity, absorbs certain dyes, and swells in certain organic solvents (e.g., silicone oil). PDMS microfluidic devices are also typically polymerized in photolithographically patterned molds, which make them difficult to bulk manufacture and commercialize. An alternative to PDMS are injection-molded thermoplastic materials such as cyclic olefin copolymer (COC) chips. The comparatively low contact angle (82°) of COC, however, makes it difficult to generate water-in-oil droplets. The research is ongoing to improve the contact angle by appropriate surface treatments.

Another challenge for the future of droplet microfluidics is in the synthesis of ideal surfactants to perform assays within microfluidic channels. Although there are many commercially available organic solvents, proper incubation of the droplet emulsions requires standardized surfactants that limit the choice of organic solvents. A major problem encountered while incubating droplets is imperfect partitioning, leading to inter-droplet cross talk, which limits the stability of the emulsions, causing droplet shrinkage or coalescence. Since this is a relatively new and rapidly developing field, more work is ongoing to resolve these issues and challenges. As the field advances, one could foresee the development of integrated droplet microfluidic platforms that are portable, low-cost and autonomous. These platforms would be able to perform many complex biological processes in shorter times, yet with high efficiency and precision.

17.3 Fundamental Designs and Techniques for Microfluidic Generation of Droplets

Emulsions are liquid droplets suspended in another immiscible liquid. There are numerous ways to generate emulsions, such as atomization, chaotic mixing of two immiscible liquids, sprays and membrane emulsification. The consequence of this stochastic generation of emulsions leads to significant droplet size variation. Over the years, microfluidic technology emerged as a powerful tool to generate uniform droplet emulsions of femtoliter to nanoliter volumes at an ultrahigh throughput. As described earlier in the chapter, microfluidic droplet generators can be categorized into active and passive methods. Active droplet generators require additional instrumentation including on-chip devices and control electronics whereas passive methods rely on the interacting flow fields and interfacial instabilities to generate droplets. Passive droplet generation can be grouped into three categories:

1. Coflowing geometry
2. Cross-flowing or T-junction geometry
3. Flow-focusing geometry.

The schematic of all three geometries are shown in Fig. 17.16. In all three cases, the dispersed phase and the continuous phase are introduced separately into the microchannels by a pressure-driven flow that is driven either at constant volumetric flowrates (using syringe pumps) or constant pressures (by pressure regulator and solenoid valves). The two phases meet at a channel junction and eventually the dispersed phase pinches off by free surface instability. The droplet pinch-off process is a result of the competition between the local fluid stress (viscous force), which causes the interface to deform while the capillary pressure (interfacial tension force) resists the deformation. The ratio of viscous stress to the capillary stress is defined by a dimensionless number called the capillary number (Ca)

$$Ca = \mu_c \frac{V}{\sigma} ,$$

where μ_c is the viscosity of the continuous phase, V is the velocity of the continuous phase and σ is the interfacial tension between continuous phase and dispersed phase. Another two dimensionless parameters that directly influence droplet breakup are the volumetric flowrate ratio (φ)

$$\varphi = \frac{Q_d}{Q_c} ,$$

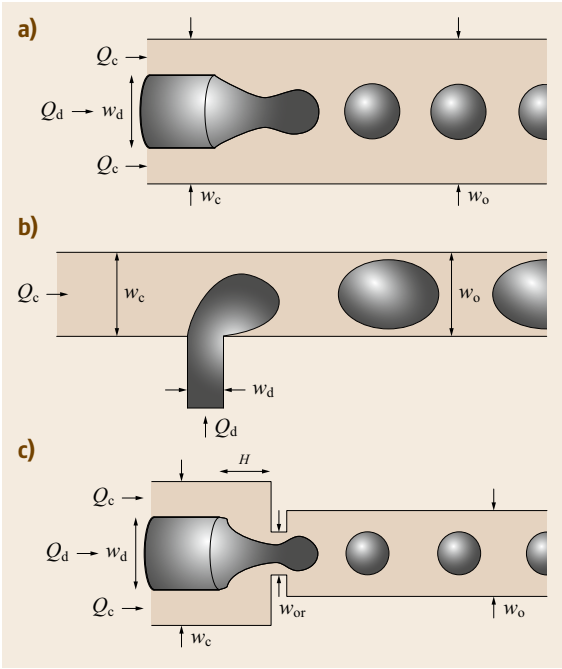

Fig. 17.16a–c Schematic of three major passive droplet generation geometries **(a)** coflowing geometry **(b)** cross-flowing or T-junction geometry **(c)** flow-focusing geometry. (After [17.38])

where Q_d is the volumetric flowrate of the dispersed phase and Q_c is the volumetric flowrate of the continuous phase, and the viscosity ratio (γ)

$$\gamma = \frac{\mu_d}{\mu_c} ,$$

where μ_d and μ_c are the viscosity of the dispersed and continuous phases, respectively.

17.3.1 Passive Droplet Generation Techniques

Coflowing Geometry

This is the simplest geometry to generate uniform droplets. The geometry consists of a set of concentric channels, where the dispersed phase is introduced through the inner concentric channel while the continuous phase flows through the exterior [17.45]. The configuration is illustrated in Fig. 17.1a. Two droplet generation regimes are observed in this configuration, dripping and jetting. The transition from dripping to jetting is observed if the continuous phase increases above a critical velocity [17.46]. The critical velocity is a function of dispersed phase velocity, interfacial tension and viscosity ratio (γ). The critical velocity decreases with increasing dispersed phase velocity and decreasing interfacial tension. Droplet size is a function of the volumetric flowrate (φ) and interfacial tension (σ). An increase in φ results in an increase in droplet size. Higher continuous flowrates exert more shear stress on the dispersed phase interface that result in smaller droplets. Similarly, an increase in σ makes the interface weaker and hence the dispersed phase can easily break off into smaller droplets. It is shown that the viscosity ratio (γ) has no significant effect on the droplet size over a wide range of continuous phase flowrates. In this regime, the predicted droplet size is given by the nondimensional equation [17.45]

$$d_1^3 - \left(1 + \frac{1}{3Ca}\right) d_1^2 - \frac{\varphi}{\alpha} d_1 + \frac{\varphi}{\alpha} = 0 ,$$

where d_1 is the ratio of droplet diameter (d) to the diameter of the inner capillary tube and $\alpha = A_d/A_c$ is the ratio of the two cross-sectional areas of the inner and outer capillary tube. If the dispersed phase flowrate is slow enough, the above equation simplifies to

$$d_1 \approx 1 + \frac{1}{3Ca} .$$

The droplet breakup and the size depends on the viscous stress and the capillary pressures. Using this geometry, highly monodisperse droplets with diameters in the range of few hundred micrometers are produced with polydispersity values ranging from 1 to 2%.

Notably, the wettability of the channel wall is crucial in determining which phase is dispersed. If the channel wall is hydrophobic (e.g., PDMS), the oil phase will wet the wall and form the continuous phase. In that case, the aqueous phase will form the droplets. Conversely, if the channel wall is hydrophilic (e.g., silicon), then the aqueous phase will form the continuous phase while the oil phase will form the droplets.

Cross-Flow or T-Junction Geometry

This is one of the simplest and common microfluidic geometries to generate monodisperse droplets [17.4, 47]. Depending on how the droplet phase fills the junction, the T-Junction geometry can be grouped into two categories, unconfined geometry and confined geometry.

Unconfined Geometry. In the unconfined geometry, the width of the continuous phase channel is at least five times larger than that of dispersed phase channel [17.48]. As the name suggests, the emerging droplets do not interact with the continuous phase channel walls and remain unconfined upon exiting the dispersed phase

inlet. The droplets generated from this geometry do not significantly disrupt the main channel flow, hence the droplet size is determined by the local shear stress at the junction. At a fixed dispersed phase flowrate, the size of the droplets decreases with increasing continuous phase flowrate. There are a few studies that show the droplet pinch-off occurring when the drag force exerted by the continuous phase flow overcomes the interfacial tension resisting the droplet deformation and the dispersed phase flowrate has little influence on the droplet breakup and the size [17.48, 49]. The droplet size in this geometry is given by

$$d_1^4 - 2d_1^3 + \frac{\epsilon}{2}d_1^2 + \frac{\alpha}{2C_\gamma Ca} = 0\,,$$

where $d_1 = d/D_c$ is the dimensionless number, which is the ratio of droplet diameter (d) to the hydraulic diameter (D_c) of the continuous phase channel

$$D_c = \frac{2w_c h}{w_c + h}\,,$$

where w_c and h are the width of the continuous phase channel and height of the channel respectively

$$\alpha = \left(\frac{w_d}{D_c}\right)^2\,,$$

where w_d is the width of the dispersed phase channel,

$$C_\gamma = \frac{\left(3 + \frac{2}{\gamma}\right)}{\left(1 + \frac{1}{\gamma}\right)}$$

is the correction factor for viscosity ratio γ and ϵ is the ratio of droplet velocity to the average continuous flow velocity. The value ranges from $0 < \epsilon < 2$ and it depends on capillary number.

Confined Geometry. In the confined geometry, the width of the dispersed phase channel is comparable to that of the continuous phase [17.50]. The droplet phase completely obstructs the continuous phase channel (except for a thin Bretherton's film between the droplet and the wall), leading to an increase in the upstream pressure driving the breakup of the interface. Under these conditions, plugs are often generated instead of droplets. Plugs can be thought of an elongated droplet or the droplets with length in the flow direction greater than its width. The neck of the plug squeezes at a rate proportional to the average velocity of the continuous phase fluid and the plug fills at a rate proportional to the dispersed phase flowrate [17.51, 52]. The final length of the plug is given by the expression

$$L_1 = \frac{L}{w_c} = 1 + \alpha\varphi\,,$$

where α is the constant that depends on the width of the thinning neck. The equation shows that at low capillary number, the length of the plug depends only on the volumetric flowrate ratio. Above a critical capillary number, the viscosity ratio plays an important role in the droplet breakup, in contrast to the unconfined geometry. In the confined geometry, the droplet formation occurs within a specific range of flow conditions. If φ approaches unity, the dispersed-phase flowrate and the continuous-phase flowrate become equal, and it is observed that two phases flow parallel to each other without breakup.

Flow-Focusing Geometry. In this configuration the dispersed phase and the continuous phase are forced to pass through a small and narrow region in the microfluidic device [17.7]. The shear applied by the continuous phase over the dispersed phase results in droplet pinch-off. Three regimes are observed in this configuration:

1. Squeezing regime or geometrically controlled regime
2. Dripping regime
3. Jetting regime.

The transition between these regimes depends on the capillary numberand the flowrate ratio. In general, microfluidic droplet generation occurs at a capillary number within the range of 10^{-3}–10^{1}. The squeezing regime occurs at low capillary numbers ($\approx 10^{-3}$). When the droplet phase enters the junction, it blocks the flow of the continuous phase and results in pressure buildup in the continuous phase inlets. The subsequent bidirectional shear results in the pressure buildup that pinches off the dispersed phase to form droplets. Notably, the pinch-off occurs right at the orifice. The droplet diameter in this regime is observed to be comparable to the orifice size and is larger than the other two regimes. As the capillary number increases, transition from squeezing regime to dripping regime is observed. In the dripping regime, the droplet breakup occurs within one characteristic diameter of the orifice [17.53, 54]. The interface after the breakup remains at a static location within the orifice. The droplets generated in this regime are smaller than the orifice diameter and are highly monodisperse (polydispersity $< 2\%$). At a fixed orifice size, the droplet diameter

decreases with increasing Ca and decreasing φ. The relationship between the droplet generation frequency (f), droplet spacing (s) and droplet velocity (U) is given by [17.55]

$$U = fs\,.$$

Zhou et al. [17.56] describe the droplet pinch-off mechanism in the dripping regime as a combination of a capillary instability, including Rayleigh capillary instability and end-pinching mechanism, shared with viscous drag exerted by the continuous phase on the droplet phase. The transition from the dripping to jetting regime occurs at a higher capillary number. In the jetting regime, as the name suggests, the dispersed phase protrudes like a long jet and it extends at least three orifice diameters outside the orifice exit. The droplets generated in this regime are polydisperse with a diameter larger than the dripping regime. The transition from the dripping to jetting regime occurs at a critical capillary number given by [17.54]

$$Ca_{\mathrm{cr}} = \frac{t_{\mathrm{pinch}}}{t_{\mathrm{growth}}} = \frac{\mu_{\mathrm{c}} Q_{\mathrm{d}}}{\sigma R_{\mathrm{jet}}^2} \approx 1\,,$$

when $Ca < Ca_{\mathrm{cr}}$. The dripping regime is observed because of the interface instability, which will not allow the growth of a long jet, whereas for $Ca > Ca_{\mathrm{cr}}$, the jetting regime is observed because the viscous stress will suppress the interface instability and allow the growth of a long jet. Droplet generation in coflowing, cross-flowing and flow-focusing geometries are illustrated in Fig. 17.17.

Passive droplet generators are widely used because of its ease of use and simplicity. Active droplets, though more complex, allow for better control over the droplet generation and production (ink jet printing technology). Active droplet generation employs piezoelectric transducers [17.57], membrane valves [17.58], electric fields [17.59] to initiate the droplet breakup.

17.4 Microfluidic Micro-/Nanodroplet Applications

Droplet microfluidics offers an excellent platform to conduct a diverse set of applications from chemical synthesis, particle manipulation, bioassays and drug discovery to point-of-care diagnostic chips [17.37, 60–62]. This section discusses the current and potential applications of droplet microfluidics.

17.4.1 Chemical Reactions in Droplets

Droplets act as isolated micro-/nanocontainers to perform chemical reactions. The exquisite control and manipulation of these droplet reactors enables one to conduct innumerable chemical reactions within the droplets [17.4]. Droplet technology offers several advantages while performing the chemical reactions:

1. Reduced consumption of reagents
2. Less exposure to hazardous chemicals
3. Large surface-to-volume ratio enables better diffusion and mass flowrates
4. Recirculation within the droplets ensures proper mixing of the reactants
5. Scale up of the process by parallelization.

The hydrolysis reaction between *p*-nitro phenyl acetate and sodium hydroxide was performed in droplets.

Sodium hydroxide forms the droplet phase and the continuous phase contains *p*-nitro phenyl acetate. The reaction occurred as result of the mass transfer of *p*-nitro phenyl acetate into the droplet phase containing sodium hydroxide. Similar work has been reported to demonstrate the increased yield in droplet-based microreactor platforms [17.65]. The neutralization reaction can also be performed in droplets [17.66]. The acetic acid present in the continuous phase diffuse into the KOH/NaOH droplets and the color variation of the pH indicator is used to monitor the reaction and calculate the diffusion rates. It has been found that the diffusion rate is faster in small droplets than plugs. Other chemical reactions include precipitation reactions [17.67], anticoagulants [17.68], organic phase reactions [17.69] and the generation of cadmium selenide (CdSe) nanoparticles inside the droplets [17.63]. Separate droplets with different reagents were merged in a controlled environment to induce reactions inside the fused droplet to produce monodispersed nanoparticles (Fig. 17.18).

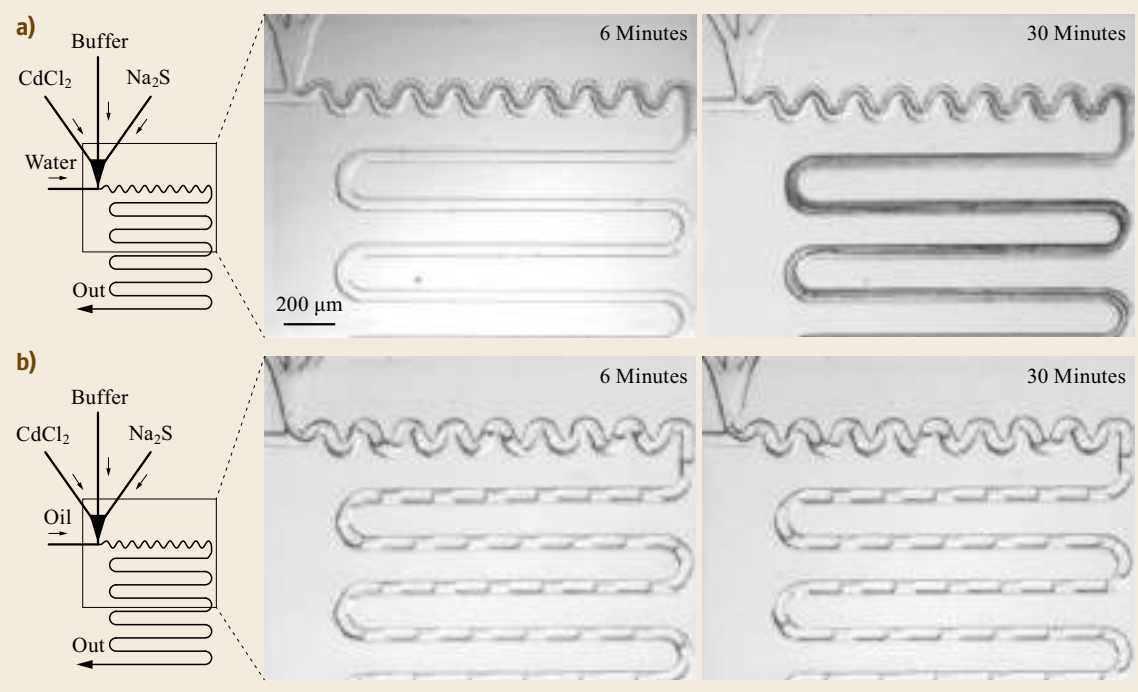

Fig. 17.18a,b Comparison of the nanoparticle (CdS) synthesis in **(a)** single-phase flow and **(b)** droplet phase. Unlike the droplet system, the single-phase system results in nanoparticle accumulation inside the channel and eventually leads to clogging. 17.4.2 Biomolecule Synthesis

Droplet microfluidics is an ideal platform to carry out controlled synthesis of a wide range of biomolecules including high- throughput directed evolution of proteins and polymerization chain reaction (PCR). The ability of droplet microfluidics to generate uniform and homogeneous droplets in a controlled environment is the fundamental requirement for the synthesis of artificial cells [17.71]. The formation of an artificial cell helps one study life's fundamental reactions. A cell-like bioreactor was produced by encapsulating the *E. coli* cell's free expression system in a phospholipid vesicle [17.64]. The phospholipid bilayer acts as a semipermeable membrane that helps in the exchange of nutrients in and out of the cell (Fig. 17.19). *Huebner* et al. demonstrated protein expression by encapsulating single cells inside droplets and detecting the expression of fluorescent proteins within the cell [17.70]. This in-vitro protein expression in droplet vesicles offers potential applications in the high-throughput directed evolution of proteins (Fig. 17.20). In genomics, droplet microfluidics offer a compelling platform to perform PCR in droplets. Compared to the conventional approach, droplet-based PCR technology offers advantages in making the process quantitative and

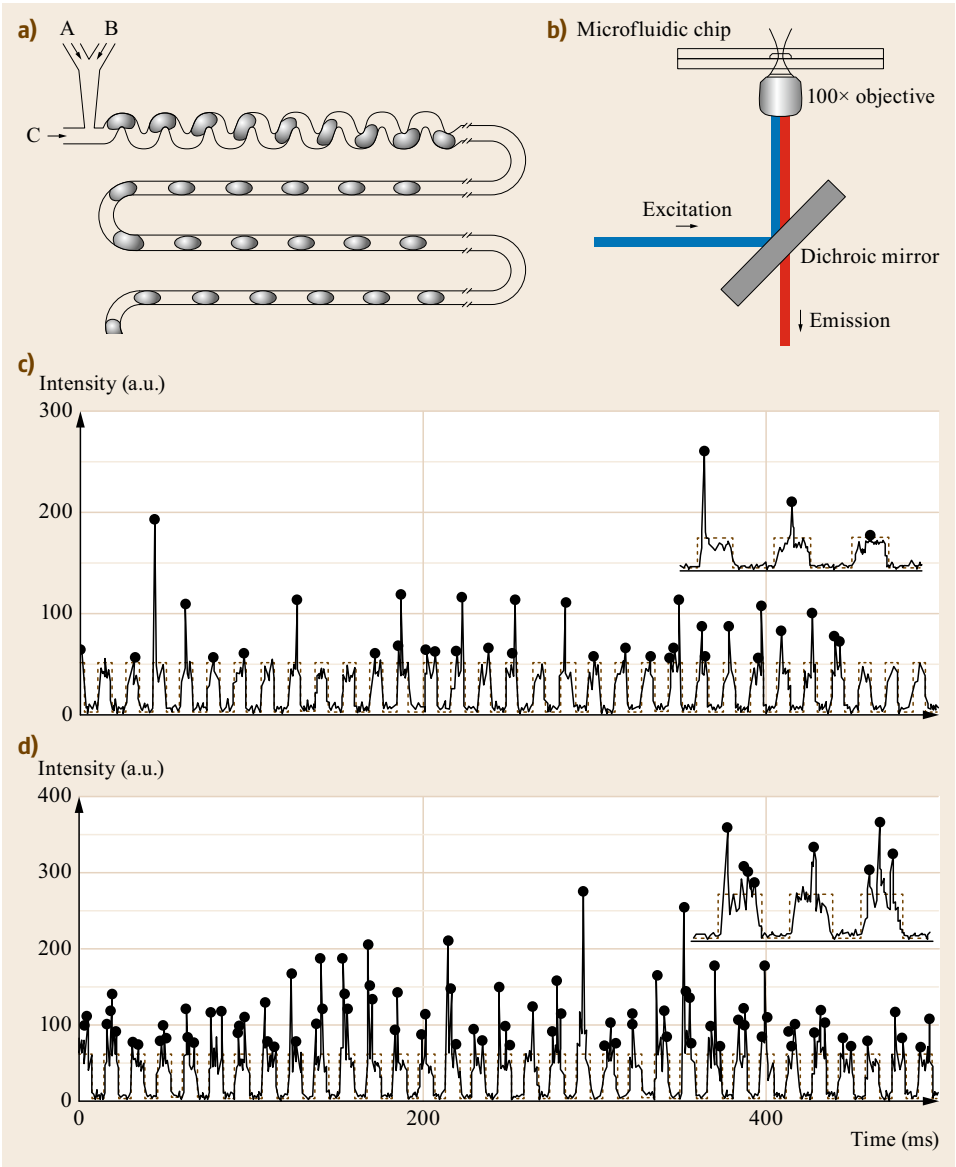

Fig. 17.20a–d Protein expression studies by encapsulating a single cell inside the droplet and detecting the expression of fluorescent proteins within the cell. Droplet-containing cells are distinguished by a vertical spike arising from the expressed fluorescent protein. Reproduced from [17.70] with the permission of the Royal Society of Chemistry

sensitive [17.72]. Droplet-based PCR also increases the amplification efficiency by minimizing the reagent dispersion and surface adsorption. Generally, droplet-based PCR is performed in two different ways. The first is a continuous flow-based approach. A droplet-based micro-oscillation flow PCR chip was designed and implemented by *Wang* et al. [17.73]. Injected droplets containing a PCR mixture, pass through the three distinct temperature zones (denaturation, extension and annealing) in the microfluidic channel to attain the required temperature transition. They successfully amplified human papillomavirus (HPV)-DNA samples and the PCR products were analyzed by gel electrophoresis. The group has also shown that the whole process takes less than 15 min, compared to 2 h for the conventional process. In the second method, microfluidic chips are used only for the generation and detection process [17.74]. This is the method that most commercial products utilize (Fig. 17.21). The process flow occurs in three steps:

1. Uniformly sized droplets with template DNA were created by a microfluidic drop generation device.
2. These droplets are transformed manually into 96-well plates and are placed in a thermocycling device that is programmed to control the temperature required for the DNA amplification.
3. Thermocycled droplets with amplicons are automatically transferred to the detection device, which has a microfluidic chip built into it.

The LIF detection system helps to quantitatively estimate the DNAexpression based on the fluorescence associated with each droplet.

17.4.3 Drug Discovery

In conjunction with high-speed and sensitive-detection technologies, such as LIF detection, mass spectroscopy, capillary electrophoresis, x-ray crystallography and HPLC, droplet microfluidics has the capability to perform HTS of target molecules against potential drugs. For example, to study the activity of a certain drug against the disease causing cells or proteins, both the labeled cells/proteins and drugs are encapsulated separately in the form of droplets using suitable droplet-generation configurations. These two specific droplet groups are subjected to droplet merging/fusion using appropriate passive or active fusion techniques. The product resulting from the reactions inside the fused droplet is picked up by fluorescence-detection techniques. Since the droplet generation frequency can reach 10 KHz, one can screen up to 10 000 droplets in one second, a speed that could revolutionize the high-throughput industry. As a result, the whole screening process has been transformed from conventional well plates to droplet technology. Another tool to perform high-throughput protein analysis is matrix-assisted desorption or ionization (MALDI). MALDI spectroscopy has been integrated with droplet technology to achieve high-throughput analysis of proteins and chemicals [17.75]. *Wheeler* et al. illustrated an EWOD-

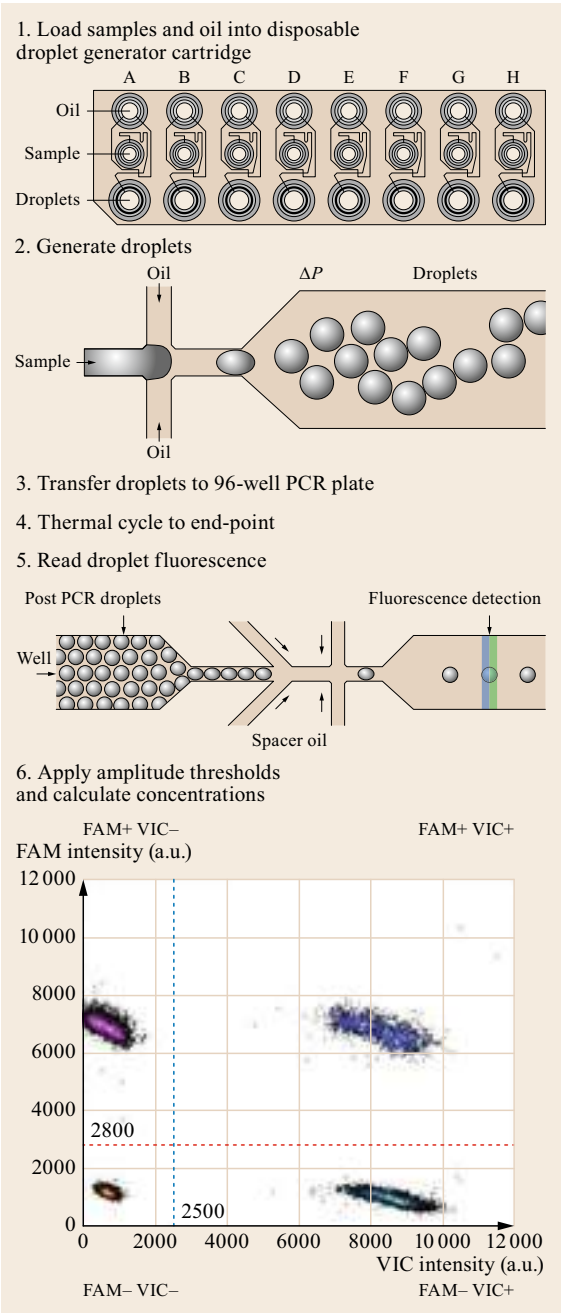

Fig. 17.21 BioRad's droplet PCR workflow

based technique to purify the sample and analyze them using matrix-assisted laser desorption ionization-time of flight mass spectrometer (MALDI-TOF) mass spectroscopy [17.76]. In this platform, the whole process is automated but the common channels still allow for potential surface cross-contamination. Protein characterization can also be done by x-ray diffraction of protein crystals. Proteins (glucose isomerase, thaumatin and ferritin) are subjected to crystallization inside the droplets and were characterized using x-ray crystallography [17.77]. Another technique to characterize a drug compound is to perform kinetic studies to explore the activity of enzymes and chemicals. *Song* and *Ismagilov* have conducted kinetic measurements of ribonuclease A (RNase A) with millisecond temporal resolution [17.78]. The enzymatic activity was determined by the fluorescence resulting from the cleavage of a fluorogenic substrate by RNase A (Fig. 17.22). The intensity of the fluorescence is used to figure out the duration of the reaction process. In general, droplet microfluidics offers a standardized platform to perform HTS of biomolecules. As such, the droplet microfluidics does not alter the format of the drug screening but it adds functionality and performance to the existing platform.

Directed evolution is another important application of droplet-based technology. Copies of genes or cells are distributed into each droplet compartment and are assayed for a specific phenotype. The positive droplets (the droplets containing the mutant genes) were sorted out and broken to recover the genotype for characterization [17.79]. Reverse-transcription PCR (RT-PCR) has emerged as a powerful technique to characterize the transcriptome of single cells in droplets [17.80]. This study will provide insights into the heterogeneity of the cells, their response to drugs or pathogens and the cause of various diseases. The single-cell transcriptomes are captured using the hydrogel microbeads, which are encapsulated in the droplets along with the cell. Entire transcriptomes of the cells were barcoded for identification purposes and this technique has reported a 13% mRNA capture efficiency (Fig. 17.23) [17.81].

17.5 Conclusion

In this chapter, we introduced droplet microfluidic technology and its ability to manipulate fluids on the micro/nanoscale. The chapter also covered droplet generation techniques, current trends in droplet microfluidics and generic applications. The field of droplet microfluidics has matured over the last decade, as droplet microfluidic technologies are now being applied to a wide variety of commercial applications. There remain technical challenges to enable large networks of microfluidic operations in integrated devices that researchers are working on. However, the future of this promising technology is bright and it is predicted that droplet microfluidics will become an indispensable tool for a wide range of fluidic diagnostic platforms.

18. Nanorobotics

Bradley J. Nelson, Lixin Dong

Nanorobotics is the study of robotics at the nanometer scale, and includes robots that are nanoscale in size and large robots capable of manipulating objects that have dimensions in the nanoscale range with nanometer resolution. With the ability to position and orient nanometer-scale objects, nanorobotic manipulation is a promising way to enable the assembly of nanosystems including nanorobots.

This chapter overviews the state of the art of nanorobotics, outlines nanoactuation, and focuses on nanorobotic manipulation systems and their application in nanoassembly, biotechnology and the construction and characterization of nanoelectromechanical systems (NEMS) through a hybrid approach.

Because of their exceptional properties and unique structures, carbon nanotubes (CNTs) and SiGe/Si nanocoils are used to show basic processes of nanorobotic manipulation, structuring and assembly, and for the fabrication of NEMS including nano tools, sensors and actuators.

A series of processes of nanorobotic manipulation, structuring and assembly has been demonstrated experimentally. Manipulation of individual CNTs in three-dimensional (3-D) free space has been shown by grasping using dielectrophoresis and placing with both position and orientation control for mechanical and electrical property characterization and assembly of nanostructures and devices. A variety of material property investigations can be performed, including bending, buckling, and pulling to investigate elasticity as well as strength and tribological characterization. Structuring of CNTs can be performed including shape modification, the exposure of nested cores, and connecting CNTs by van der Waals forces, electron-beam-induced deposition and mechanochemical bonding. Nanorobotics provides novel techniques for exploring the biodomain by manipulation and characterization of nanoscale objects such as cellular membranes, DNA and other biomolecules. Nano tools, sensors and actuators can provide measurements and/or movements that are calculated in nanometers, gigahertz, piconewtons, femtograms, etc., and are promising for molecular machines and bio- and nanorobotics applications. Efforts are focused on developing enabling technologies for nanotubes and other nanomaterials and structures for NEMS and nanorobotics. By combining bottom-up nanorobotic manipulation and top-down nanofabrication processes, a hybrid approach is demonstrated for creating complex 3-D nanodevices. Nanomaterial science, bionanotechnology, and nanoelectronics will benefit from advances in nanorobotics.

18.1 Overview of Nanorobotics

Progress in robotics over the past years has dramatically extended our ability to explore the world from perception, cognition and manipulation perspectives at a variety of scales extending from the edges of the solar system down to individual atoms (Fig. 18.1). At the bottom of this scale, technology has been moving toward greater control of the structure of matter, suggesting the feasibility of achieving thorough control of the molecular structure of matter atom by atom as *Richard Feynman* first proposed in 1959 in his prophetic article on miniaturization [18.1]:

> *What I want to talk about is the problem of manipulating and controlling things on a small scale... I am not afraid to consider the final question as to whether, ultimately – in the great future – we can arrange the atoms the way we want: the very atoms, all the way down!*

He asserted that:

> *At the atomic level, we have new kinds of forces and new kinds of possibilities, new kinds of effects. The problems of manufacture and reproduction of materials will be quite different. The principles of physics, as far as I can see, do not speak against the possibility of maneuvering things atom by atom.*

This technology is now labeled *nanotechnology*.

The *great future* of Feynman began to be realized in the 1980s. Some of the capabilities he dreamed of have been demonstrated, while others are being developed. Nanorobotics represents the next stage in miniaturization for maneuvering nanoscale objects. Nanorobotics is the study of robotics at the nanometer scale, and includes robots that are nanoscale in size, i. e., nanorobots, and large robots capable of manipulating objects that have dimensions in the nanoscale range with nanometer resolution, i. e., nanorobotic manipulators. The field of nanorobotics brings together several disciplines, including nanofabrication processes used for producing nanoscale robots, nanoactuators, nanosensors, and physical modeling at nanoscales. Nanorobotic manipulation technologies, including the assembly of nanometer-sized parts, the manipulation of biological cells or molecules, and the types of robots used to perform these types of tasks also form a component of nanorobotics.

As the 21st century unfolds, the impact of nanotechnology on the health, wealth, and security of humankind is expected to be at least as significant as the combined influences in the 20th century of antibiotics, the integrated circuit, and human-made polymers. For example, *Lane* stated in 1998 [18.2]:

> *If I were asked for an area of science and engineering that will most likely produce the breakthroughs*

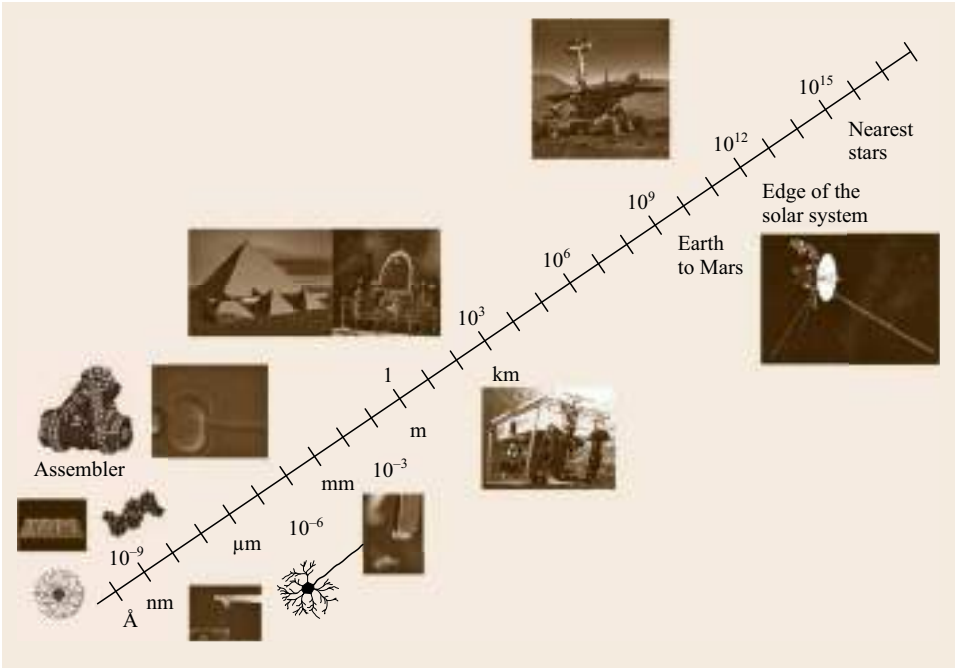

Fig. 18.1 Robotic exploration

of tomorrow, I would point to nanoscale science and engineering.

The great scientific and technological opportunities nanotechnology presents have stimulated extensive exploration of the nanoworld and initiated an exciting worldwide competition, which has been accelerated by the publication of the *National Nanotechnology Initiative* by the US government in 2000 [18.3]. Nanorobotics will play a significant role as an enabling nanotechnology and could ultimately be a core part of nanotechnology if *Drexler*'s machine-phase nanosystems based on self-replicative molecular assemblers via mechanosynthesis can be realized [18.4].

By the early 1980s, scanning tunneling microscopes (STMs) [18.5] radically changed the ways in which we interacted with and even regarded single atoms and molecules. The very nature of proximal probe methods encourages exploration of the nanoworld beyond conventional microscopic imaging. Scanned probes now allow us to perform engineering operations on single molecules, atoms, and bonds, thereby providing a tool that operates at the ultimate limits of fabrication. They have also enabled exploration of molecular properties on an individual nonstatistical basis.

STMs and other nanomanipulators are nonmolecular machines but use bottom-up strategies. Although performing only one molecular reaction at a time is obviously impractical for making large amounts of a product, it is a promising way to provide the next generation of nanomanipulators. Most importantly, it is possible to realize the directed assembly of molecules or supermolecules to build larger nanostructures through nanomanipulation. The products produced by nanomanipulation could be the first step of a bottom-up strategy in which these assembled products are used to self-assemble into nanomachines.

One of the most important applications of nanorobotic manipulation will be nanorobotic assembly. However, it appears that until assemblers capable of replication can be built, the parallelism of chemical synthesis and self-assembly are necessary when starting from atoms; groups of molecules can self-assemble quickly due to their thermal motion, enabling them to *explore* their environments and find (and bind to) complementary molecules. Given their key role in natural molecular machines, proteins are obvious candidates for early work in self-assembling artificial molecular systems. *Degrado* [18.6] demonstrated the feasibility of designing protein chains that predictably fold into solid molecular objects. Progress is also being made in artificial enzymes and other relatively small molecules that perform functions like those of natural proteins; the 1987 Nobel prize for chemistry went to *Cram* and *Lehn* for such work on supramolecular chemistry [18.7]. Several bottom-up strategies using self-assembly appear feasible [18.8]. *Fujita* et al.'s pioneering work has shown that self-assembly can be directed by adroitly exploiting the chemical and electrical bonds that hold natural molecules together, and hence get molecules to form desired nanometer-scale structures [18.9]. Chemical synthesis, self assembly, and supramolecular chemistry make it possible to provide building blocks at relatively large sizes beginning from the nanometer scale. Nanorobotic manipulation serves as the base for a hybrid approach to construct nanodevices by structuring these materials to obtain building blocks and assembling them into more complex systems.

This chapter focuses on nanorobotics including actuation, manipulation and assembly at the nanoscale. The main goal of nanorobotics is to provide an effective technology for the experimental exploration of the nanoworld, and to push the boundaries of this exploration from a robotics research perspective.

18.2 Actuation at Nanoscales

The positioning of nanorobots and nanorobotic manipulators depends largely on nanoactuators. While nanosized actuators for nanorobots are still under exploration and relatively far from implementation, microelectromechanical system (MEMS)-based efforts are focused on shrinking their sizes [18.10]. Nanometer-resolution motion has been extensively investigated and can be generated using various actuation principles. Electrostatics, electromagnetics, and piezoelectrics are the most common ways to realize actuation at nanoscales. For nanorobotic manipulation, besides nanoresolution and compact sizes, actuators generating large strokes and high forces are best suited for such applications. The speed criteria are of less importance as long as the actuation speed is in the range of a couple of hertz and above. Table 18.1 provides a small selection of early works on actuators [18.11–16] suitable in actuation principle actuators suitable for nanorobotic applications (partially adapted from [18.10]).

Several extensive reviews on various actuation principles have been published [18.17–21]. During the design of an actuator, the tradeoffs among range of motion, force, speed (actuation frequency), power

Table 18.1 Actuation with MEMS

Actuation principle	Type of motion	Volume (mm^3)	Speed (s^{-1})	Force (N)	Stroke (m)	Resolution (m)	Power density (W/m^3)	Ref.
Electrostatic	Linear	400	5000	1×10^{-7}	6×10^{-6}	n/a	200	[18.12]
Magnetic	Linear	$0.4\times0.4\times0.5$	1000	2.6×10^{-6}	1×10^{-4}	n/a	3000	[18.13]
Piezoelectric	Linear	$25.4\times12.7\times1.6$	4000	350	1×10^{-3}	7×10^{-8}	n/a	[18.14]
Actuation principle	**Type of motion**	**Volume (mm^3)**	**Speed (rad/s)**	**Torque (N m)**	**Stroke (rad)**	**Resolution (rad)**	**Power density (W/m^3)**	**Ref.**
Electrostatic	Rotational	$\pi/4\times0.5^2\times3$	40	2×10^{-7}	2π	n/a	900	[18.15]
Magnetic	Rotational	$2\times3.7\times0.5$	150	1×10^{-6}	2π	$5/36\pi$	3000	[18.16]
Piezoelectric	Rotational	$\pi/4\times1.5^2\times0.5$	30	2×10^{-11}	0.7	n/a	n/a	[18.17]

consumption, control accuracy, system reliability, robustness, load capacity, etc. must be taken into consideration. This section reviews basic actuation technologies and potential applications at nanometer scales.

18.2.1 Electrostatics

Electrostatic charge arises from a build up or deficit of free electrons in a material, which can exert an attractive force on oppositely charged objects, or a repulsive force on similarly charged objects. Since electrostatic fields arise and disappear rapidly, such devices will likewise demonstrate very fast operation speeds and be little affected by ambient temperatures.

Recent investigations have produced many examples of miniature devices using electrostatic force for actuation including silicon micro motors [18.22, 23], microvalves [18.24], and microtweezers [18.25]. This type of actuation is important for achieving nanosized actuation.

Electrostatic fields can exert great forces, but generally across very short distances. When the electric field must act over larger distances, a higher voltage will be required to maintain a given force. The extremely low-current consumption associated with electrostatic devices makes for highly efficient actuation.

18.2.2 Electromagnetics

Electromagnetism arises from electric current moving through a conducting material. Attractive or repulsive forces are generated adjacent to the conductor and proportional to the current flow. Structures can be built which gather and focus electromagnetic forces, and harness these forces to create motion.

Electromagnetic fields arise and disappear rapidly, thus permitting devices with very fast operation speeds. Since electromagnetic fields can exist over a wide range of temperatures, performance is primarily limited by the properties of the materials used in constructing the actuator.

One example of a microfabricated electromagnetic actuator is a microvalve which uses a small electromagnetic coil wrapped around a silicon micromachined valve structure [18.26]. However, the downward scalability of electromagnetic actuators into the micro- and nanorealm may be limited by the difficulty of fabricating small electromagnetic coils. Furthermore, most electromagnetic devices require perpendicularity between the current conductor and the moving element, presenting a difficulty for planar fabrication techniques commonly used to make silicon devices.

An important advantage of electromagnetic devices is their high efficiency in converting electrical energy into mechanical work. This translates into less current consumption from the power source.

18.2.3 Piezoelectrics

Piezoelectric motion arises from the dimensional changes generated in certain crystalline materials when subjected to an electric field or to an electric charge. Structures can be built which gather and focus the force of the dimensional changes, and harness them to create motion. Typical piezoelectric materials include quartz (SiO_2), lead zirconate titanate (PZT), lithium niobate, and polymers such as polyvinyledene fluoride (PVDF).

Piezoelectric materials respond very quickly to changes in voltages and with great repeatability. They can be used to generate precise motions with repeatable oscillations, as in quartz timing crystals used in many electronic devices. Piezo materials can also act as sensors, converting tension or compression strains to voltages.

On the microscale, piezoelectric materials have been used in linear inchworm drive devices [18.27], and micropumps [18.28]. STMs and most nanomanipulators use piezoelectric actuators.

Piezo materials operate with high force and speed, and return to a neutral position when unpowered. They exhibit very small strokes (under 1 %). Alternating electric currents produce oscillations in the piezo

Table 18.2 Comparison of nanoactuators

Method	Efficiency	Speed	Power density
Electrostatic	Very high	Fast	Low
Electromagnetic	High	Fast	High
Piezoelectric	Very high	Fast	High
Thermomechanical	Very high	Medium	Medium
Phase change	Very high	Medium	High
Shape memory	Low	Medium	Very high
Magnetostrictive	Medium	Fast	Very high
Electrorheological	Medium	Medium	Medium
Electrohydrodynamic	Medium	Medium	Low
Diamagnetism	High	Fast	High

material, and operation at the sample's fundamental resonant frequency produces the largest elongation and highest power efficiency [18.29]. Piezo actuators working in the stick–slip mode can provide millimeter to centimeter strokes. Most commercially available nanomanipulators adopt this type of actuators, such as Picomotors from New Focus and Nanomotors from Klock.

18.2.4 Other Techniques

Other techniques include thermomechanical, phase change, shape memory, magnetostrictive, electrorheological, electrohydrodynamic, diamagnetism, magnetohydrodynamic, shape changing, polymers, biological methods (living tissues, muscle cells, etc.) and so on. Table 18.2 lists a comparison of these.

18.3 Nanorobotic Manipulation Systems

18.3.1 Overview

Nanomanipulation, or positional and/or force control at the nanometer scale, is a key enabling technology for nanotechnology by filling the gap between top-down and bottom-up strategies, and may lead to the appearance of replication-based molecular assemblers [18.4]. These types of assemblers have been proposed as general-purpose manufacturing devices for building a wide range of useful products as well as copies of themselves (self-replication).

Presently, nanomanipulation can be applied to the scientific exploration of mesoscopic physical phenomena, biology and the construction of prototype nanodevices. It is a fundamental technology for property characterization of nanomaterials, structures and mechanisms, for the preparation of nanobuilding blocks, and for the assembly of nanodevices such as nanoelectromechanical systems (NEMS).

Nanomanipulation was enabled by the inventions of the STM [18.5], atomic force microscope (AFM) [18.30], and other types of scanning probe microscope (SPM). Besides these, optical tweezers (laser trapping) [18.31] and magnetic tweezers [18.32] are also possible nanomanipulators. Nanorobotic manipulators (NRMs) [18.33, 34] are characterized by the capability of 3-D positioning, orientation control, independently actuated multiple end-effectors, and independent real-time observation systems, and can be integrated with scanning probe microscopes. NRMs largely extend the complexity of nanomanipulation.

A concise comparison of STM, AFM, and NRM technology is shown in Fig. 18.2. With its incomparable imaging resolution, an STM can be applied to particles as small as atoms with atomic resolution. However, limited by its two-dimensional (2-D) positioning and available strategies for manipulations, standard STMs

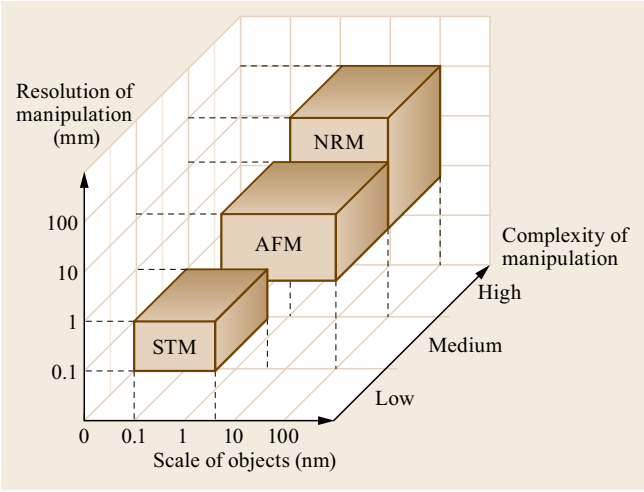

Fig. 18.2 Comparison of nanomanipulators

are ill-suited for complex manipulation and cannot be used in 3-D space. An AFM is another important type of nanomanipulator. There are three imaging modes for AFMs, i. e., contact mode, tapping mode (periodic contact mode), and non-contact mode. The latter two are also called dynamic modes and can attain higher imaging resolution than the contact mode. Atomic resolution is obtainable with non-contact mode. Manipulation with an AFM can be done in either contact or dynamic mode. Generally, manipulation with an AFM involves moving an object by touching it with a tip. A typical manipulation is like this: image a particle first in non-contact mode, then remove the tip oscillation voltage and sweep the tip across the particle in contact with the surface and with the feedback disabled. Mechanical pushing can exert larger forces on objects and, hence, can be applied for the manipulation of relatively larger objects. One-dimensional (1-D) to 3-D objects can be manipulated on a 2-D substrate. However, the manipulation of individual atoms with an AFM remains a challenge. By separating the imaging and manipulation functions, nanorobotic manipulators can have many more degrees of freedom including rotation for orientation control, and, hence, can be used for the manipulation of zero-dimensional (0-D, symmetric spheres) to 3-D objects in 3-D free space. Limited by the relative lower resolution of electron microscopes, NRMs are difficult to use for the manipulation of atoms. However, their general robotic capabilities including 3-D positioning, orientation control, independently actuated multiple end-effectors, separate real-time observation system, and integrations with SPMs inside makes NRMs quite promising for complex nanomanipulation.

The first nanomanipulation experiment was performed by *Eigler* and *Schweizer* in 1990 [18.35]. They used an STM and materials at low temperatures (4 K) to position individual xenon atoms on a single-crystal nickel surface with atomic precision. The manipulation enabled them to fabricate rudimentary structures of their own design, atom by atom. The result is the famous set of images showing how 35 atoms were moved to form the three-letter logo *IBM*, demonstrating that matter could indeed be maneuvered atom by atom as *Feynman* suggested [18.1].

A nanomanipulation system generally includes nanomanipulators as the positioning device, microscopes as *eyes*, various end-effectors including probes and tweezers among others as its *fingers*, and types of sensors (force, displacement, tactile, strain, etc.) to facilitate the manipulation and/or to determine the properties of the objects. Key technologies for nanomanipulation include observation, actuation, measurement, system design and fabrication, calibration and control, communication, and human–machine interface.

Strategies for nanomanipulation are basically determined by the environment – air, liquid or vacuum – which is further decided by the properties and size of the objects and observation methods. Figure 18.3 depicts the microscopes, environments and strategies of nanomanipulation. In order to observe manipulated objects, STMs can provide subangstrom imaging resolution, whereas AFMs can provide atomic resolution. Both can obtain 3-D surface topology. Because AFMs can be used in an ambient environment, they provide a powerful tool for biomanipulation that may require a liquid environment. The resolution of scanning electron microscopes (SEMs) is limited to about 1 nm, whereas field-emission SEMs (FESEMs) can achieve higher resolutions. SEMs/FESEMs can be used for 2-D real-time observation for both the objects and end-effectors of manipulators, and large ultrahigh-vacuum (UHV) sample chambers provide enough space to contain an NRM with many degrees of freedom (DOFs) for 3-D nanomanipulation. However, the 2-D nature of the observation makes positioning along the electron-beam direction difficult. High-resolution transmission electron microscopes (HRTEMs) can provide atomic resolution. However, the narrow UHV specimen chamber makes it difficult to incorporate large manipulators. In principle, optical microscopes (OMs) cannot be used for nanometer-scale (smaller than the wavelength of visible lights) observation because of diffraction limits. Scanning near-field OMs (SNOMs) break this limitation and are promising as a real-time observation

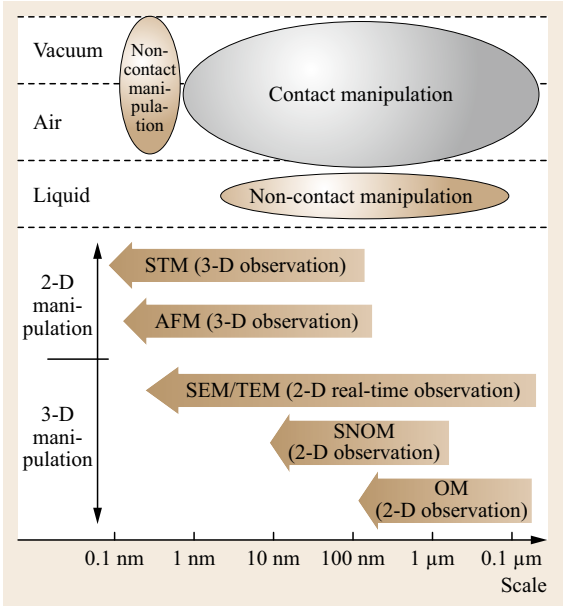

Fig. 18.3 Microscopes, environments and strategies of nanomanipulation

device for nanomanipulation, especially for ambient environments. SNOMs can be combined with AFMs, and potentially with NRMs for nanoscale biomanipulation.

Nanomanipulation processes can be broadly classified into three types: (1) lateral non-contact, (2) lateral contact, and (3) vertical manipulation. Generally, lateral non-contact nanomanipulation is mainly applied for atoms and molecules in UHV with an STM or bio-object in liquid using optical or magnetic tweezers. Contact nanomanipulation can be used in almost any environment, generally with an AFM, but is difficult for atomic manipulation. Vertical manipulation can be performed by NRMs. Figure 18.4 shows the processes of the three basic strategies.

Motion of the lateral noncontact manipulation processes are shown in Fig. 18.4a. Applicable effects [18.36] able to cause the motion include long-range van der Waals (vdW) forces (attractive) generated by the proximity of the tip to the sample [18.37], electric-field-induced fields caused by the voltage bias between the tip and the sample [18.38, 39], tunneling current local heating or inelastic tunneling vibration [18.40, 41]. With these methods, some nanodevices and molecules have been assembled [18.42, 43]. Laser trapping (optical tweezers) and magnetic tweezers are possible for non-contact manipulation of nanoorder biosamples, e.g., DNA [18.44, 45].

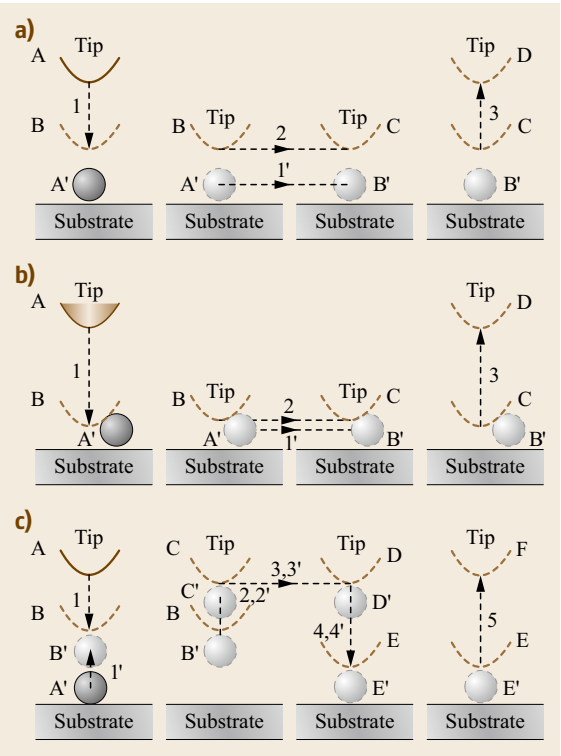

Fig. 18.4a–c Basic strategies of nanomanipulation. In the figure, A, B, C, ... represent the positions of end-effector (e.g., a tip), A′, B′, C′, ... the positions of objects, 1, 2, 3, ... the motions of end-effector, and 1′, 2′, 3′, ... the motions of objects. Tweezers can be used in pick-and-place to facilitate the picking-up, but are generally not necessarily helpful for placing. **(a)** Lateral non-contact nanomanipulation (sliding), **(b)** lateral contact nanomanipulation (pushing/pulling), **(c)** vertical nanomanipulation (picking and placing)

Non-contact manipulation combined with STMs has revealed many possible strategies for manipulating atoms and molecules. However, for the manipulation of CNTs no examples have been demonstrated.

Pushing or pulling nanometer objects on a surface with an AFM is a typical manipulation using this method as shown in Fig. 18.4b. Early work showed the effectiveness of this method for the manipulation of nanoparticles [18.46–49]. This method has also been shown in nanoconstruction [18.50] and biomanipulation [18.51]. A virtual-reality interface facilitates such manipulation [18.52, 53] and may create an opportunity for other types of manipulation. This technique has been used in the manipulation of nanotubes on a surface, and some examples will be introduced later in this chapter.

The pick-and-place task as shown in Fig. 18.4c is especially significant for 3-D nanomanipulation since its main purpose is to assemble prefabricated building blocks into devices. The main difficulty is in achieving sufficient control of the interaction between the tool and object and between the object and the substrate. Two strategies have been presented for micromanipulation [18.54] and have also proven to be effective for nanomanipulation [18.34, 55]. One strategy is to apply a dielectrophoretic force between a tool and an object as a controllable additional external force by applying a bias between the tool and the substrate on which the object is placed. Another strategy is to modify the van der Waals and other intermolecular and surface forces between the object and the substrate. For the former, an AFM cantilever is ideal as one electrode to generate a nonuniform electrical field between the cantilever and the substrate.

18.3.2 Nanorobotic Manipulation Systems

Nanorobotic manipulators are the core components of nanorobotic manipulation systems. The basic requirements for a nanorobotic manipulation system for 3-D manipulation include nanoscale positioning resolution, a relative large working space, enough DOFs including rotational ones for 3-D positioning and orientation

control of the end-effectors, and usually multiple end-effectors for complex operations.

A commercially available nanomanipulator (MM3A from Kleindiek) installed inside a SEM (Carl Zeiss DSM962) is shown in Fig. 18.5. The manipulator has three degrees of freedom, and nanometer to subnanometer-scale resolution (Table 18.3). Calculations show that, when moving/scanning in *A*/*B*-direction by joint q_1/q_2, the additional linear motion in *C* is very small. For example, when the arm length is 50 mm, the additional motion in the *C*-direction is only 0.25–1 nm when moving in the *A*-direction for 5–10 μm; these errors can be ignored or compensated with an additional motion of the prismatic joint p_3, which has a 0.25 nm resolution.

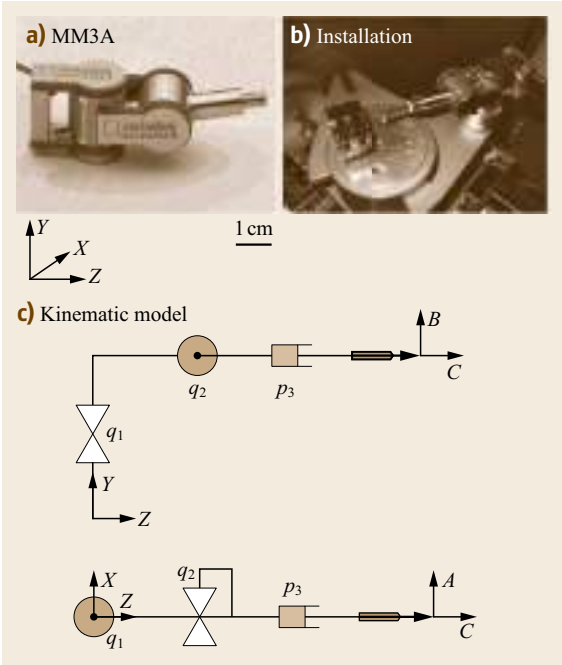

Fig. 18.5a–c Nanomanipulator (MM3A from Kleindiek) inside an SEM

Table 18.3 Specifications of MM3A

Item	Specification
Operating range q_1 and q_2	240°
Operating range *Z*	12 mm
Resolution *A* (horizontal)	10^{-7} rad (5 nm)
Resolution *B* (vertical)	10^{-7} rad (3.5 nm)
Resolution *C* (linear)	0.25 nm
Fine (scan) range *A*	20 μm
Fine (scan) range *B*	15 μm
Fine (scan) range *C*	1 μm
Speed *A*, *B*	10 mm/s
Speed *C*	2 mm/s

Figure 18.6a shows a nanorobotic manipulation system that has 16 DOFs in total and can be equipped with three to four AFM cantilevers as end-effectors for both manipulation and measurement. Table 18.4 lists the specifications of the system. Table 18.5 shows the functions of the nanorobotic manipulation system for nanomanipulation, nanoinstrumentation, nanofabrication and nanoassembly. The positioning resolution is subnanometer order and strokes are centimeter scale. The manipulation system is not only for nanomanipulation, but also for nanoassembly, nanoinstrumentation and nanofabrication. Four-probe semiconductor measurements are perhaps the most complex manipulation this system can perform, because it is necessary to actuate four probes independently by four manipulators. Theoretically, 24 DOFs are needed for four manipulators for general-purpose manipulations, i. e., 6 DOFs for each manipulator for complete control of three linear DOFs and three rotation DOFs. However, 16 DOFs are sufficient for this specific purpose. In general, two manipulators are sufficient for most tasks. More probes

Table 18.4 Specifications of a nanorobotic manipulation system

Item	Specification
Nanorobotic manipulation system	
DOFs	Total: 16 DOFs
	Unit 1: 3 DOFs (x, y and β; coarse)
	Unit 2: 1 DOF (z; coarse), 3-DOF (x, y and z; fine)
	Unit 3: 6 DOFs (x, y, z, α, β, γ; ultrafine)
	Unit 4: 3 DOFs (z, α, β; fine)
Actuators	4 Picomotors (Units 1 & 2)
	9 PZTs (Units 2 & 3)
	7 Nanomotors (Units 2 & 4)
End-effectors	3 AFM cantilevers + 1 substrate or
	4 AFM cantilevers
Working space	18 mm × 18 mm × 12 mm × 360° (coarse, fine),
	26 μm × 22 μm × 35 μm (ultrafine)
Positioning resolution	30 nm (coarse), 2 mrad (coarse), 2 nm (fine), sub-nm (ultrafine)
Sensing system	FESEM (imaging resolution: nm) and AFM cantilevers
Nanoinstrumentation system	
FESEM	Imaging resolution: 1.5 nm
AFM cantilever	Stiffness constant: 0.03 nN/nm
Nanofabrication system	
EBID	FESEM emitter: T-FE
	CNT emitter

Table 18.5 Functions of a nanorobotic manipulation system

Functions	Manipulations involved
Nanomanipulation	Picking up nanotubes by controlling intermolecular and surface forces, and positioning them together in 3-D space
Nanoinstrumentation	Mechanical properties: buckling or stretching
	Electrical properties: placing between two probes (electrodes)
Nanofabrication	EBID with a CNT emitter and parallel EBID
	Destructive fabrication: breaking
	Shape modification: deforming by bending and buckling, and fixing with EBID
Nanoassembly	Connecting with van der Waals
	Soldering with EBID
	Bonding through mechanochemical synthesis

provide for more potential applications. For example, three manipulators can be used to assemble a nanotube transistor, a third probe can be applied to cut a tube supported on the other two probes, four probes can be used for four-terminal measurements to characterize the electric properties of a nanotube or a nanotube cross-junction. There are many potential applications for the manipulators if all four probes are used together. With the advancement of nanotechnology, one could shrink the size of nanomanipulators and insert more DOFs inside the limited vacuum chamber of a microscope, and, perhaps, the molecular version of manipulators such as that dreamed of by *Drexler* could be realized [18.4].

For the construction of multiwalled carbon nanotubes (MWNT)-based nanostructures, manipulators position and orient nanotubes for the fabrication of nanotube probes and emitters, for performing na-

nosoldering with electron-beam-induced deposition (EBID) [18.56], for the property characterization of single nanotubes for selection purposes and for characterizing junctions to test connection strength.

A nanolaboratory is shown in Fig. 18.6b, and its specifications are listed in Table 18.4. The nanolaboratory integrates a nanorobotic manipulation system with a nano analytical system and a nanofabrication system, and can be applied for manipulating nanomaterials, fabricating nanobuilding blocks, assembling nanodevices, and for in situ analysis of the properties of such materials, building blocks and devices. Nanorobotic manipulation within the nanolaboratory has opened a new path for constructing nanosystems in 3-D space, and will create opportunities for new nanoinstrumentation and nanofabrication processes.

18.4 Nanorobotic Assembly

18.4.1 Overview

Nanomanipulation is a promising strategy for nanoassembly. Key techniques for nanoassembly include the structuring and characterization of nanobuilding blocks, the positioning and orientation control of the building blocks with nanometer-scale resolution, and effective connection techniques. Nanorobotic manipulation, which is characterized by multiple DOFs with both position and orientation controls, independently actuated multi-probes, and a real-time observation system, have been shown to be effective for assembling nanotube-based devices in 3-D space.

The well-defined geometries, exceptional mechanical properties, and extraordinary electric characteristics, among other outstanding physical properties (as listed in Table 18.6), of CNTs [18.57] qualify them for many potential applications (as concisely listed in Table 18.7), especially in nanoelectronics [18.58–60], NEMS, and other nanodevices [18.61]. For NEMS, some of the most important characteristics of nanotubes include their nanometer diameter [18.62], large aspect ratio (10−1000) [18.63, 64], TPa-scale Young's modulus [18.65–71], excellent elasticity [18.33, 72], ultrasmall interlayer friction, excellent capability for field emission, various electric conductivities [18.73–75], high thermal conductivity [18.76], high current-carrying capability with essentially no heating [18.77, 78], sensitivity of conductance to various physical or chemical changes, and charge-induced bond-length change.

Helical 3-D nanostructures, or nanocoils, have been synthesized from various materials, including helical carbon nanotubes [18.79] and zinc oxide nanobelts [18.80]. A new method of creating structures with nanometer-scale dimensions has recently been presented [18.81] and can be fabricated in a controllable way [18.82]. The structures are created through a top-down fabrication process in which a strained nanometer-thick heteroepitaxial bilayer curls up to form 3-D structures with nanoscale features. Helical geometries and tubes with diameters between 10 nm and 10 μm have been achieved. Because of their interesting morphology, mechanical, electrical, and electromagnetic properties, potential applications of these nanostructures in NEMS include nanosprings [18.83], electromechanical sensors [18.84], magnetic-field detectors, chemical or biological sensors, generators of magnetic beams, inductors, actuators, and high-performance electromagnetic-wave absorbers.

Table 18.6 Properties of carbon nanotubes

Property	Item	Data
Geometrical	Layers	Single/multiple
	Aspect ratio	10−1000
	Diameter	≈ 0.4 nm to > 3 nm (SWNTs)
		≈ 1.1 to > 100 nm (MWNTs)
	Length	Several μm (rope up to cm)
Mechanical	Young's modulus	≈ 1 TPa (steel: 0.2 TPa)
	Tensile strength	45 GPa (steel: 2 GPa)
	Density	1.33−1.4 g/cm^3 (Al: 2.7 g/cm^3)
Electronic	Conductivity	Metallic/semiconductivity
	Current carrying	
	Capacity	≈ 1 TA/cm^3 (Cu: 1 GA/cm^3)
	Field emission	Activate phosphorus at 1−3 V
Thermal	Heat transmission	> 3 kW/(m K) (diamond: 2 kW/(m K))

Table 18.7 Applications of carbon nanotubes

State	Device	Main properties applied
Bulk/array	Composite	High strength, conductivity, etc.
	Field emission devices: flat display, lamp, gas discharge tube, x-ray source, microwave generator, etc.	Field emission: stable emission, long lifetimes, and low emission threshold potentials, high current densities
	Electrochemical devices: supercapacitor, battery cathode, electromechanical actuator, etc.	Large surface area conductivity, high strength, high reversible component of storage capacity
	Fuel cell, hydrogen storage, etc.	Large surface area
Individual	Nanoelectronics: wire, diode, transistor, switch memory, etc.	Small sizes, semiconducting/metallic
	NEMS: probe, tweezers, scissors, sensor, actuator, bearing, gear, etc.	Well-defined geometrics, exceptional mechanical and electronic properties

NEMS based on individual single- or multi-walled carbon nanotubes (SWNTs [18.85, 86] or MWNTs [18.57]) and nanocoils are of increasing interest, indicating that capabilities for incorporating these individual building blocks at specific locations on a device must be developed. Random spreading [18.87], direct growth [18.88], self-assembly [18.89], dielectrophoretic assembly [18.90] and nanomanipulation [18.91] have been demonstrated for positioning as-grown nanotubes on electrodes for the construction of these devices. However, for nanotube-based structures, nanorobotic assembly is still the only technique capable of in situ structuring, characterization and assembly. Because the as-fabricated nanocoils are not free-standing from their substrate, nanorobotic assembly is virtually the only way to incorporate them into devices at present.

18.4.2 Carbon Nanotubes

Nanotube manipulation in two dimensions on a surface was first performed with an AFM by contact pushing on a substrate. Figure 18.7 shows the typical methods for 2-D pushing. Although similar to that shown in Fig. 18.4b, the same manipulation caused various results because nanotubes cannot be regarded as 0-D points. The first demonstration was given by *Lieber* and coworkers for measuring the mechanical properties of a nanotube [18.66]. They used the method shown in Fig. 18.7b, i. e., bending a nanotube by pushing on one end of it and fixing the other end. The same strategy was used for the investigation of the behaviors of nanotubes under large strain [18.92]. *Dekker* and coworkers applied the strategies shown in Fig. 18.7c,d to get a kinked junction and crossed nanotubes [18.93, 94]. *Avouris* and coworkers combined this technique with an inverse process, namely straightening by pushing along a bent tube, and realized the translation of the tube to another location [18.95] and between two electrodes to measure the conductivity [18.96], and to form a field-effect transistor (FET) [18.97]. This technique was also used to place a tube on another tube to form a single electron transistor (SET) with cross-junction of nanotubes [18.98]. Pushing-induced breaking (Fig. 18.7d) has also been demonstrated for an adsorbed nanotube [18.95] and a freely suspended SWNT rope [18.72]. The simple assembly of two bent tubes and a straight one formed the Greek letter θ.

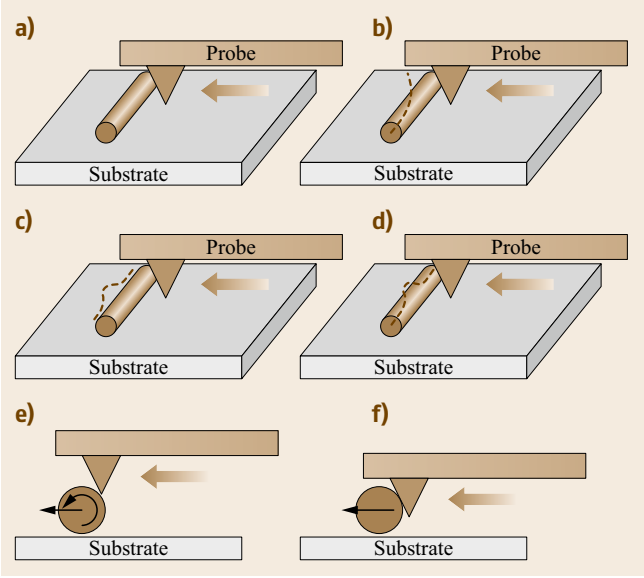

Fig. 18.7a–f 2-D manipulation of CNTs. Starting from the original state shown in **(a)**, pushing the tube at a different site with a different force may cause the tube to deform as in **(b)** and **(c)**, to break as in **(d)**, or to move as in **(e)** and **(f)**. **(a)** Original state, **(b)** bending, **(c)** kinking, **(d)** breaking, **(e)** rolling, **(f)** sliding

To investigate the dynamics of rolling at the atomic level, rolling and sliding of a nanotube (as shown in Fig. 18.7e,f) are performed on graphite surfaces using an AFM [18.99, 100].

Manipulation of CNTs in 3-D space is important for assembling CNTs into structures and devices. The basic techniques for the nanorobotic manipulation of carbon nanotubes are shown in Fig. 18.8 [18.101]. These serve as the basis for handling, structuring, characterizing and assembling NEMS.

The basic procedure is to pick up a single tube from nanotube soot, Fig. 18.8a. This has been shown first by using dielectrophoresis [18.34] through nanorobotic manipulation (Fig. 18.8b). By applying a bias between a sharp tip and a plane substrate, a nonuniform electric field can be generated between the tip and the substrate with the strongest field near the tip. This field can cause a tube to orient along the field or further *jump* to the tip by electrophoresis or dielectrophoresis (determined by the conductivity of the objective tubes). Removing the bias, the tube can be placed at other locations at will. This method can be used for free-standing tubes on nanotube soot or on a rough surface on which surface van der Waals forces are generally weak. A tube strongly rooted in CNT soot or lying on a flat surface cannot be picked up in this way. The interaction be-

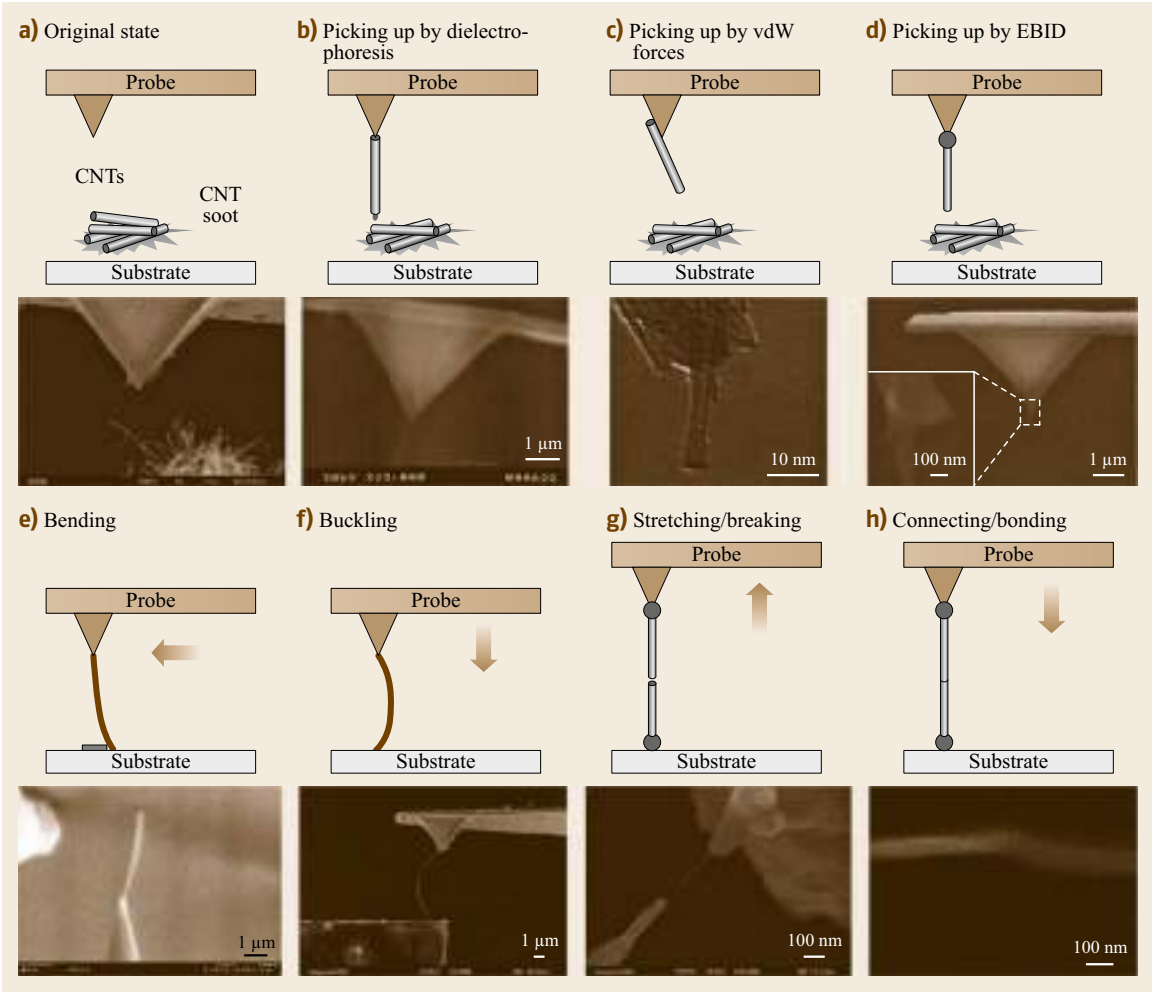

Fig. 18.8a–h Nanorobotic manipulation of CNTs. The basic technique is to pick up an individual tube from CNT soot **(a)** or from an oriented array; **(b)** shows a free-standing nanotube picked up by dielectrophoresis generated by a nonuniform electric field between the probe and substrate, **(c)** (after [18.102]) and **(d)** show the same manipulation by contacting a tube with the probe surface or fixing (e.g., with EBID) a tube to the tip (*inset* shows the EBID deposit). Vertical manipulation of nanotubes includes bending **(e)**, buckling **(f)**, stretching/breaking **(g)**, and connecting/bonding **(h)**. All examples with the exception of **(c)** are from the authors' work

tween a tube and the atomically flat surface of the AFM cantilever tip has been shown to be strong enough to pick up a tube with the tip [18.102] (Fig. 18.8c). By using EBID, it is possible to pick up and fix a nanotube onto a probe [18.103] (Fig. 18.8d). For handling a tube, a weak connection between the tube and the probe is desired.

Bending and buckling a CNT as shown in Fig. 18.8e,f are important for in situ property characterization of a nanotube [18.104, 105], which is a simple way to get the Young's modulus of a nanotube without damaging the tube (if performed within its elastic range) and, hence, can be used for the selection of a tube with desired properties. The process is shown in Fig. 18.9a. The left figure shows an individual MWNT, whereas the right four show a bundle of MWNTs being buckled. Figure 18.9b depicts the property curve of the elastic and plastic deformations of the MWNT (∅133 nm × 6.055 µm), where d and F are the axial deformation and buckling force, as shown in Fig. 18.9a (top). By using the model and analysis method presented in [18.55], the flexural rigidity of the MWNT bundle shown in Fig. 18.9a (bottom) is found to be $EI = 2.086 \times 10^{-19}$ [N m^2]. This result suggests that the diameter of the nanotube is 46.4 nm if the theoretical value of the Young's modulus of the nanotube $E = 1.26$ TPa is used. The SEM image shows that the bundle of nanotubes includes at least three single ones with diameters of 31, 34, and 41 nm. Hence, it can be determined that there must be damaged parts in the bundle because the stiffness is too low, and it is necessary to select another one without defects. By buckling an MWNT over its elastic limit, a kinked structure can be obtained. After three loading/releasing rounds, as shown in Fig. 18.9b, a kinked structure is obtained, as shown in Fig. 18.10a [18.106]. To obtain any desired angle for a kinked junction it is possible to fix the shape of a buckled nanotube within its elastic limit by using EBID (Fig. 18.10b) [18.107]. For a CNT, the maximum angular displacement will appear at the fixed left end under pure bending or at the middle point under pure buckling. A combination of these two kinds of loads will achieve a controllable position of the kink point and a desired kink angle θ. If the deformation is within the elastic limit of the nanotube, it will recover as the load is released. To avoid this, EBID can be applied at the kink point to fix the shape.

Stretching a nanotube between two probes or a probe and a substrate has generated several interesting results (Fig. 18.8g). The first demonstration of 3-D nanomanipulation of nanotubes took this as an example to show the breaking mechanism of an MWNT [18.33], and to measure the tensile strength of CNTs [18.71]. By breaking an MWNT in a controlled manner, interesting nanodevices have been fabricated. This technique – destructive fabrication – has been presented to get sharpened and layered structures of nanotubes and to improve control of the length of nanotubes [18.108]. Typically, a layered and a sharpened structure can be obtained from this process, similar to that achieved from electric pulses [18.109]. Bearing motion has also been observed in an incompletely broken MWNT (Fig. 18.11). As shown in Fig. 18.11a, an MWNT is supported between a substrate (left end) and an AFM cantilever (right end). Figure 18.11b shows a zoomed image of the centrally blocked part of Fig. 18.11a, and the inset shows its structure schematically. It can be found that the nanotube has a thinner neck (part B in Fig. 18.11b) that was formed by destructive fabrication, i. e., by moving the cantilever to the right. To move it further in the same direction, a motion like a linear bearing is observed, as shown in Fig. 18.11c and schematically by the inset. By comparing Fig. 18.11b,c, we find that part B remained

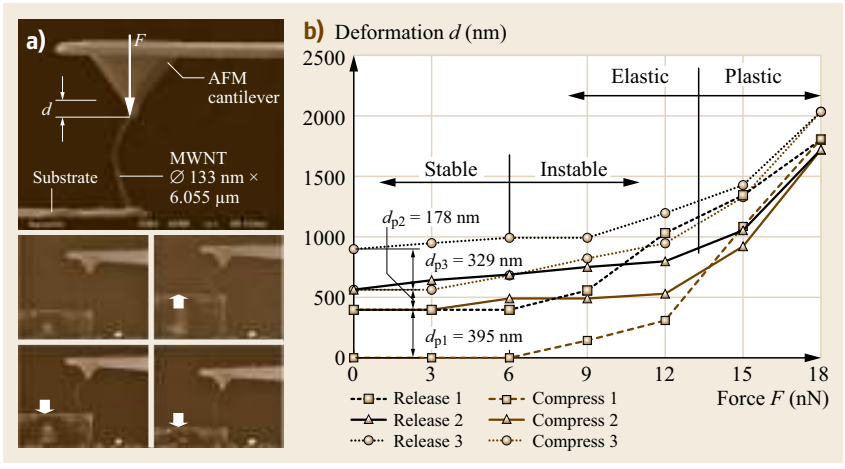

Fig. 18.9a,b In-situ mechanical property characterization of a nanotube by buckling it (scale bars: 1 µm). **(a)** Process of buckling, **(b)** elastic and plastic properties of an MWNT

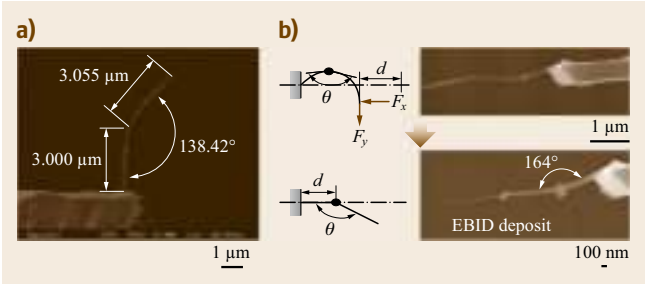

Fig. 18.10a,b Shape modification. **(a)** Kinked structure of a MWNT through plastic deformation, **(b)** shape modifications of a MWNT by elastic bending and buckling deformation and shape fixing through EBID

unchanged in its length and diameter, while its two ends brought out two new parts I and II from parts A and B, respectively. Part II has uniform diameter (∅ 22 nm), while part I is a tapered structure with a smallest diameter of ∅ 25 nm. The interlayer friction has been predicted to be very small [18.110], but direct measurement of the friction remains a challenging problem.

The reverse process, namely the connection of broken tubes (Fig. 18.8h), has been demonstrated recently, and the mechanism is revealed as rebonding of unclosed dangling bonds at the ends of broken tubes [18.111]. Based on this interesting phenomenon, mechanochemical nanorobotic assembly has been performed [18.112].

Assembly of nanotubes is a fundamental technology for enabling nanodevices. The most important tasks include the connection of nanotubes and placing of nanotubes onto electrodes. Pure nanotube circuits [18.113–115] created by interconnecting nanotubes of different diameters and chirality could lead to further size reductions in devices. Nanotube intermolecular and intramolecular junctions are basic elements for such systems. An intramolecular kink junction behaving like a rectifying diode has been reported [18.116]. Room-temperature (RT) SETs [18.117] have been shown with a short (≈ 20 nm) nanotube section that is created by inducing local barriers into the tube with an AFM, and Coulomb charging has been observed. With a cross-junction of two SWNTs (semiconducting/metallic), three- and four-terminal electronic devices have been

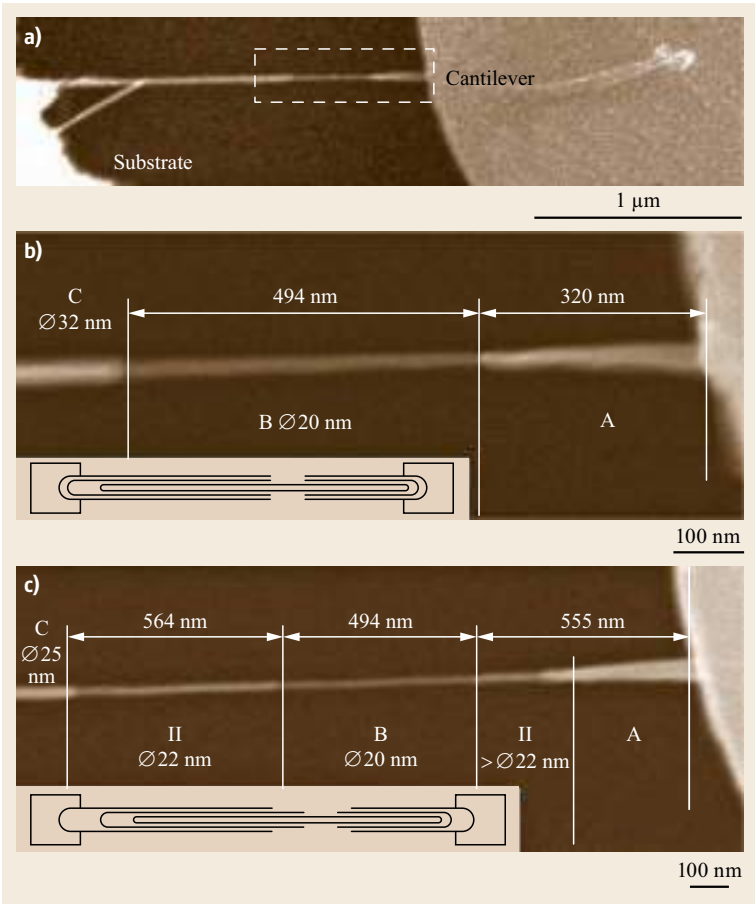

Fig. 18.11a–c Destructive fabrication of a MWNT and its bearing-like motion

made [18.118]. A suspended cross-junction can function as electromechanical nonvolatile memory [18.119].

Although some kinds of junctions have been synthesized with chemical methods, there is no evidence yet showing that a self-assembly-based approach can provide more complex structures. SPMs were also used to fabricate junctions, but they are limited to a 2-D plane. We have presented 3-D nanorobotic manipulation-based nanoassembly, which is a promising strategy, both for the fabrication of nanotube junctions and for the construction of more complex nanodevices with such junctions as well.

Nanotube junctions can be classified into different types by: the kind of components – SWNTs or MWNTs; geometric configuration – V (kink), I, X- (cross), T-, Y- (branch), and 3-D junctions; conductivity – metallic or semiconducting; and connection methods – intermolecular (connected with van der Waals force, EBID, etc.) or intramolecular (connected with chemical bonds) junctions. Here we show the fabrication of several kinds of MWNT junctions by emphasizing the connection methods. These methods will also be effective for SWNT junctions. Figure 18.12 shows CNT junctions constructed by connecting with van der Waals forces (a), joining by electron-beam-induced deposition (b), and bonding through mechanochemistry (c).

MWNT junctions connected with van der Waals forces are the basic forms of junctions. To fabricate such junctions, the main process is to position two or more nanotubes together with nanometer resolution; they will then be connected naturally by intermolecular van der Waals forces. Such junctions are mainly for structures where contact rather than strength is emphasized. Placing them onto a surface can make them more stable. In some cases, when lateral movement along the surface of nanotubes is desired while keeping them in contact, van der Waals-type connections are the only ones that are suitable.

Figure 18.12a shows a T-junction connected with van der Waals forces, which is fabricated by positioning the tip of an MWNT onto another MWNT until they form a bond. The contact is checked by measuring the shear connection force.

EBID provides a soldering method to obtain stronger nanotube junctions than those connected through van der Waals forces. Hence, if the strength of nanostructures is emphasized, EBID can be applied. Figure 18.12b shows an MWNT junction connected through EBID, in which the upper MWNT is a single one with a diameter of 20 nm and the lower one is a bundle of MWNTs with an extruded single CNT with ∅30 nm. The development of conventional EBID has been limited by the expensive electron filament used and low productivity. We have presented a parallel EBID system by using CNTs as emitters because of their excellent field-emission properties [18.120, 121]. The feasibility of parallel EBID is presented. It is a promising strategy for large-scale fabrications of nanotube junctions. Similar to its macro counterpart, welding, EBID works by adding material to obtain stronger connections, but in some cases, added material might influence normal functions for nanosystems. So, EBID is mainly applied to nanostructures rather than nanomechanisms.

To construct stronger junctions without adding additional material, mechanochemical nanorobotic assembly is an important strategy. Mechanochemical nanorobotic assembly is based on solid-phase chemical reactions, or mechanosynthesis, which is defined as chemical synthesis controlled by mechanical systems operating with atomic-scale precision, enabling direct positional selection of reaction sites [18.4]. By picking up atoms with dangling bonds rather than natural atoms only, it is easier to form primary bonds, which provides a simple but strong connection. Destructive fabrication provides a way to form dangling bonds at the ends of broken tubes. Some of the dangling bonds may close with neighboring atoms, but generally a few bonds will remain dangling. A nanotube with dangling bonds at its end will bind more easily to another

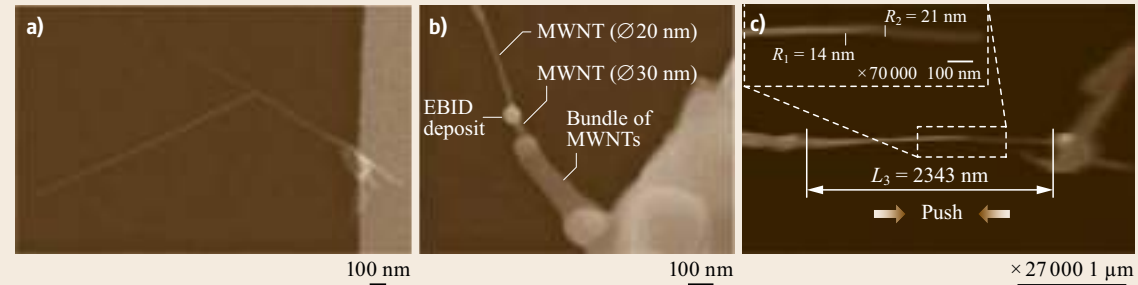

Fig. 18.12a–c MWNT junctions. **(a)** MWNTs connected with van der Waals force. **(b)** MWNTs joined with EBID. **(c)** MWNTs bonded with a mechanochemical reaction

to form intramolecular junctions. Figure 18.12c shows such a junction. An MWNT (length $L_1 = 1329$ nm, diameter $D_1 = 42$ nm) is placed between a substrate and an AFM cantilever with a CNT tip, and the two ends are fixed. By pulling the two ends of the MWNT, it is broken into two parts. By pushing the two nanotubes head to head close enough, a new one is formed. To test the strength of this nanotube, it was broken again. The fact that the nanotube breaks at a different site suggests that the tensile strength of the connected nanotubes is not weaker than that of the original nanotube itself. We have determined that no type of connection based on van der Waals interactions can provide such a strong connection strength [18.112]. Also, we have shown that, from the measured tensile strength (1.3 TPa), chemical bonds must have been formed when the junction formed, and that these are most likely to be covalent bonds (sp^2-hybrid type, as in a nanotube).

3-D nanorobotic manipulation has opened a new route for structuring and assembly nanotubes into nanodevices. However, at present nanomanipulation is still performed in a serial manner with master–slave control, which is not a large-scale production-oriented technique. Nevertheless, with advances in the exploration of mesoscopic physics, better control of the synthesis of nanotubes, more accurate actuators, and effective tools for manipulation, high-speed and automatic nanoassembly will be possible. Another approach might be parallel assembly by positioning building blocks with an array of probes [18.122] and joining them together simultaneously, e.g., with the parallel EBID [18.103] approach we presented. Further steps might progress towards exponential assembly [18.123], and in the far future to self-replicating assembly [18.4].

18.4.3 Nanocoils

The construction of nanocoil-based NEMS involves the assembly of as-grown or as-fabricated nanocoils, which is a significant challenge from a fabrication standpoint. Focusing on the unique aspects of manipulating nanocoils due to their helical geometry, high elasticity, single end fixation, and strong adhesion to the substrate from wet etching, a series of new processes is presented using a manipulator (MM3A, Kleindiek) installed in an SEM (Zeiss DSM962). As-fabricated SiGe/Si bilayer nanocoils are shown in Fig. 18.13. Special tools have been fabricated including a nanohook prepared by controlled *tip-crashing* of a commercially available tungsten sharp probe (Picoprobe T-4-10-1 mm and T-4-10) onto a substrate, and a *sticky* probe prepared by tip dipping into a double-sided SEM silver conductive tape (Ted Pella, Inc.). As shown in Fig. 18.14, experiments demonstrate that nanocoils can be released from a chip by

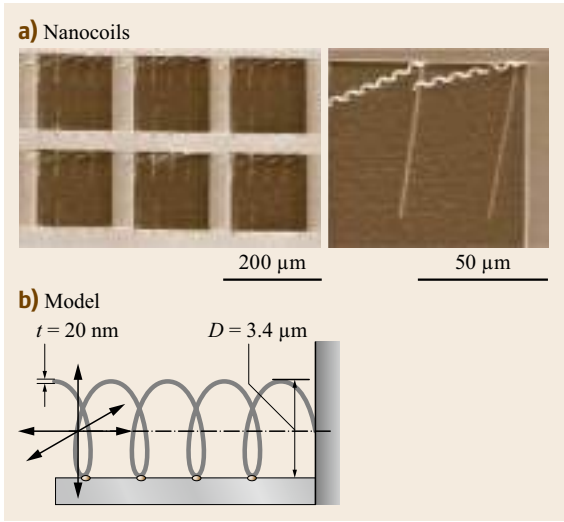

Fig. 18.13a,b As-fabricated nanocoils with a thickness of $t = 20$ nm (without Cr layer) or 41 nm (with Cr layer). Diameter: $D = 3.4\,\mu$m

lateral pushing, picked up with a nanohook or a *sticky* probe, and placed between the probe/hook and another probe or an AFM cantilever (Nanoprobe, NP-S). Axial pulling/pushing, radial compressing/releasing, and bending/buckling have also been demonstrated. These processes have shown the effectiveness of manipulation for the characterization of coil-shaped nanostructures and their assembly for NEMS, which have been otherwise unavailable.

Configurations of nanodevices based on individual nanocoils are shown in Fig. 18.15. Cantilevered nanocoils as shown in Fig. 18.15a can serve as nanosprings. Nanoelectromagnets, chemical sensors and nanoinductors involve nanocoils bridged between two electrodes, as shown in Fig. 18.15b. Electromechanical sensors can use a similar configuration but with one end connected to a moveable electrode, as shown in Fig. 18.15c. Mechanical stiffness and electric conductivity are fundamental properties for these devices that must be further investigated.

As shown in Fig. 18.14h, axial pulling is used to measure the stiffness of a nanocoil. A series of SEM images are analyzed to extract the AFM tip displacement and the nanospring deformation, i. e., the relative displacement of the probe from the AFM tip. From this displacement data and the known stiffness of the AFM cantilever, the tensile force acting on the nanospring versus the nanospring deformation was plotted. The deformation of the nanospring was measured relative to the first measurement point. This was necessary because proper attachment of the nanospring to the AFM cantilever must be verified. Afterwards, it was not pos-

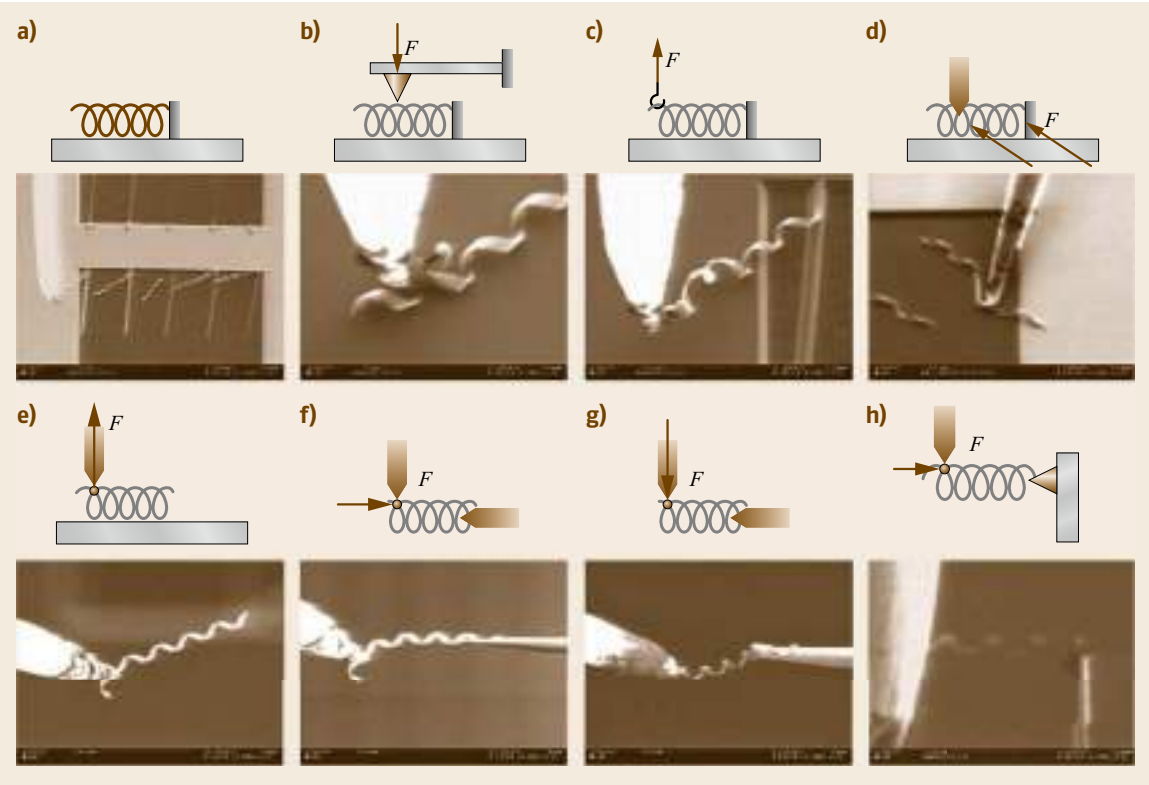

Fig. 18.14a–h Nanorobotic manipulation of nanocoils: **(a)** original state, **(b)** compressing/releasing, **(c)** hooking, **(d)** lateral pushing/breaking, **(e)** picking, **(f)** placing/inserting, **(g)** bending, and **(h)** pushing and pulling

sible to return to the point of zero deformation. Instead, the experimental data, as presented in Fig. 18.15d, has been shifted such that, with the calculated linear elastic spring stiffness, the line begins at zero force and zero deformation. From Fig. 18.15d, the stiffness of the spring was estimated to be 0.0233 N/m. The linear elastic region of the nanospring extends to a deformation of 4.5 μm. An exponential approximation was fitted to the nonlinear region. When the applied force reached 0.176 μN, the attachment between the nanospring and the AFM cantilever broke. Finite element simulation (ANSYS 9.0) was used to validate the experimental data [18.84]. Since the exact region of attachment cannot be identified according to the SEM images, simulations were conducted for 4, 4.5, and 5 turns to get an estimate of the possible range, given that the apparent number of turns of the nanospring is between 4 and 5. The nanosprings in the simulations were fixed on one end and had an axial load of 0.106 μN applied to the other end. The simulation results for the spring with 4 turns yield a stiffness of 0.0302 N/m; for the nanospring with 5 turns it is 0.0191 N/m. The measured stiffness falls into this range at 22.0% above the minimum value and 22.8% below the maximum value, and very close to the stiffness of a 4.5 turn nanospring, which has a stiffness of 0.0230 N/m according to the simulation.

Figure 18.15e shows the results from electrical characterization experiments on a nanospring with 11 turns using the configuration as shown in Fig. 18.14g. The *I–V* curve is nonlinear, which may be caused by the resistance change of the semiconductive bilayer due to ohmic heating. Another possible reason is the decrease in contact resistance caused by thermal stress. The maximum current was found to be 0.159 mA under an 8.8 V bias. Higher voltage causes the nanospring to *blow off*. From the fast scanning screen of the SEM, the extension of the nanospring on the probes was observed around the peak current so that the current does not drop abruptly. At 9.4 V, the extended nanospring is broken down, causing an abrupt drop in the *I–V* curve.

From fabrication and characterization results, the helical nanostructures appear to be suitable to function as inductors. They would allow further miniaturization compared to state-of-the-art microinductors. For this purpose, higher doping of the bilayer and an additional metal layer would result in the required conductance. Conductance, inductance, and quality factor can be

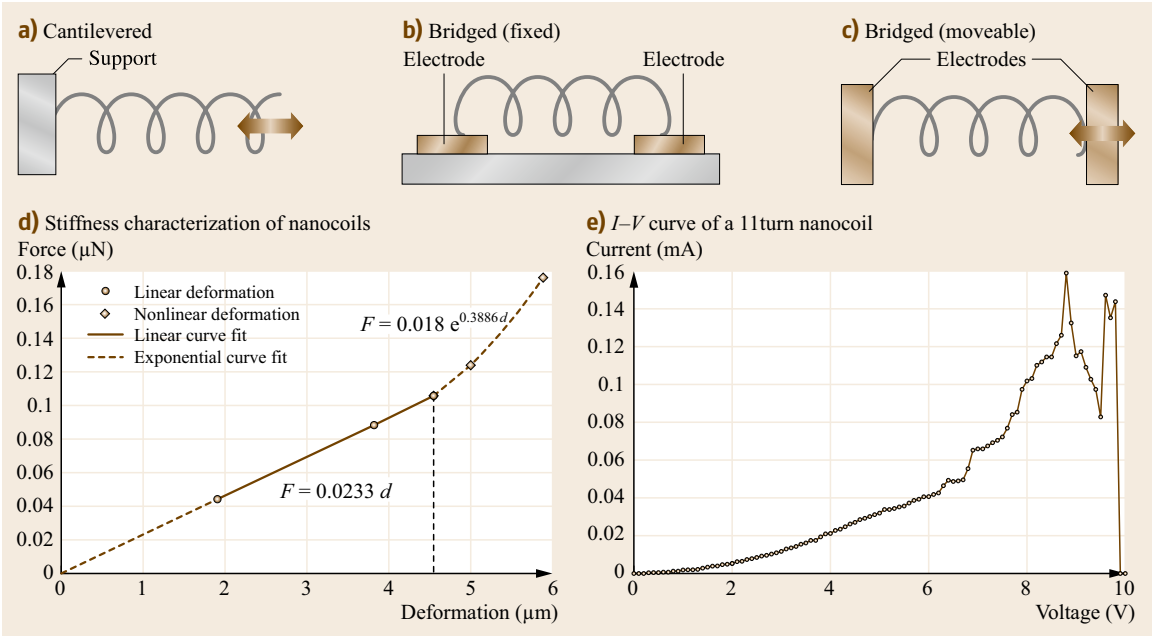

Fig. 18.15a–e Nanocoil-based devices. Cantilevered nanocoils **(a)** can serve as nanosprings. Nanoelectromagnets, chemical sensors, and nanoinductors involve nanocoils bridged between two electrodes **(b)**. Electromechanical sensors can use a similar configuration but with one end connected to a moveable electrode **(c)**. Mechanical stiffness **(d)** and electric conductivity **(e)** are basic properties of interest for these devices

further improved if, after curling up, additional metal is electroplated onto the helical structures. Moreover, a semiconductive helical structure, when functionalized with binding molecules, can be used for chemical sensing using the same principle as demonstrated with other types of nanostructures [18.124]. With bilayers in the range of a few monolayers, the resulting structures would exhibit a very high surface-to-volume ratio with the whole surface exposed to an incoming analyst.

18.5 Applications

Material science, biotechnology, electronics, and mechanical sensing and actuation will benefit from advances in nanorobotics. Research topics in bionanorobotics include the autonomous manipulation of single cells or molecules, the characterization of biomembrane mechanical properties using nanorobotic systems with integrated vision and force-sensing modules, and more. The objective is to obtain a fundamental understanding of single-cell biological systems and provide characterized mechanical models of biomembranes for deformable cell tracking during biomanipulation and cell injury studies. Robotic manipulation at nanometer scales is a promising technology for structuring, characterizing and assembling nanobuilding blocks into NEMS. Combined with recently developed nanofabrication processes, a hybrid approach is realized to build NEMS and other nanorobotic devices from individual carbon nanotubes and SiGe/Si nanocoils.

18.5.1 Robotic Biomanipulation

Biomanipulation – Autonomous Robotic Pronuclei DNA Injection

To improve the low success rate of manual operation, and to eliminate contamination, an autonomous robotic system (shown in Fig. 18.16) has been developed to deposit DNA into one of the two nuclei of a mouse embryo without inducing cell lysis [18.125, 126]. The laboratory's experimental results show that the success rate for the autonomous embryo pronuclei DNA injection is dramatically improved over manual conventional injection methods. The autonomous robotic system features a hybrid controller that combines visual servoing

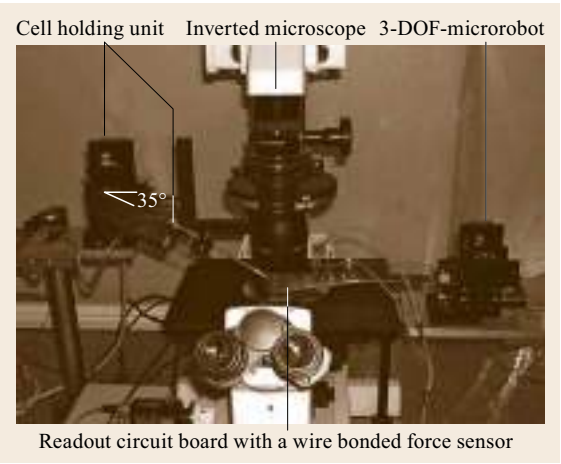

Fig. 18.16 Robotic biomanipulation system with vision and force feedback

and precision position control, pattern recognition for detecting nuclei, and a precise autofocusing scheme. Figure 18.17 illustrates the injection process.

To realize large-scale injection operations, a MEMS cell holder was fabricated using anodic wafer-bonding techniques. Arrays of holes are aligned on the cell holder, which are used to contain and fix individual cells for injection. When well-calibrated, the system with the cell holder makes it possible to inject large numbers of cells using position control. The cell-injection operation can be conducted in a move–inject–move manner.

Successful injection is determined greatly by injection speed and trajectory, and the forces applied to cells (Figure 18.17). To further improve the robotic system's performance, a multi-axial MEMS-based capacitive cellular force sensor is being designed and fabricated to provide real-time force feedback to the robotic system. The MEMS cellular force sensor also aids our research in biomembrane mechanical property characterization.

MEMS-Based Multi-Axis Capacitive Cellular Force Sensor

The MEMS-based two-axis cellular force sensor [18.127] shown in Fig. 18.18 is capable of resolving normal forces applied to a cell as well as tangential forces generated by improperly aligned cell probes. A high-yield microfabrication process was developed to form the 3-D high-aspect-ratio structure using deep reactive ion etching (DRIE) on silicon-on-insulator (SOI) wafers. The constrained outer frame and the inner movable structure are connected by four curved springs. A load applied to the probe causes the inner structure to move, changing the gap between each pair of interdigitated comb capacitors. Consequently, the total capacitance change resolves the applied force. The interdigitated capacitors are orthogonally configured to

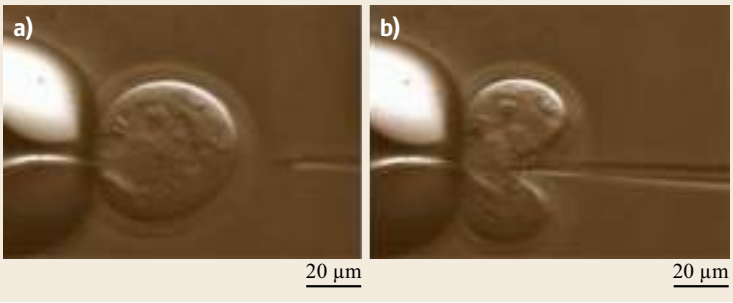

Fig. 18.17a,b Cell injection process. **(a,b)** Cell injection of a mouse oocyte

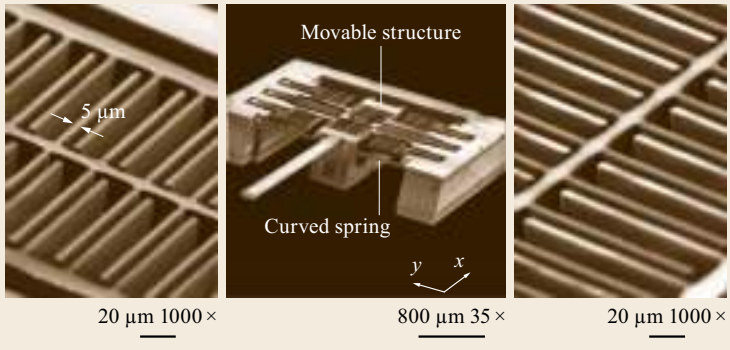

Fig. 18.18 A cellular force sensor with orthogonal comb drives detailed

make the force sensor capable of resolving forces in both the x- and y-directions. The cellular force sensors used in the experiments are capable of resolving forces up to 25 μN with a resolution of 0.01 μN.

Tip geometry affects the quantitative force measurement results. A standard injection pipette (Cook K-MPIP-1000-5) tip section with a tip diameter of 5 μm is attached to the probe of the cellular force sensors.

The robotic system and high-sensitivity cellular force sensor are also applied to biomembrane mechanical property studies [18.128]. The goal is to obtain a general parameterized model describing cell membrane deformation behavior when an external load is applied. This parameterized model serves two chief purposes. First, in robotic biomanipulation, it allows online parameter recognition so that cell membrane deformation behavior can be predicted. Second, for a thermodynamic model of membrane damage in cell injury and recovery studies, it is important to appreciate the mechanical behavior of the membranes. This allows the interpretation of such reported phenomena as mechanical resistance to cellular volume reduction during dehydration, and its relationship to injury. The establishment of such a biomembrane model will greatly facilitate cell injury studies.

Experiments demonstrate that robotics and MEMS technology can play important roles in biological studies such as automating biomanipulation tasks. Aided by robotics, the integration of vision and force-sensing modules, and MEMS design and fabrication techniques, investigations are being conducted in biomembrane mechanical property modeling, deformable cell tracking, and single-cell and biomolecule manipulation.

18.5.2 Nanorobotic Devices

Nanorobotic devices involve tools, sensors, and actuators at the nanometer scale. Shrinking device size makes it possible to manipulate nanosized objects with nanosized tools, measure mass in femtogram ranges, sense force at piconewton scales, and induce GHz motion, among other amazing advancements.

Top-down and bottom-up strategies for manufacturing such nanodevices have been independently investigated by a variety of researchers. Top-down strategies are based on nanofabrication and include technologies such as nanolithography, nanoimprinting, and chemical etching. Presently, these are 2-D fabrication processes with relatively low resolution. Bottom-up strategies are assembly-based techniques. At present, these strategies include such techniques as self-assembly, dip-pen lithography, and directed self-assembly. These techniques can generate regular nanopatterns at large scales. With the ability to position and orient nanometer-scale objects, nanorobotic manipulation is an enabling technology for structuring, characterizing and assembling many types of nanosystems [18.101]. By combining bottom-up and top-down processes, a hybrid nanorobotic approach (as shown in Fig. 18.19) based on nanorobotic manipulation provides a third way to fabricate NEMS by structuring as-grown nanomaterials or nanostructures. This new nanomanufacturing technique can be used to create complex 3-D nanodevices with such building blocks. Nanomaterial science, bionanotechnology, and nanoelectronics will also benefit from advances in nanorobotic assembly.

The configurations of nanotools, sensors, and actuators based on individual nanotubes that have been experimentally demonstrated are summarized as shown in Fig. 18.20.

For detecting deep and narrow features on a surface, cantilevered nanotubes (Fig. 18.20a, [18.103]) have been demonstrated as probe tips for an AFM [18.129], an STM and other types of SPM. Nanotubes provide ultrasmall diameters, ultralarge aspect ratios, and excellent mechanical properties. Manual assembly, direct growth [18.130] and nanoassembly [18.131] have proven effective for their construction. Cantilevered nanotubes have also been demonstrated as probes for the measurement of ultrasmall physical quantities, such as femtogram masses [18.67], mass flow sensors [18.132], and piconewton-order force sensors [18.133] on the basis of their static deflections or change of resonant frequencies detected within an electron microscope. Deflections cannot be measured from micrographs in real time, which limits the application of this kind of sensor. Interelectrode distance changes cause emission current variation of a nanotube emitter and may serve as a candidate to replace microscope images.

Bridged individual nanotubes (Fig. 18.20b, [18.134]) have been the basis for electric characterization. A nanotube-based gas sensor adopted this configuration [18.135].

Opened nanotubes (Fig. 18.20c, [18.136]) can serve as an atomic or molecular container. A thermometer based on this structure has been shown by monitoring the height of the gallium inside the nanotube using TEM [18.137].

Bulk nanotubes can be used to fabricate actuators based on charge-injection-induced bond-length change [18.138], and, theoretically, individual nanotubes also work on the same principle. Electrostatic deflection of a nanotube has been used to construct a relay [18.139]. A new family of nanotube actuators can be constructed by taking advantage of the ultralow inter-layer friction of a multiwalled nanotube. Linear bearings based on telescoping nanotubes have been demonstrated [18.110]. Recently, a micro actu-

ator with a nanotube as a rotation bearing has been demonstrated [18.140]. A preliminary experiment on a promising nanotube linear motor with field emission current serving as position feedback has been shown with nanorobotic manipulation (Fig. 18.20d, [18.136]).

Cantilevered dual nanotubes have been demonstrated as nanotweezers [18.141] and nanoscissors (Fig. 18.20e, [18.91]) by manual and nanorobotic assembly, respectively.

Based on electric resistance change under different temperatures, nanotube thermal probes (Fig. 18.20f) have been demonstrated for measuring the temperature at precise locations. These thermal probes are more advantageous than nanotube-based thermometers because the thermometers require TEM imaging. The probes also have better reproducibility than devices based on dielectrophoretically assembled bulk nanotubes [18.142]. Gas sensors and hot-wire-based mass-flow sensors can also be constructed in this configuration rather than a bridged one.

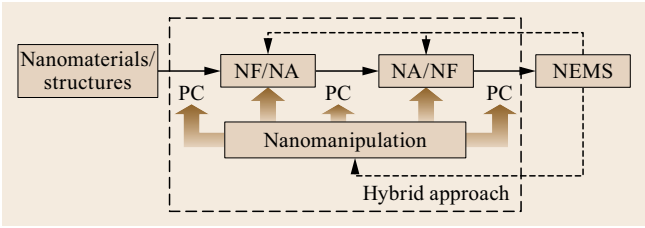

Fig. 18.19 Hybrid approach to NEMS (PC: property characterization, NF: nanofabrication, NA: nanoassembly)

The integration of these devices can be realized using the configurations shown in Figs. 18.20g [18.143] and 18.20h [18.90]. Arrays of individual nanotubes can also be used to fabricate nanosensors, such as position encoders [18.144].

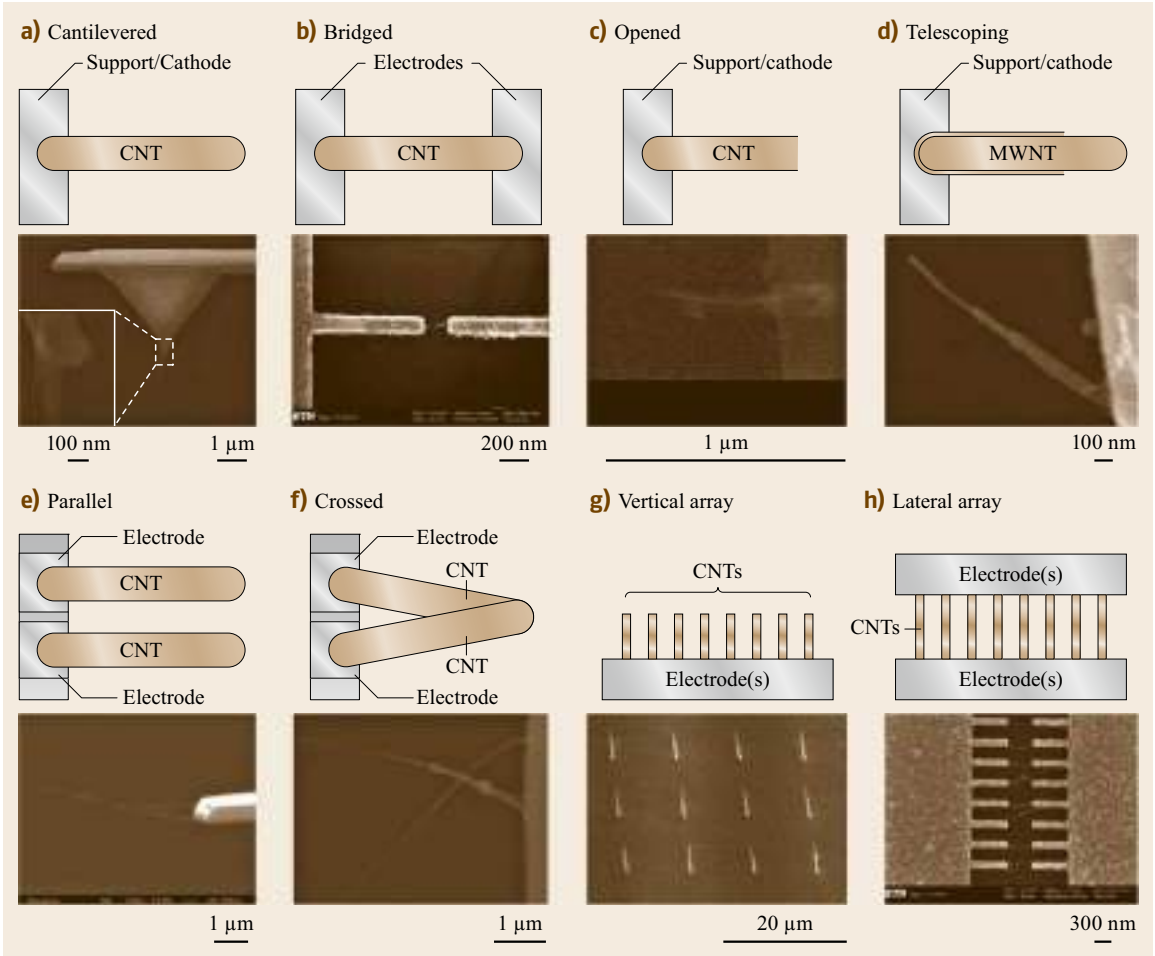

Fig. 18.20a–h Configurations of individual nanotube-based NEMS. *Scale bars*: **(a)** 1 µm (*inset*: 100 nm), **(b)** 200 nm, **(c)** 1 µm, **(d)** 100 nm, **(e)** and **(f)** 1 µm, **(g)** 20 µm, and **(h)** 300 nm. All examples are from the authors' work

Nanotube-based NEMS remains a rich research field with a large number of open problems. New materials and effects at the nanoscale will enable a new family of sensors and actuators for the detection and actuation of ultrasmall quantities or objects with ultrahigh precision and frequencies. Through random spreading, direct growth, and nanorobotic manipulation, prototypes have been demonstrated. However, for integration into NEMS, self-assembly processes will become increasingly important. Among them, we believe that dielectrophoretic nanoassembly will play a significant role for large-scale production of 2-D regular structures.

19. Applications of MEMS to Cell Biology

Georg E. Fantner, Pascal D. Odermatt, Haig Alexander Eskandarian

Relatively simple microscale devices such as cantilevers already have found distinct applications in the study of cells and subcellular structures. The ability to measure small forces, small features, and small masses has led to unique and elegant measurement solutions. In this chapter, we give a brief background of some relevant fundamental biology and provide examples of research in cell biology, ranging from mechanobiology, physiology, microbiology to cancer biology, where MEMS- and NEMS-based methods have had a significant and, most likely, lasting impact.

In size, NEMS and MEMS are on a similar scale as many of the important building blocks of life (Fig. 19.1). This makes them amenable tools for studying these biological entities in a variety of new ways. A nanowire can be used to measure the mass of individual molecules on the order of tens to hundreds of angstroms in size. An atomic force microscope (AFM)-cantilever tip has a radius of around 1–10 nm, similar to molecules like DNA (Deoxyribonucleic acid). The height of the tip is around 10 μm, which makes it a suitable tool to measure bacterial and yeast cells, which are on the order of 0.5–3 μm in height. An AFM-cantilever body has dimensions of around 70 μm in length and 10 μm in width, on which bacterial micro-colonies and single cells, as well as individual eukaryotic cells, may be placed in order to measure the cell mass. Yet thicker cantilevers that have been made hollow permit cells to pass through the cantilever body, allowing for the measurement of buoyant mass. Taken together, the diversity of micro- and nano-electro-mechanical systems being developed is directly contributing to the broadening of human understanding of the animate sphere and its morphogenesis.

In the next section, we describe briefly some fundamental aspects of biology that should aid the reader to understand the use of MEMS and NEMS in the cell-biology applications discussed in the later sections.

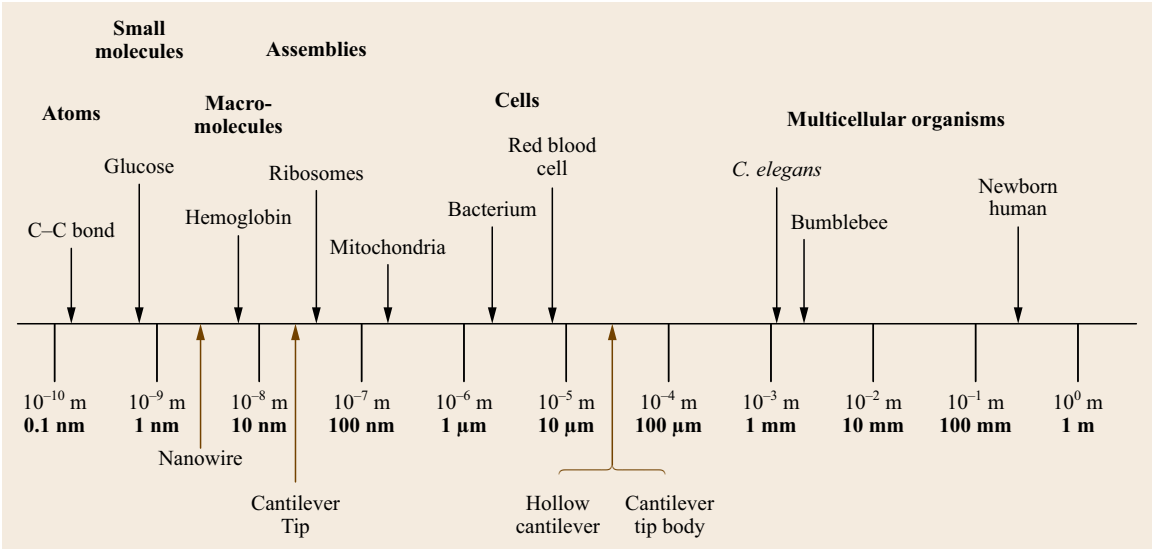

Fig. 19.1 Components of life range in size from sub-nanometers to meters. Above the marginal line are components of life and below are the sizes the specific MEMS devices. These MEMS devices are mainly utilized to measure living components smaller in size than the dimensions of the device, itself

19.1 Biological Background

The most basic unit of animate life is the cell. While cells vary in their form, composition, and morphogenesis, certain fundamental components are conserved [19.1]. Lipid-bilayer membranes enclose all cells. The internal compartment is a hydrophilic space known as the cytosol. It is filled with components necessary for sustaining and propagating life. These components are wide ranging and can be categorized into raw materials, as well as synthesized biochemical compounds. The reactions that produce these chemicals are the result of catalysis by sequences of enzymatically active amino acids, known as peptides or proteins, or ribonucleic-acid sequences, RNAs. These enzymatic components are constructed and encoded by a core of biochemical components common to all known life forms. The concept that describes these core components from which life is comprised is called the *Central Dogma*. Protein synthesis (known as translation) is catalyzed by a molecule known as the ribosome. Ribosomes are structurally composed of proteins and function enzymatically through the activity of RNA molecules. The amino-acid sequence of proteins is encoded by other RNA sequences. However, unprotected RNA molecules in the cytosol have a low half-life, which means that the sequence specificity of unique proteins and RNA must be encoded by another chemical component retained within the cell. This molecule happens to be deoxyribonucleic acid, DNA. Specific proteins known as polymerases read the DNA code and catalyze the synthesis of RNA molecules. The process of RNA synthesis from DNA is known as transcription. DNA encodes the traits that are inherited for a specific species from one generation to the next. In order to equally partition the genetic code among cellular progeny, a new copy of DNA is synthesized in a process known as replication. Building upon the central dogma are multiple regulatory systems that control the expression of RNA sequences and the ensuing enzymatic processes. Some basic regulatory attributes are conserved among the various kingdoms of life, although some attributes are also the main conduit to cell differentiation and specialization. The ability for life to exist and thrive in a multitude of diverse environmental conditions underlies the multitude of ways in which these regulatory mechanisms manipulate the basic building blocks of the central dogma.

The physical and chemical constraints of the environment can have a high selective pressure on cell survival. Species of the various kingdoms of life have developed unique attributes to counter these specific physical attributes to which they are constrained. One physical property that constrains cell structure and function is osmotic pressure. In order for cells to carry out various biochemical functions, particles and ions

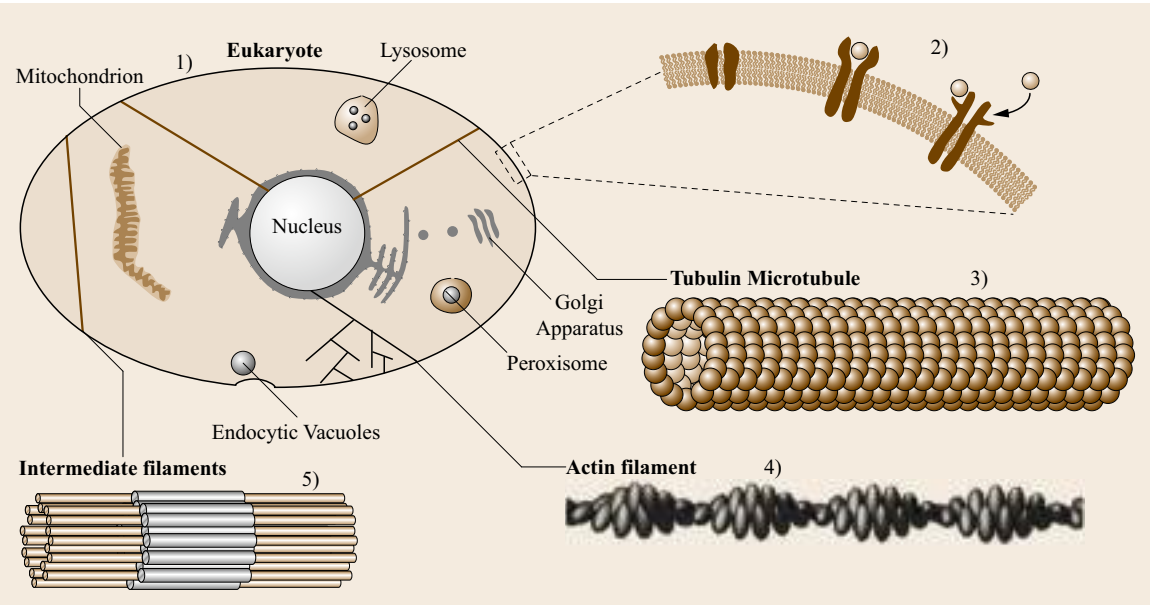

Fig. 19.2 Components and structure of eukaryotic cells, including basic organelles and the parts of the cytoskeleton. Pictured clockwise from the top left are 1) a schematic representation of a eukaryotic cells with some of its most fundamental components; followed by 2) the cell membrane, which is composed of a lipid bilayer and protein pores and signaling receptors (*red*) that are activated upon binding of their specific agonist (*yellow*); 3) a microtubule, composed of tubulin monomers; 4) actin filaments; and finally, 5) intermediate filaments

are concentrated in the cytoplasm. Without the proper structural and biophysical constraints, once an ionic flux has been created, water molecules would rush in to equilibrate the colligative properties of the cell and, in the process, burst cells open. How therefore do cells maintain a high internal osmotic pressure? In order to address this question central to the existence of life, we must describe the core structural and biochemical components of cell.

Two major groups of life forms (called kingdoms) are conceptually of particular interest: prokaryotes and eukaryotes. Prokaryotes are largely unicellular organisms that range in size from several hundred nanometers (nm) to about 10 micrometers (μm) (Fig. 19.1). Bacteria are one of the most prominent representatives of this group. In contrast, eukaryotes are comprised of both unicellular (yeast) and multicellular organisms (animals, plants). Eukaryotic cells are on the order of tens to hundreds of micrometers in size (Fig. 19.1) and possess internal compartments within the cytoplasm, called organelles (Fig. 19.2). A eukaryote's organelles can be classified into two groups. The first are believed to be derived from prokaryotes and form a symbiotic relationship with the eukaryotic host. These organelles are called the mitochondrion among members of the animal kingdom and the chloroplasts in plants. The second group of eukaryotic organelles is derived from the cell membrane. These organelles enclose essential components destined for core-cell biochemical functions and more refined intercellular communication. These organelles include the nuclear membrane, endoplasmic reticulum, Golgi apparatus, lysosomes, peroxisomes, vacuoles (both endocytic and exocytic), and various types of inclusion bodies (Fig. 19.2). In order to maintain these organelles' functioning, the cell must provide basic nutrients, ions, and biochemical gradients. Eukaryotes use passive and active diffusion of particles through pores which are gated by the presence of specific ions and the hydrolysis of energy-storing molecules. Cells maintain these selective pores at the cell surface in order to regulate the level of permeability of the cell membrane. However, as ionic concentration increases inside cells, so does the turgor pressure, which puts stress on the cell membrane, compartmentalizing the internal cellular components. To maintain a cell's morphological integrity, eukaryotes use three types of mechano-proteins to form mechanically rigid filaments of actin or tubulin and intermediate filaments (Fig. 19.2). All three groups of proteins require the hydrolysis of energy-storing molecules to catalyze the formation of filaments. In many cells, actin filaments form a semi-rigid network known as the cell cortex, offering some coherent morphology near the

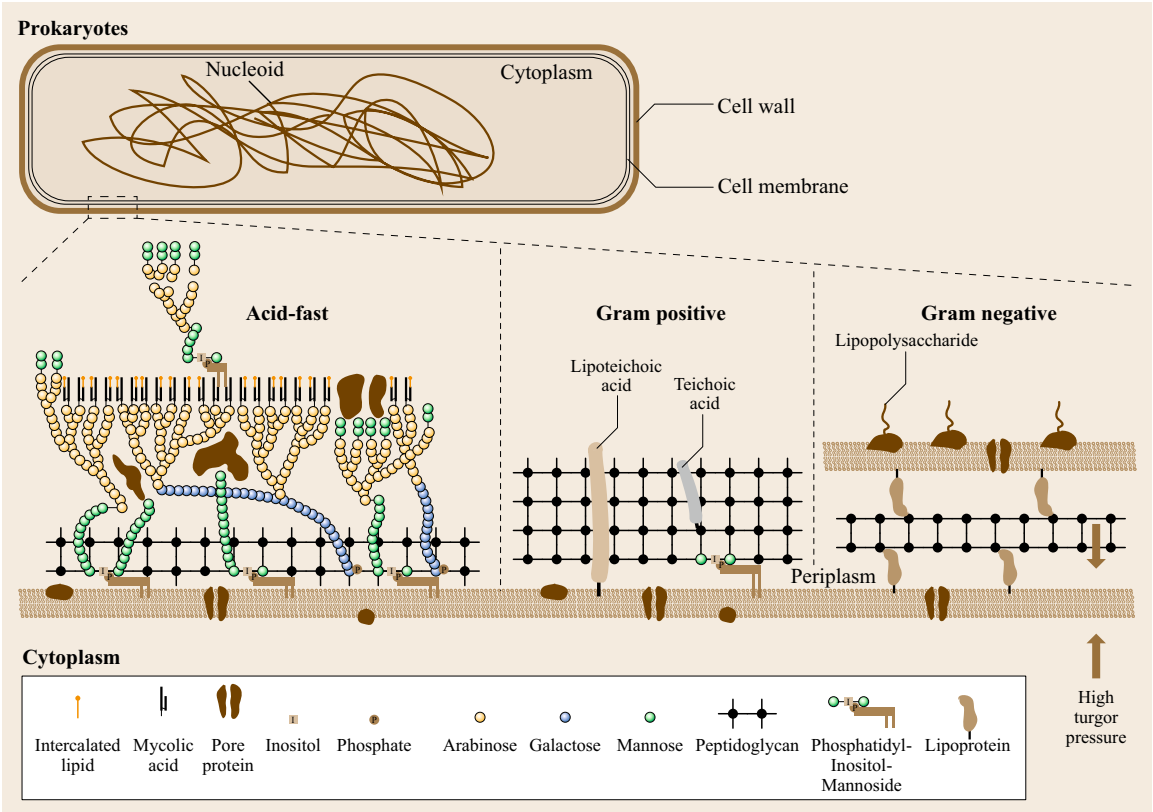

Fig. 19.3 Bacterial cell structure and components of the cell wall. Bacteria can be classified into several groups based on the composition of their cell wall. Depicted are the cell walls of three major types of bacteria based on their pattern of staining with specific dyes. Acid-fast bacteria include actinomycetes like mycobacteria and are comprised of a mycolic acid layer at its surface, conferring a high level of hydrophobicity. Gram-positive bacteria are composed of a thick peptidoglycan layer, giving the cell structural rigidity. Gram-negative bacteria have a second lipid-bilayer surrounding the peptidoglycan providing extra selectivity for molecules that may gain access to the cell cytoplasm

cell surface. The second group of mechano-proteins, the tubulins, is described as fibrous molecules enabling cells to perform active transport of cargo molecules within the cytoplasm. The third group of mechano-proteins, intermediate filaments, is believed to support tension though it cannot create it [19.2]. Together, these mechano-proteins comprise what is considered as the cytoskeleton.

Prokaryotes are not considered to possess cytoskeletal elements functioning to maintain cell morphology. In contrast, most bacteria are able to maintain a high-turgor pressure by mechanically constraining the impermeable cytosolic membrane with the formation of chemical components cross-linked into a rigid meshwork on the outer side of the cell membrane. This outer shell is known as the cell wall and is essential for maintaining bacterial cell morphology and impermeability to ions and water. The cell wall is composed of functional units of carbohydrate and peptide chains which are connected to one another by bonding adjoining sugar molecules forming a stress-resistant sacculus. These sugar bonds provide the bulk of the mechanical rigidity of the bacterial cell wall. The sugar molecules are portions of individual component units of the cell wall, for which the peptidoglycan layer is a central component of most bacterial cell walls. The peptidoglycan layer contains a specific sugar, called muramic acid, which helps to incorporate peptides into the cell wall (Fig. 19.3). The outer layers of the cell wall differ among bacteria. Some, known as the Gram-negative bacteria have a second impermeable cell membrane surrounding the peptidoglycan layer. Yet other bacteria lack a second lipid bilayer and are traditionally classified by the various dyes that they retain while staining, like Gram-staining or the acid-fast stain, Ziehl–Neelsen. One class of bacteria, the actinomycetes, possesses yet other thick layers above the peptidoglycan layer which provide the cell

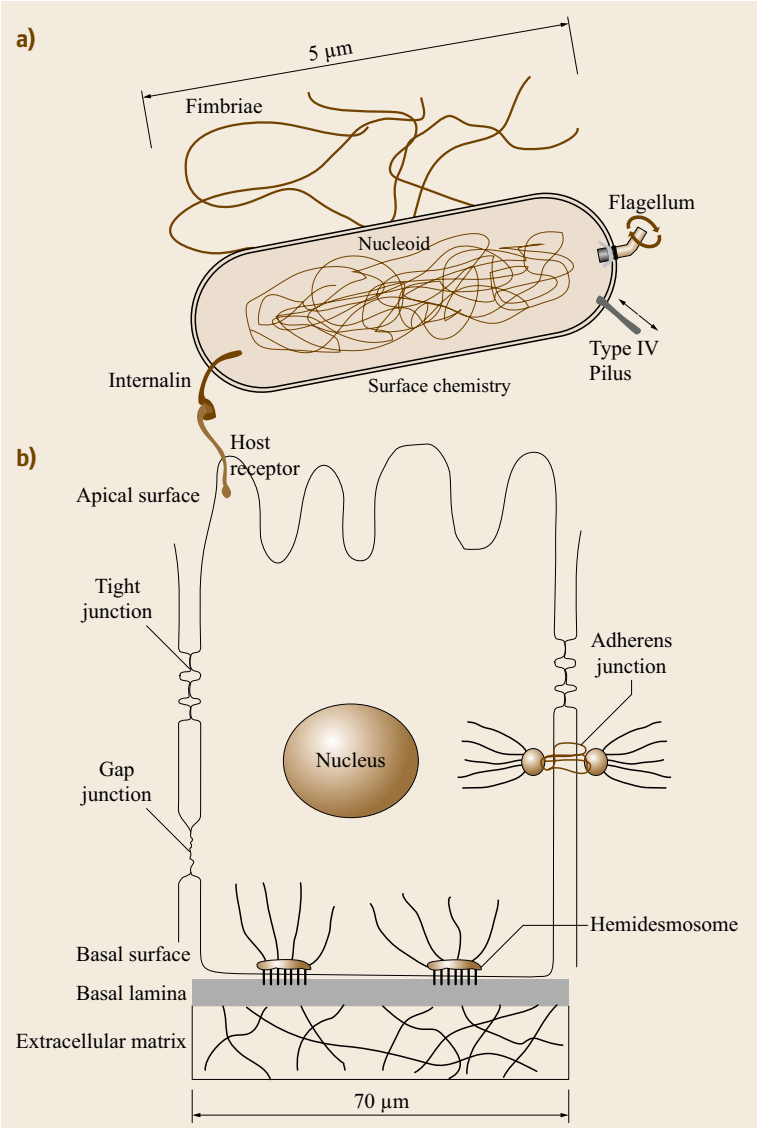

Fig. 19.4a,b Components of prokaryotic and eukaryotic cell adherence. **(a)** Components of bacterial cells conferring adherence on surfaces are diverse in morphology and chemistry. The cell surface provides nonspecific adherence, like the fibrous fimbriae. Fimbriae are passive pili, which is in contrast to type IV pili that can extend and contract in order to provide motion and reorientation to bacterial cells. Flagella provide motion for bacteria, but are also identifiable by receptors of the host immune system. Bacteria also exhibit molecules involved in inducing internalization, like listerial internalins. Internalins bind to host signaling receptors like cadherins or Met. **(b)** Adherence in higher eukaryotes is made by membrane–protein interactions and protein–protein interactions. Tight junctions provide close connections and cell impermeability. Gap junctions also are tight connections between cells, which provide pores at their protein center through which small molecules from either cell cytoplasm can be exchanged. Hemi-desmosomes and desmosomes provide connections with basal laminar layers and with neighboring cells, respectively. Adherens junctions are just one sort of cell-adherence molecules (CAMs) connecting neighboring cells to one another

with increased selectivity in the permeability of small molecules and water. Taken together, the cell wall in prokaryotes and the cytoskeleton in eukaryotes act to counter the effects of turgor pressure, a major physical force affecting cells.

Another biophysical process that cells must undertake is adherence to a cell surface. Both prokaryotes and eukaryotes have developed a variety of mechanisms to confer specificity in surface adherence. Adherence provides bacteria with numerous functions, including: 1) host-cell invasion as the first step of pathogenesis; and 2) the transfer of genetic material between bacterial cells in a process known as conjugation (Fig. 19.4a). Among eukaryotic cells, which possess only an amoebic lipid bilayer to separate the cytoplasm from the extracellular space, surface adhesion is dependent on adherence molecules recognizing specific ligands. A ligand is a molecule that can form a complex with another biomolecule on the host cell, called the receptor. Adhesion molecules provide eukaryotic cells the ability to bind to surfaces, cells, or particles (Fig. 19.4), which play important functions in accumulating nutrients, cell growth, division, and differentiation (otherwise known as morphogenesis).

Prokaryotes are found in various environments, both inanimate and those teeming with life. In instances when bacteria encounter chemical or physical

stresses, they can utilize adherence as a tool to initiate a process of host-cell invasion wherein they access a new environment void of the stresses they previously encountered. Often, this process is associated with disease in host cells, even though the aim of the pathogen is to access an environment supportive of growth. Bacteria exhibit both nonspecific and selective methods by which to confer adherence. Among nonspecific adherence is the chemical characteristic of the cell wall. For example, mycobacteria exhibit mycolic acids on their outer surfaces, which are hydrophobic in nature. Another method of adherence employs fimbriae, thin strands of protein associated together in a filament that reaches several micrometers in length. Shorter versions of fimbriae are known as pili and provide cells selective attachment to bacteria and host cells, alike. The mechanics of pili interactions include both: 1) rigid bodies that provide bacteria tunnel-like structures through which to exchange DNA and small particles; and 2) contractile filaments, which are involved in bacterial–host cell interactions and ratcheting bacteria into close proximity and in an ideal orientation for host-cell invasion. Bacteria also exhibit receptors on their surfaces that bind as ligands to host-cell receptors and induce the process of host internalization. Many of these bacterial factors involved in host-cell interactions and internalization are considered virulence factors, as they induce a pathogenic process resulting in disease in the host organism.

Eukaryotes express a variety of adherence factors necessary for cell–cell, cell–matrix, cell–bacterial, and cell–antigen interactions (Fig. 19.4b). Tight-junctions provide cells the ability to hold together in tissues. Tight-junctions are sometimes called occluding junctions since they serve the purpose of sealing gaps between cells in order to make impermeable cell barriers. Structurally, tight-junctions are composed of proteins known as cell-adhesion molecules (CAMs). CAMs and focal adhesions function to bind cells together and cells to extracellular matrix (ECM). The ECM is a structurally rigid material composed of a mesh-like network of proteins (such as collagens) and sugars (polysaccharides) that are secreted by cells. Adherence between cells can also serve as a mechanism of inter-cytosolic communication through gap junctions. Another group of CAMs, adherens junctions and desmosomes, function to produce cell–cell specific interactions. Binding of these molecules induces receptors signaling a cascade of chemical reactions downstream leading to changes in gene regulation. This is a general concept by which cells can sense interactions and modify their behaviors. Together, these interactions provide cells the uncanny ability to make many types of connections with substances in their surrounding environment, ranging in size from small antigens on the order of several nanometers to eukaryotic cells of several hundred micrometers.

In this chapter we explore approaches taken to uncover some fundamental principles governing cell structure, cell growth, and cell behavior under conditions of stress and disease. We will highlight the use of micro- and nano-electro-mechanical systems (MEMS and NEMS) for making these fundamental discoveries in biology possible.

19.2 High Resolution Microscopy Methods for Live Cell Imaging

Due to the small size scale of most cells, high-magnification microscopy methods are required to study the subcellular structures. Additionally, the frequent need to observe the cells in their living state limits the number of applicable microscopy techniques. Atomic force microscopy (AFM) and optical microscopy techniques are both amenable to image living cells and often the sample preparation is similar for both methods. A sample prepared for optical microscopy imaging can often be used for AFM measurements as well. While the AFM enables one to characterize the surface, optical microscopy can map labeled structures of a transparent sample.

The combination of these techniques therefore enables access to the surface to measure the structure and mechanical properties of the sample, while optical microscopy can identify the biochemical nature of the sample, supplying complementary information. This combination has been implemented for some time and instruments combining an inverted optical microscope and an AFM are commercially available. Using optical microscopy in conjunction with AFM is the basis for many of the measurements of cell mechanics, cell adhesion, and the cell diagnostic and manipulation experiments described later in this chapter.

In combined systems, AFM normally gains access to the sample from the top, while the optical technique accesses the sample deposited on a transparent coverslip from the bottom, using high-numerical aperture objectives on an inverted optical microscope (Fig. 19.5). The optical microscope helps to screen the sample and to choose a region of interest before starting AFM experiments. Thereby, regions of the sample containing cells or biomolecules of interest can be located quickly.

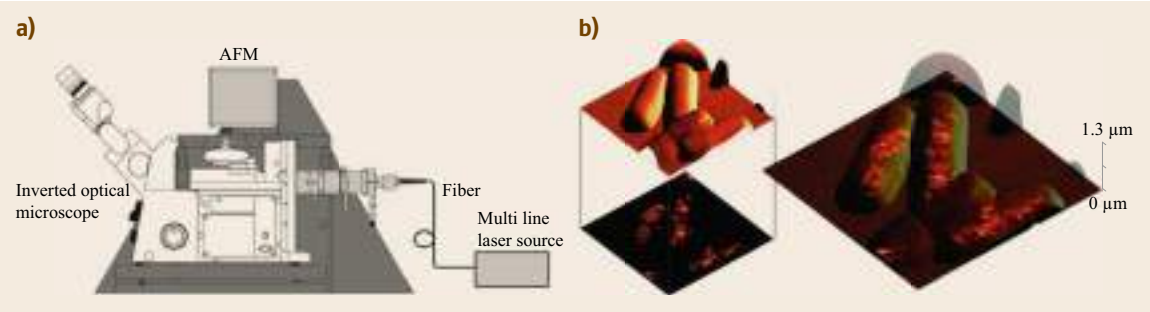

Fig. 19.5 **(a)** Schematic of a combined atomic force and optical microscopy setup. The inverted optical fluorescence microscope is set below the atomic force microscope. A large metal base stabilizes the AFM and sample above the inverted microscope so as to reduce mechanical noise. **(b)** Correlated AFM-PALM imaging of *E. coli* labelled with RNAP-mEos2 (after [19.3])

It also enables one to optically observe mechanical manipulations done by the AFM.

While AFM imaging on living cells can reach a resolution of $\approx 10\,\text{nm}$, conventional fluorescent microscopy suffers from the fundamental resolution limit described in [19.4]. The fundamental diffraction limited or optical resolution limit is dependent on the wavelength and the numerical aperture of the optical system, and is typically in the order of 150–250 nm, which is more than ≈ 10 times larger than the resolution achieved by AFM on living cells. Using advanced microscopy techniques, such as single molecule localization microscopy (SMLM) (e.g., photo-activated localization microscopy (PALM) [19.5, 6], (direct) stochastic optical reconstruction microscopy (dSTORM) [19.7], or stimulated emission depletion microscopy (STED) [19.8]), make it possible to decrease the resolution limit by a factor of ≈ 10. These super-resolution optical techniques thereby approach the resolution of the AFM. Thus, biological structures can be studied using both methods (AFM and super-resolution microscopy) at a similar resolution, providing complementary information about two different aspects of the same biological sample. The combined technique was demonstrated on various static biological samples including biomolecules, bacteria, and mammalian cells, using various super-resolution techniques, e.g., STED, (d-)STORM, and PALM [19.3, 9, 10]. Recently, a high-speed AFM combined with time-resolved PALM imaging even enabled the study of transient processes, such as focal adhesion dynamics in a correlated manner on living cells [19.3]. Such advances in correlated AFM/optical microscopy will greatly aid in areas such as mechanobiology.

19.3 Measuring Mechanical Properties on Living Cells

Quantitatively measuring mechanical properties of living cells has become of great interest, as recent results have shown a correlation between the mechanical properties of a cell and its function. Altered cell functions due to a disease can severely influence mechanical properties of the cell, or vice versa, and altered mechanical properties can lead to a change in the function of the cell or affect its behavior. Cancer, malaria, kidney disease, and many other pathological conditions have been attributed to adverse mechanical properties of cells [19.11–13]. Thus, quantitative information about the mechanical properties of cells could help to establish accurate diagnosis and early detection of a disease or to evaluate prognosis.

19.3.1 Using MEMS Cantilevers to Measure Cell Mechanical Properties

Probing mechanical properties requires applying a physical force to the cell and detecting its physical response. If the amount of force applied is known and the physical response can be measured precisely, the mechanical properties can be quantified. The AFM enables one to apply a specified force on the sample using a calibrated cantilever while constantly recording its position and deflection [19.14].

Most measurements of cell mechanical properties using MEMS cantilevers are done with AFM equipment, based on the recording of a force–distance curve (Fig. 19.6). For a desired position of the sample, the

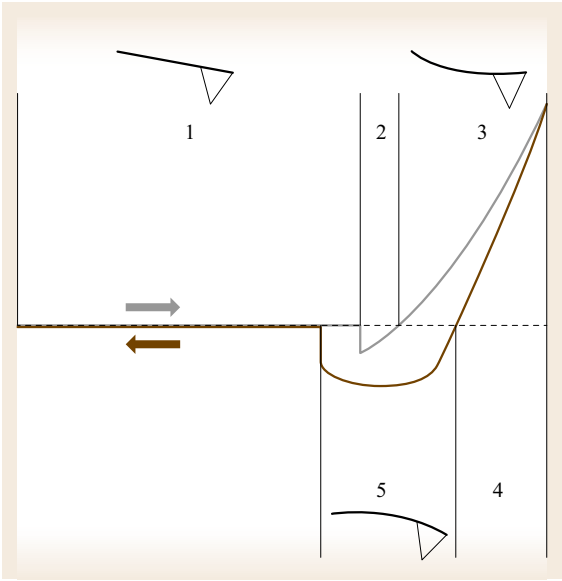

Fig. 19.6 Schematic representation of a force curve. 1) The cantilever begins at an extended above the sample surface. 2) The cantilever tip is subject to weak chemical forces and snaps onto the sample surface. 3) The cantilever deflects away from the cell surface as it is approached nearer the cell surface. 4) Once the force set-point is reached (at the apex of the y-axis), the cantilever is retracted away from the surface. 5) Once more, the cantilever is subject to adhesion and weak chemical forces before losing contact with the sample surface. The approach curve is labeled in *gray* and the retraction curve is labeled in *brown*

cantilever is brought to the sample, often using piezoelectric positioners, and the deflection of the cantilever is recorded as a function of the piezo-extension. The force-distance curve can be divided into five regions:

1. Region without contact (baseline)
2. Snap in with point of contact
3. Compressive loading of the material (indentation)
4. Relaxation
5. Adhesion.

Region 1 is used as the baseline, and its intersection with region 3 is often defined as the contact point. For perfectly elastic materials, regions 3 and 4 overlap, however with real materials the deviation of region 4 from region 3 gives information about the plastic or viscoelastic properties of the material. In region 5, the cantilever is bent in the other direction due to adhesion with the sample. Regions 1, 2 and 3 constitute the approach – regions 4, and 5 are the retract curve. The area between the approach and retract curve corresponds to the energy dissipated during one loading cycle. Different biologically relevant aspects of cell behavior can be extracted from the various parts of the force curve. In order to obtain quantitative measures of these aspects, both the MEMS cantilevers, as well as the AFM instrument, need to be properly calibrated.

19.3.2 Cantilever Calibration

The cantilever of an AFM can be characterized as a spring with an intrinsic spring constant, a resonance frequency, and a quality factor. According to the simplified Hooke's law, the spring constant is

$$k = \frac{F}{\Delta x} ,$$

which is the force required per unit of displacement (N/m). Two frequently used methods, the thermal noise method [19.15] and the Sader method [19.16], are generally employed to precisely calibrate the spring constant of an AFM cantilever.

In the thermal-noise method, the cantilever is treated as a simple harmonic oscillator (SHO). The spring constant k is calculated by relating the thermal (i. e., Brownian) motion of the cantilever's fundamental mode to its thermal energy [19.15]

$$k = \frac{k_B T}{\langle z_c \rangle^2} ,$$

where k_B is the Boltzmann constant, T the temperature, and $\langle z_c \rangle^2$ the squared mean displacement of the cantilever. Various corrections for the methods have been proposed [19.17–19].

The Sader method uses the in-plane dimensions of the cantilever, the density (ρ), and the viscosity (η) of the medium in which they are measured, and the cantilever resonance frequency f_R and quality factor Q to calculate the spring constant [19.16]. The thermal spectrum of a rectangular cantilever can be fitted with the SHO model to extract f_R and Q. The spring constant is then given by [19.16]

$$k = 7.5246 \rho b^2 L \Gamma_i(Re) f_R^2 Q \quad \text{with}$$

$$Re = \frac{\pi \rho b^2 f_R}{2\eta} ,$$

where b is the width of the cantilever, L the length of the cantilever, and Γ_i the imaginary part of the hydrodynamic function [19.18, 20].

19.3.3 Instrument Calibration

The deflection of the cantilever in most AFMs is measured based on the change of the angle of a laser beam

reflected off the backside of the cantilever. The change of the position of the reflected laser beam will change the voltage on a position-sensitive detector (PSD), which is determining its position. The signal from the PSD needs to be correlated to the actual cantilever-tip displacement by recording a force–distance curve on a hard surface. Because on a hard surface there is theoretically no indentation of the tip into the substrate, a *deflection sensitivity* can be derived from the linear portion of region 3 of the force–distance curve. This value can then be used to correlate a specific value read from the PSD with a specific cantilever deflection, and, in turn (using the spring constant of a cantilever), to a specific force.

Many factors influence the accurate measurement of cell's mechanical properties, leading to a large spread in the values reported in the literature. Therefore, in order for quantitative cell-mechanical properties measured by AFM to be comparable across different labs a standardized procedure for the calibration of the cantilever and the read-out system is required. In this regard, researchers across various labs in Europe have developed a procedure, called the Dubrovnik procedure [19.21].

19.3.4 Extracting Materials Properties from Cell–Indentation Measurements

From the properly calibrated and transformed force–distance curves, mechanical information about the sample can be extracted, such as the stiffness and the indentation depth. The Young's modulus is a measurement of a substances' resistance to being elastically strained when a stress is applied to it. It can be derived from the slope of the stress–strain curve in the elastic deformation region. However, the geometry of the indentor (AFM tip) has to be known for proper calculation of the Young's modulus. One way to describe the interaction between a spherical tip of known radius and a cell is the Hertz contact model of two elastic bodies [19.22–24]. The Hertz model is valid under the assumption of elastic deformation of two homogenous smooth surfaces in contact [19.25].

Assuming the Hertz contact model and that the tip used for probing is infinitely stiff compared to the cell, the relationship between the indentation δ, and the loading force F is given by

$$F = \frac{4ER^{1/2}\delta^{3/2}}{3(1-\nu^2)} ,$$

$$F = \frac{4}{3}E * R^{1/2}\delta^{3/2} ,$$

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} ,$$

where E is the elastic modulus of the cell, ν the Poisson ratio of the cell and R_1 and R_2 the radii of the cell and the cantilever tip, respectively.

Under the assumption that the cell can be described as a homogeneous and isotropic (similar in all dimensions) material, valid for small-indentation depth only, the cell can be approximately described by two numbers, for example, by the Young's modulus and the Poisson ratio. The Poisson ratio for soft materials typically ranges 0.3–0.5. Since the maximum error due to the unknown Poisson ratio is small, it is typically sufficient to characterize soft materials with just the Young's modulus [19.26, 27]. Thus knowing the force, the radii, and the indentation depth are enough to calculate the Young's modulus using the equations above [19.28].

Other models applied to mechanical measurements done by AFM include the Johnson–Kendall–Roberts (JKR) and Derjaguin–Muller–Toporov (DMT) models [19.29, 30]. The DMT model [19.30] is applicable to stiff contacts with small tip radii and low adhesion forces. The JKR model is best suited for situations with relatively low stiffness samples, large tip radii, and high adhesion forces [19.31]. It should be noted, however, that all the above-mentioned models have been derived for uniform materials. As described earlier, cells are very complex structures consisting of many different materials in a variety of geometries (cell membrane, cytoskeleton, etc.). Numbers derived from these models should therefore be understood as *equivalent Young's modulus*, and we use the term Young's modulus as such in this chapter.

As the measurements of Young's modulus is dependent on the loading rate due to the viscous contribution, measurements of mechanical properties have been done at rather slow speeds, minimizing the viscous effect, with typical rates of 1–2 Hz. By performing multiple force curves in a raster pattern, the topography and mechanical properties can be recorded simultaneously (force–volume mode [19.32]). To speed up the measurement acquisition, several *fast-force curve* modes have been developed where hundreds or thousands of ramps are performed per second. To deal with the increasing speed, deviations from the linear trajectory have been introduced, and the triggering on the peak force has been replaced by a constant feedback loop on the measured peak force (Quantitative Nanomechanical Mapping (PF-QNM), Bruker, HybriD mode, NT-MDT) [19.33, 34].

For a small scan area within bacterial cells it was found that elastic models remain relevant for indentation frequencies below 20 Hz, while above this frequency incorrect apparent Young's moduli were calculated [19.28]. Additionally, an effect of penetration depth on the modulus values was observed as well.

A too-low penetration depth (< 20 nm) leads to an increase of measured modulus, as the hard cell wall is tested. On the other hand, too high penetration depths also dramatically increased the elastic moduli due to the hard-substrate effect and incompressibility of the cellular membrane. This introduces artifacts for very thin cells adhered to substrates, which is for example the case for fibroblasts (connective tissue cells) [19.35]. However, even thin materials can still be reliably measured with conically shaped tips by applying a correction factor, namely, the bottom-effect cone correction (BECC) [19.36].

Further instrument development, standardization of experimental procedures, and improvements in data analysis will make it possible to measure quantitatively mechanical properties of biological samples, which can be compared across different laboratories and instruments. This is particularly important to be able to use mechanical-property measurements of biological samples for diagnostic or prognostic purposes.

19.4 Cancer Detection Using Nanomechanical Sensors

> *Cancer is the uncontrolled growth of cells, which can invade and spread to distant sites of the body. Cancer can have severe health consequences, and is a leading cause of death.* [...] *Early detection, accurate diagnosis, and effective treatment* [...] *help increase cancer survival rates and reduce suffering* – World Health Organization [19.37]

The World Health Organization states that the number of new cancer cases is expected to rise by about 70% over the next two decades, while already now 8.2 million people die each year from cancer. The major cause of death from cancer is metastases. In order for metastases to occur, the cells have to complete a series of steps:

1. Normal benign cells have to undergo transformation acquiring a cancerous state that leads to uncontrolled growth.
2. The primary tumor initially nourished by diffusion requires the development of new blood vessels in order to grow beyond 1–2 mm in diameter [19.38–41].
3. Tumor cells then invade the connective tissue surrounding the organ [19.42], detach from their primary site and penetrate the blood vessels (intravasation) [19.43].
4. The cells are then disseminated via the blood vessels and become trapped in the capillary beds of distant organs by adhering to the capillary walls [19.44].
5. Cells then penetrate the capillary walls and invade the tissue at the distant site by crossing the extracellular matrix barrier.
6. Finally, cell growth and division within the distant organ completes the metastatic process (Fig. 19.7).

To continue growing, the micrometastasis must develop a vascular network and evade destruction by the host's defenses. The cells can then invade blood vessels, enter the circulation, and produce additional metastases [19.38, 45–49]. Thus, in order to successfully metastasize, a cell faces many challenges on its journey. During entry into, and exit from, the vascular system, tumor cells undergo dramatic shape changes driven by cytoskeletal remodeling [19.50]. Such remodeling of the cytoskeleton affects the mechanical properties of cells [19.51, 52]. A reduction in elastic modulus of cells therefore could facilitate substantial, rapid, and reversible migration of tumor cells through small pores that are often present in tumors infiltrating blood vessels [19.11, 53, 54]. Measurements of the mechanical properties of cells could be used as indicators of their biological states and could offer valuable insights into the pathogenic basis of disease [19.11, 53, 55–57]. Therefore, effort has been put into understanding how changes in the biomechanical properties of cells influence, and are influenced by, the onset and progression of human disease. Several techniques have been developed in order to assess the mechanical properties of cells or tissues. These include micropipette aspiration [19.58–61], magnetic-bead twisting [19.62], microfluidics [19.63], and optical tweezers [19.64] or atomic force microscopy (AFM) [19.65, 66]. The main advantage of these techniques lies in their capability to measure living cells on a single-cell level and in liquid conditions, imitating their natural environment [19.67]. It has been found that cancerous-breast epithelial cells are more deformable than nontumorigenic epithelial cells, and that the metastatic variant is even more deformable [19.68]. Various cell-model systems have been applied to correlate the mechanical properties of a cell with their metastatic potential. For some cells, it is possible to regulate the metastatic potential by modulating the expression of specific genes, such as breast cancer metastasis suppressor 1 (BRMS1) or Syk, a protein involved in many different cell-signaling cascades in breast cancer cells [19.69, 70]. Cells expressing BRMS1 or Syk generally exhibited lower metastatic

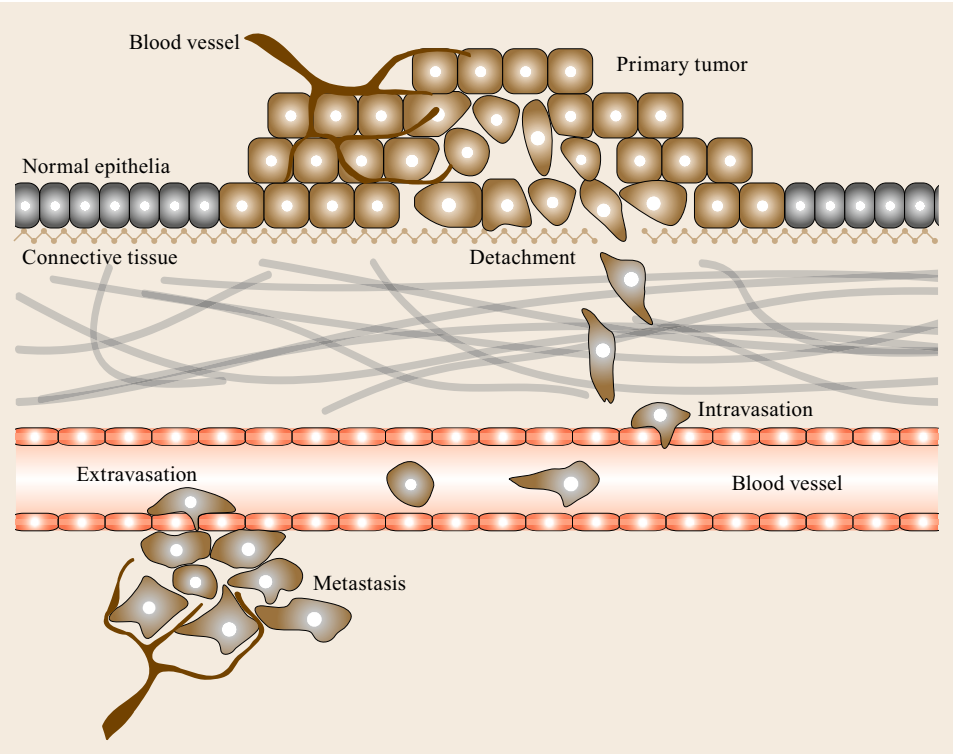

Fig. 19.7 Graphical representation of cancer cells, their spread, tissue invasion, and tumor formation

potential, while expression of BMP2 [19.71] promotes migration and invasion. Specifically, these cells exhibited increased cell adhesion, cellular spring constant, Young's modulus, and viscosity [19.72]. Additionally, an altered cellular topography, including reduction in cell height and a more substantial and stable microtubule network, was observed [19.51]. These results show that a number of relevant mechanical properties change as the cell undergoes transformation from a benign to malignant state. Similarly, using colloidal AFM probes, it was found for a variety of ovarian cell lines that stiffer cells exhibited a lower migratory and invasive potential than the softer cells. A decrease in cell stiffness was found to correlate with a low degree of coalignment of cytoskeletal microfilaments [19.73]. This suggests that the structure of the cytoskeleton affects the mechanical properties, which in turn influence the migratory and invasive potential of cells, and, in consequence, the metastatic potential [19.74].

In accordance with these results, a decrease of the elastic modulus was found upon drug-induced destabilization of actin filaments of noncancer cells [19.75, 76]. Transformed fibroblasts, besides being softer than the nontransformed cells, showed disorganization of the actin cytoskeleton, lack of actin stress fibers, and decline in the number and size of focal adhesions [19.77]. Similarly, in a study comparing three epithelial breast-cancer cell lines with various degrees of malignancy, it was found that local stiffness is at a maximum where filamentous actin is organized as well-aligned stress fibers. A difference was also found in the spatial distribution of actin stress fibers. In tumorigenic cells, actin stress fibers appeared only at basal regions (facing the substrate), where they cannot contribute to the stiffness probed by AFM. In contrast, in healthy cells, actin stress fibers were present at apical regions (facing away from the substrate), where they contribute to the stiffness measured by AFM [19.78].

Using patient samples, the group of Gimzewski measured by AFM the elastic moduli of metastatic cells obtained from body (pleural) fluids from patients with suspected lung, breast, and pancreas cancer. Compared to benign cells, metastatic cells were 70% softer. The study showed that a shift in biologically-driven biomechanical properties towards a decrease in cell stiffness correlates with an increase in metastatic potential [19.12]. Demonstrating that nanomechanical characterization could be applied to patient samples to reliably provide information about the progression of the disease makes this biomarker an additional tool with diagnostic potential.

However, whether the elastic modulus is a general biomechanical marker for cancer progression is not entirely clear. A comparison of bladder-cancer cells

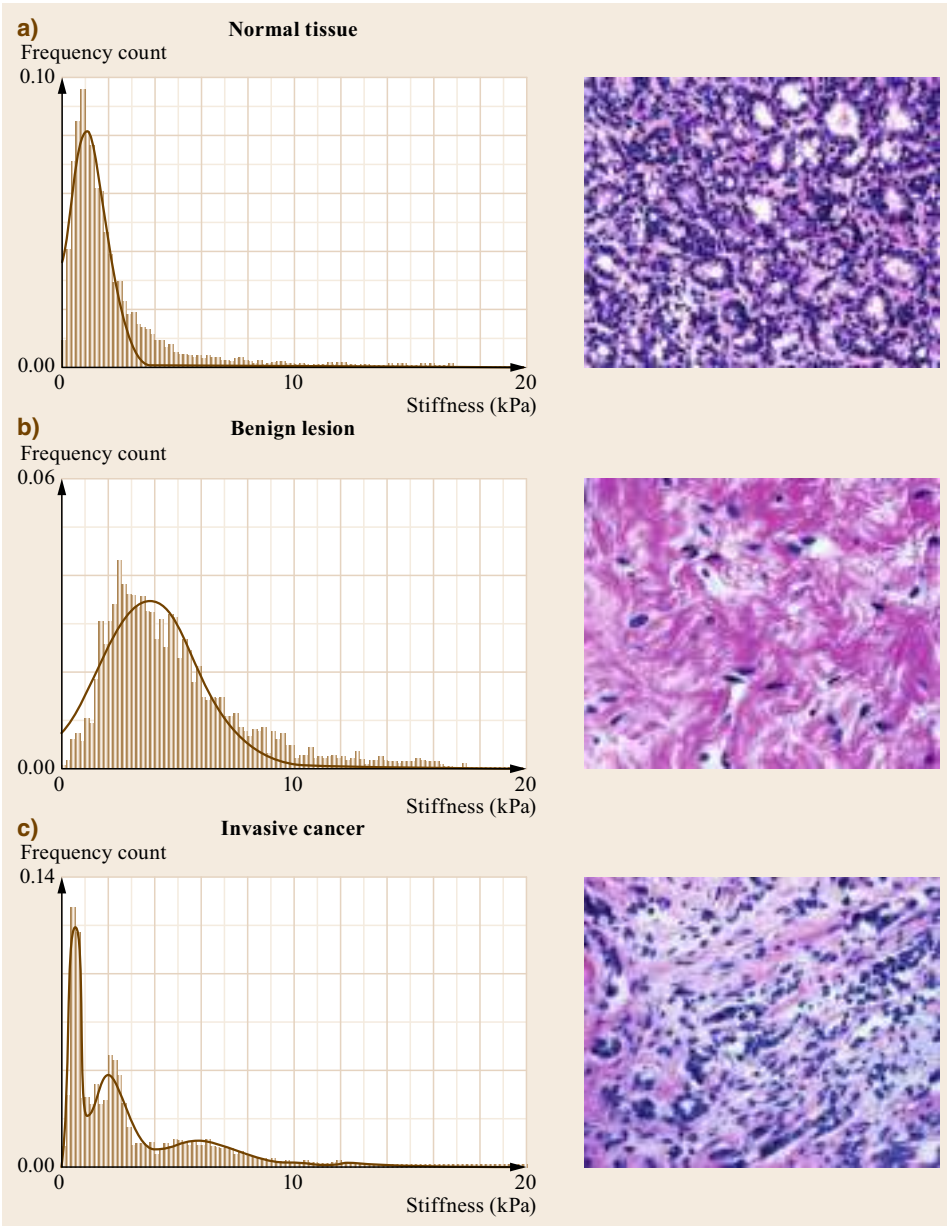

Fig. 19.8a–c Graphical representation of the mechanical properties measured on the surface of breast-cancer tissue sections. On the *left* are graphs of the distribution in the mechanical properties of **(a)** normal tissue, **(b)** benign lesions, and **(c)** invasive cancers. On the *right* are tissue slices with dyes of cell nuclei (*purple*) and proteins (*pink*) (after [19.79])

from various histological stages of cancer progression showed that cancerous cells are more deformable than nonmalignant cells. But, this was regardless of the state of cancer progression. Soft cells thus indicated a malignant phenotype. But, the histologically-determined tumor grade does not seem to be directly reflected in the elastic properties of the cells. Cancer cells from advanced stages of tumor progression were not softer than cancer cells from earlier stages [19.80]. This suggests that just determining elastic properties of individual cells might reflect a qualitative state of the cell in relation to cancer, but might not enable one to link it to the severity of the disease. Some researchers therefore suggested that stiffness is a dynamic property, and proposed that, rather than a general decrease in cell stiffness, the cells' ability to vary their degree of stiffness towards both very low and very high values as a marker of malignancy [19.81].

Stiffness at the tissue level might as well be different from the stiffness measurements presented above, which almost exclusively focused on measurements of single isolated cells. Paradoxically, and counterintu-

itive to the results obtained on single cells, cancerous tissues are often found to appear stiffer than normal tissue, for example, in breast-cancer tissue [19.82, 83]. A comprehensive study of breast-cancer biopsies, correlating histopathological information with nanomechanical measurements on a tissue-scale using AFM, has been reported by *Plodinec* et al. [19.79]. Nanomechanical stiffness measurements were done on breast-cancer biopsies of ex vivo human and mice samples under physiological buffer conditions. It was found that healthy tissue exhibited a uniform stiffness profile, characterized by a unimodal distribution with a single distinct peak (Fig. 19.8). Similarly, while the stiffness of tissue samples containing benign lesions remained uniform, the values were higher than in the normal tissue. The biopsies of tissues with cancerous lesions, on the other hand, exhibited a distribution of stiffness values that was much broader and contained a long tail at higher values. A dominant peak was measured at a value at least a factor of two softer than healthy mammary-gland epithelium, which corresponds to regions densely populated with cancer cells. This suggests that individual cancerous cells in the tissue are softer, confirming the results obtained on single cells. However, the nanomechanical signature of cancer tissue included a second peak at higher values, which corresponds to fibrotic regions (regions with extensive extracellular matrix material).

Taken together, all these nanomechanical cues suggest that abnormal mechanical properties are general traits of cancerous cells. Efforts are under way to utilize this in clinical research and diagnostics. Additionally, there is still much room for fundamental research and technology development in this area.

19.5 Measurement of Cell Adhesion Using Cantilever Based Force Sensor

Specific molecular recognition as well as nonspecific adhesion, are important events regulating and influencing a vast range of biochemical processes and biological behaviors in living organisms [19.84]. Cell adhesion molecules are involved in regulating fundamental processes in multicellular organisms, such as embryonic development, binding of white blood cells to the walls of blood vessels, and neuromigration. These diverse processes are enabled by a multitude of various adhesion molecules present on cell surfaces [19.85].

Cantilever-based force spectroscopy can be used to measure these adhesions. It is quantitative and has a very-wide force range from 10 pN to 1 μN [19.86]. This excellent force resolution, coupled with the positional precision, enable the use of this technique for measurements at the single-molecule level. Small adhesion forces are exhibited between biomolecules, such as receptor-ligand association, DNA entanglement [19.87], antigen-antibody complexes [19.88], and cell-integrin binding [19.89]. Besides single-molecule measurements, the binding strength between individual cells or between a cell and a substrate can be measured under physiological conditions [19.85, 90].

19.5.1 Tip Functionalization Methods

A requirement for such an experiment is the functionalization of the cantilever. One part, e.g., the ligand, is chemically tethered at the tip of an AFM cantilever. This cantilever can then be brought into contact with the other part, e.g., the receptor, which is adsorbed on the substrate or present on the cell membrane. The AFM cantilever motion can be precisely controlled, allowing one to modulate parameters such as contact time, contact force or speed of approach/retraction.

A force–distance curve can be obtained by recording the deflection of the cantilever during such a contact/release cycle and applying Hooke's law to the cantilever deflection (Fig. 19.6). The cantilever starts deflecting when it touches the surface, and e.g., the ligand and receptor start to interact consequently. The position can then be held constant during a certain length of time before the cantilever is retracted again from the surface and the deflection reverses, until the force applied on the surface is again zero. If there is an interaction between, e.g., the ligand on the cantilever and the receptor on the surface, the deflection of the cantilever increases in the opposite direction because it is held down by the molecular interaction. At some point, the pulling force is higher than the molecular interaction, and the connection will break. The profile of the adhesion and the strength of the interaction can thus be quantified by analyzing the deflection during retraction of the cantilever [19.91]. Parameters that are conventionally extracted from such data are the maximum force applied during the detachment process, the work of detachment, the distance of detachment, and the contour length [19.92].

The required cantilever functionalization can be achieved by either coating or grafting the material on the pinpoint of the tip [19.91] or attaching a functionalized bead on a tip-less cantilever [19.94]. Force-spectroscopy experiments using a functionalized tip have successfully been performed to study many spe-

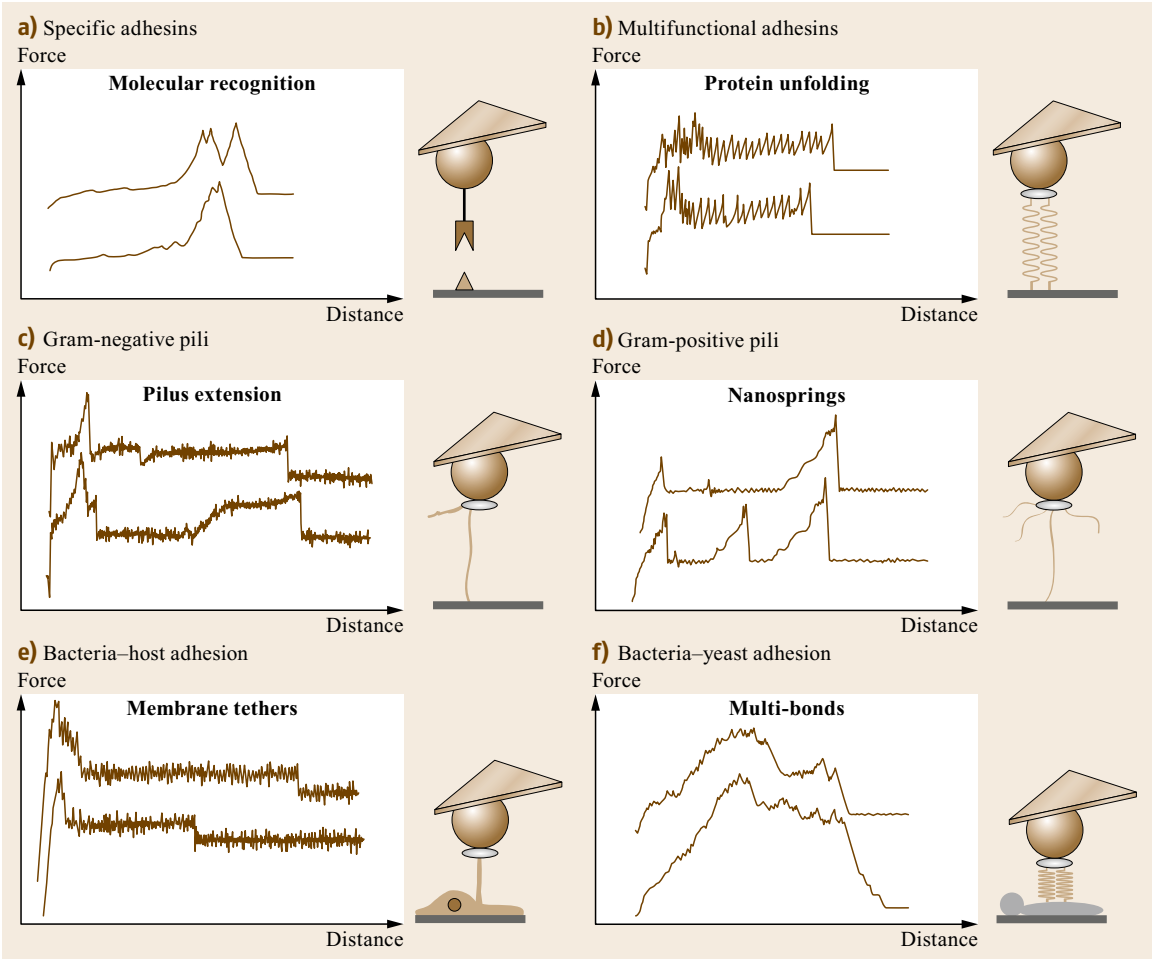

Fig. 19.9a–f Schematic representation of a variety of cell-adhesion experiments and their representative force spectrum (after [19.93])

cific interaction, ranging from the interaction between avidin and biotin and antibody and antigen [19.95] to the interaction between the individual-cell adhesion proteoglycan (AP) chains of the marine sponge *Microciona prolifera* as a model [19.84] (Fig. 19.9).

To measure cell–cell or cell–surface interactions, cells can be directly immobilized on the bottom side of a cantilever. To pick up single mammalian cells, cantilevers are previously functionalized with biomolecules that bind factors present on the cell surface, such as Concanavalin A (ConA) [19.96]. The living cell on the cantilever can then be used as a bioprobe allowing a wide range of experiments, where variables such as the surface decoration, the contact time, and the proteins expressed at the surface can be modulated [19.92, 97–100].

Various tip functionalizations have been reported to attach bacterial cells on cantilevers, including the use of poly-L-lysine (PLL), polyethyleneimine (PEI), lectin, silane, ConA, and a bioinspired-polydopamine wet adhesive (Cell-Tak) [19.85, 86, 101–106]. Bioinspired polydopamine was used to measure adhesion between single bacteria or fungi and metal surfaces [19.107], or using functionalized colloidal probes to measure the adhesion forces between single bacteria and biotic (lectin monolayer) or abiotic (hydrophobic monolayer) surfaces [19.108, 109].

19.5.2 Bacterial Adhesion

Bacterial adhesion on biomaterial surfaces is the initial step in establishing infections and leads to the formation of biofilms [19.110]. *Boks* et al. reported that there are likely differences between adhesion to hydrophilic or hydrophobic surfaces [19.103]. The authors studied the time-dependent adhesion of four strains of *Staphylo-*

coccus epidermidis to hydrophobic and hydrophilic surfaces. They found that, over time, strengthening of the adhesion forces was virtually absent on hydrophobic-coated glass, while on hydrophilic glass strengthening of the adhesion occurred within 5–35 s. This suggests that the hydrophobic effect causes instantaneous adhesion, while strengthening of the bonds on hydrophilic surfaces is dominated by noninstantaneous hydrogen-bond formation.

Various experiments have been reported demonstrating how the contribution of various bacterial biomolecules or structures to the adhesion can be assessed. Type IV pili (T4P), for example, are very thin protein filaments produced by a large number of bacteria. They play key roles in a wide variety of processes, including attachment to surfaces, bacteriophage attachment, twitching motility on surfaces and virulence [19.111–114]. Results suggest that adhesion via T4P is mediated by a low-affinity, high-avidity type of attachment to surfaces where nonspecific adhesion occurs along the length of the pili. Consistent with this model, force plateaus were observed that were attributed to the forced desorption or peeling of extended lengths of T4P from both hydrophilic and hydrophobic substrates [19.115, 116].

In *E. coli*, mutational studies indicate that type I pili play a critical role in biofilm formation [19.117]. Adhesion between type I pili expressing bacteria and various surfaces (fluorinated, aminated and PEG-like monolayers, silicon wafer, and mica) revealed a distinct adhesion profile for each case in terms of both force and distance, highlighting the cells' ability to adapt their adhesive properties to disparate surfaces [19.118].

19.5.3 Cell–Substrate Interaction (Biomaterials/Tissue Engineering)

Adhesion of cells to a substrate is a critical step in the successful integration of biomaterials for medical applications [19.119]. Bioactive glasses, an oxide-based biocompatible ceramic, is routinely used for orthopaedic and dental purposes [19.120]. Osteoblasts (bone-synthesizing cells) deposit new bone on the surface of the bioactive ceramics [19.121], which gradually replaces damaged or diseased bones in the body [19.122]. Gluing various bioactive glass microspheres on cantilevers and placing them in contact with the osteoblasts grown on a culture dish can measure adhesion between osteoblasts and bioactive glasses. Such colloidal probe experiments enable the study of the adhesion of cells to biomaterials of varying composition and the dynamics of the adhesion over time. It was found that osteoblasts reacted most rapidly and strongly with calcium borate glasses [19.122–127]. In a similar experiment with chitosan microspheres, osteoblasts exhibited particularly-high adhesion forces compared to other cell types. Chitosan is a widely-used biomaterial with reported osteo-conductive and osteo-inductive properties [19.91, 128, 129].

Besides overall cell adhesion to biomaterials the effect of specific adhesion-mediating proteins expressed on the cell surface can be studied in detail using a similar approach. By attaching single cells expressing certain integrin receptors that are specific for, e.g., fibrillar collagen type I on the AFM cantilever, the adhesion dynamics can be assessed. Integrins are a family of receptors involved in cell–cell adhesion and cell attachment to the extracellular matrix [19.130, 131]. After a contact time of > 60 s, overall adhesion strongly increased with the smallest, discrete rupture events, increasing above single-integrin levels. This suggests the establishment of cooperative integrin-receptor binding after an initial weak single-integrin-mediated binding event [19.100].

Conversely, by detaching cells from their substrate, the adhesion of living cells grown on various substrates can be studied. From the cantilever deflection during the detachment process [19.86, 132, 133], parameters, such as percentage of cell detachment, maximum force of detachment, distance of detachment, and work of detachment, can be analyzed. This method enables the study of long-term adhesion and the effects of surface topography [19.92].

19.5.4 Cell–Cell Interaction

Specific recognition of cell-surface molecules between single cells is essential for multicellular development. Combining single-molecule force spectroscopy with genetic manipulation, Benoit and co-workers quantified de-adhesion forces at the resolution of individual cell-adhesion molecules using eukaryotic cells of *Dictyostelium discoideum* [19.85]. These cells expressed only one particular type of adhesion molecules (contact site A (csA)). This way, the expression of a gene was linked to the function of its product in cell adhesion on a single biomolecule interaction level using whole cells [19.134].

Cell–cell interactions also play a major role during the immune response. One of the first steps, in recruiting white blood cells to a site of infection, is the specific interaction between factors expressed on the blood-vessel wall and receptors present on the membrane of circulating white-blood cells [19.135]. This specific interaction is dependent on various sets of cell-adhesion molecules [19.136–138]. AFM shows that the adhesion between white blood cells and endothelial cells is a complex process involving several step-like rupture

events and the viscoelastic deformation of cells on the scale of several microns [19.139].

Cancer research is another area where adhesion forces are of particular interest. Cancerous cells need to detach from their neighboring cells in order to metastasize [19.140]. An altered expression profile of adhesion molecules has been reported in breast cancer cells [19.141, 142]. Epithelial cadherin (E-cadherin), a cell adhesion molecule responsible for providing firm adhesion between two epithelial cells, is downregulated, while N-cadherins are upregulated. The loss of E-cadherin facilitates cell disconnection and invasion of malignant cells [19.143, 144]. Single-cell force spectroscopy revealed that the unbinding force between two E-cadherin molecules is much higher than that of two N-cadherin molecules [19.145, 146]. Thus, the low expression of E-cadherin and its replacement by N-cadherin generate lower cell–cell adhesiveness and assist in the detachment of cancerous cells from their primary tumor. Force-spectroscopy measurements showed that cells with increased invasion potential exhibited decreasing adhesion force, demonstrating the role of adhesion in metastasis [19.147].

Measurements done using the detachment approach of cells from their substrate, with subsequent analysis of the deflection during detachment, suffer from some major limitations [19.148]. Each cantilever has to be functionalized in order for cells to firmly attach. Strong attachment often requires one to stay in contact with the cell for tens of minutes, which is a time-consuming step. What's more, this procedure might even require changing the cantilever after a successful detachment of a single cell. To get statistically relevant data, higher throughput methods are required. Recent advances in MEMS fabrication offer routes towards such methods.

19.6 Manipulation of Cells Using MEMS Cantilevers

Among the various MEMS techniques available for imaging and manipulating cells, fluid-force microscopy (FluidFM) is a recent development. FluidFM relies on the conventional capabilities of an atomic force microscope by which a cantilever is resonated above a surface in order to measure the height. However, where FluidFM goes beyond conventional AFM is in the use of a cantilever that has a hollow fluidic channel connecting a reservoir of fluid to the cantilever tip, where fluid can be dispensed, making it a micropipette. The ability to dispense fluid through this hollow cantilever makes possible precise targeting of single cells and sample regions to administer various chemical treatments in an otherwise controlled environment. The functional use of FluidFM can be categorized into four distinct applications:

1. Measuring surface adhesion
2. Displacing cells and cell sorting
3. Fluid delivery
4. Access to the cell interior through injection/extraction (Fig. 19.10).

For cell-adhesion measurements, conventional AFM relies on the specific interactions between a chemically functionalized cantilever and the receptor of interest. Such functionalization is tedious and limits the throughput to one cell per cantilever. Using hollow cantilevers, however, controlled pressure in the channel can be used to pick up cells mechanically. The cells can then be tested against the target surface and subsequently released from the cantilever to make room for the next cell, enabling high-throughput experiments [19.145]. Such studies have been conducted on eukaryotic samples including the yeast, *Candida albicans*, and human cell lines [19.149, 150].

The ability to pick up cells by suction control also means that cells can be manipulated spatially, wherein cells in disparate locations can be made to interact with one another at close range. This technique has been demonstrated with bacteria, yeast, and mammalian cells [19.151, 152]. These manipulations provide an interesting perspective for isolating specific cells of interest for further analysis. To that end, bacteria exhibiting specific phenotypic traits could be isolated and genotyped by 16S rRNA gene amplification and sequencing at a later time [19.153]. Recently, one report demonstrated the possibility that eukaryotic cells could be probed for analysis of specific biomolecules produced in the cell cytoplasm and nucleus [19.154]. The possibility to probe cells at specific sites makes possible the determination of the composition and behavior of cells in ways that are otherwise not feasible or destructive to cell physiology.

The delivery of molecules to cells by a micropipette has been used to control the dosage and location at which a cell was treated with a bioactive molecule [19.152]. To date, it has been demonstrated that a membrane-impermeable dye could be injected into the host cytosol and nucleus [19.155, 156], whereby intracellular material and space can be marked with markers normally not present inside

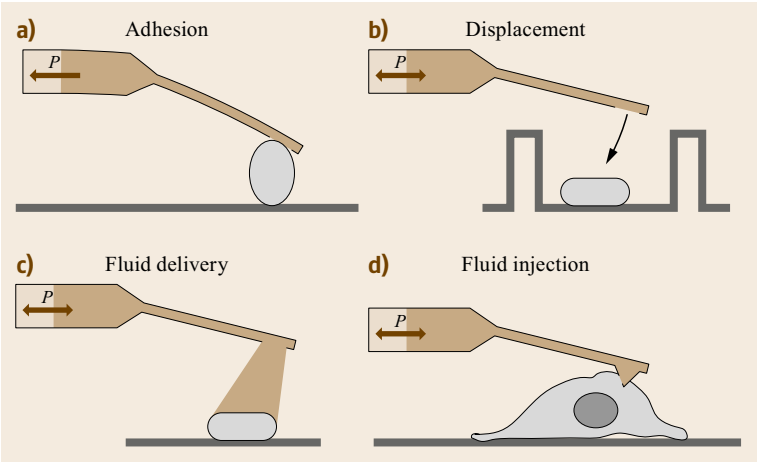

Fig. 19.10a–d Schematic representation of the versatile uses of FluidFM. **(a)** FluidFM can be used to adhere cells by aspirating the cell with the hollow cantilever tip by the use of the pressure controller. **(b)** Cell can be displaced space by aspiration, displacement of the cantilever and/or the stage, and by out-pressure to break the adherence between the cell and the tip. Finally, fluid can be delivered to the outside of the cell **(c)** or injected into the cytoplasm or nucleus of the cell **(d)**

the cell. Future study may aim to inject controlled amounts of nucleic acids or other exogenous materials to study cell processes with single-cell resolution that have only otherwise been studied using bulk measurement techniques on hundreds and thousands of cells.

Another field that may benefit from the controlled delivery of biomolecules to living cells is host–pathogen interactions, namely, in the controlled release of a virus above human cells [19.157]. Many of the physical principles underlying the process of viral infection remain poorly understood.

19.7 Mass Measurements of Single Cells Using Resonant Cantilevers

Determining the characteristics of whole-cell physiology at the single-cell level requires techniques sensitive to subtle and dynamic changes. While many behavioral and physiological phenotypes can be quantified at the whole-cell level, one such physiological attribute of cells that is of particular interest in biology is cell size. Fundamental behavioral processes, like growth and division, regulate cell size. How *cell size* is quantified is determined by the tools available to measure it. Optical microscopy is used to measure cell length and width. Together, these measures can provide an estimate of cell volume [19.158]. However, cell size is also a representation of the molecular contents which together are organized into a cellular compartment. One way to measure the full contents of a cell is to quantify its mass. Here, resonant mechanical sensors provide a unique opportunity.

19.7.1 Resonant Mechanical Sensors

Beam-based mass sensors comprise cantilevers (singly clamped), bridges (doubly clamped), and more complex geometries such as membranes. Cantilevers can have various geometries, including simple rectangular beams ranging from hundreds of micrometers in length down to single micrometers [19.159]. The minimum detectable mass is related to the ratio of mass and resonance frequency of the beam [19.160]. Beam size, geometry, fluidic environment, and the quality factor (Q-factor) of the beam material also play crucial roles. Manipulating each of these factors impacts the sensitivity of the beam for measuring the mass of a loaded sample. Cantilevers can be used in various ways to measure cell mass. They use the principle that cells attached on the cantilever affect its resonance frequency [19.161] (Fig. 19.11). The shift in resonance frequency is related to the mass of the sample, as well as where cells are located on, or in, the cantilever [19.162]. Functionalizing the cantilever surface allows for the adherence and immobilization of cells in specific sites along the beam [19.163]. Cantilevers can be functionalized with antibodies raised against specific bacterial receptors [19.161] or with agarose, which acts as an indiscriminate immobilization platform [19.163]. An alternative method to use cantilevers for cell-mass measurement is to flow cells through a hollow microchannel resonator within the beam. This has additional advantages, as the mass sensitivity is dependent on the resonance frequency and the Q-factor. Having the liquid medium on the inside of the cantilever and surrounding it with a vacuum make possible much higher resonance frequencies and Q-factors than achievable for cantilever

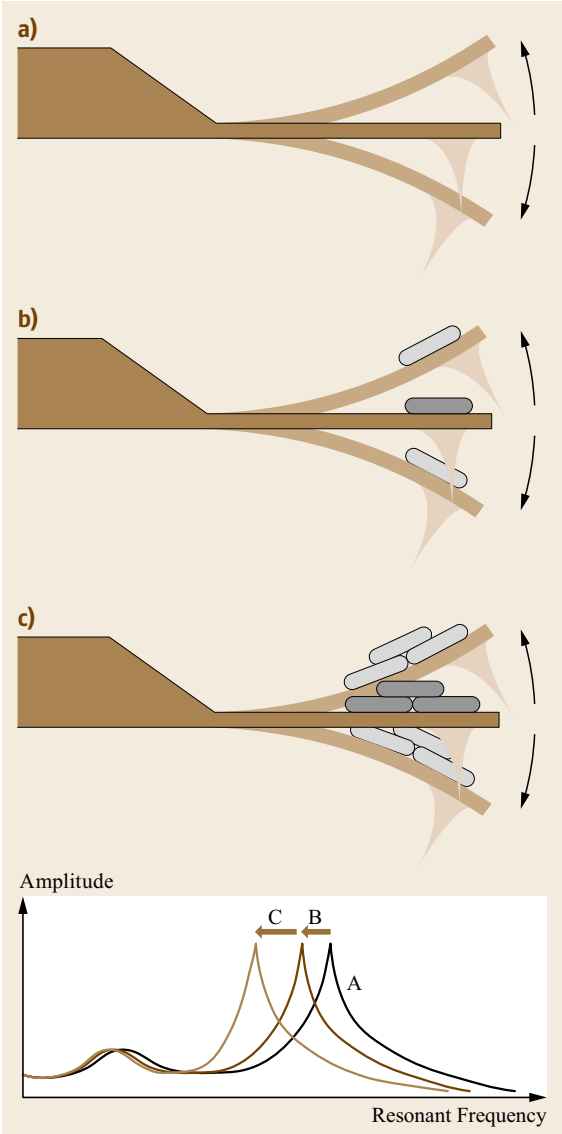

Fig. 19.11a–c Mass measurement of particles/cells adhered to the cantilever-tip surface. The resonant frequency of a cantilever is shifted depending on the mass loaded on the cantilever-tip end, while the amplitude remains constant. **(a–c)** depict schematic representations of how the cantilever-tip body can be loaded with various quantities of mass. The graph *below* depicts how the addition of increased mass shifts the resonance frequency peak downward

resonators immersed in cell medium [19.164]. These suspended micro-channel resonators (SMRs) have the benefit that the medium, in which single cells can flow back and forth through the micro-cantilever channel, can be exchanged rapidly to detect very minute changes in cell physiology (Fig. 19.12). Together, these methods for mass measurement provide unique opportunities to characterize cell growth in terms of added cell mass. Hereafter, we describe the ways in which mass measurement is used to uncover fundamental principles of cell physiology and behavior.

19.7.2 Cellular Growth

A critical factor regulating cell size is growth. Cell growth is dependent on the addition of new cell-wall material, as well as the accumulation of cytosolic components. The rate at which each of these processes function in relation to one another has a direct impact on cell morphology. Specific protein systems are involved in synthesizing components of which the various wall layers are comprised. Peptidoglycan, lipid, and sugar molecules together contribute to maintaining cell impermeability and morphology. The space in the bacterial-cell cytoplasm is comprised primarily of water, ions, DNA, and proteins. The accumulation of material within the cytoplasm is dependent on the influx of water, ions, and small molecules, and their conversion into the synthesized biological factors necessary for life. The rate of synthesis within the cytosol directly impacts the rate of mass accumulation. While volume can change reversibly under various switches in physiological environment [19.165], mass accumulates as a function of the retention and synthesis of materials necessary for sustaining and propagating life.

One method by which to measure the *instantaneous* growth rate is to quantify the cell mass, which represents the amount of material from which a cell is constituted. Researchers have used agarose-coated resonant cantilevers to measure growth dynamics at the micro-colony level, where they observed the same growth dynamics as do spectrophotometry measurements in bulk cultures of bacteria [19.163]. The growth of yeast cells is one example of a more complex organism that has been studied [19.166]. Together with previous bacterial growth studies, it was reported that, as in bacteria, a micro-colony of yeast grows in multiple phases, including a lag phase, an exponential growth phase, and a plateau [19.166, 167]. Another example that MEMS resonators can be adapted to measuring cell mass of higher organisms is the mass measurement of human cell lines [19.168]. This last study employed arrays of MEMS resonator sensors, by which high-throughput, single-cell studies can be achieved on a population of cells. Whereas in this last study they used arrays of cantilever beams, they later reported the use of four beam-spring sensor arrays to record human cell growth for over 50 hours, a relevant time scale for following 2–3 generations of cell growth

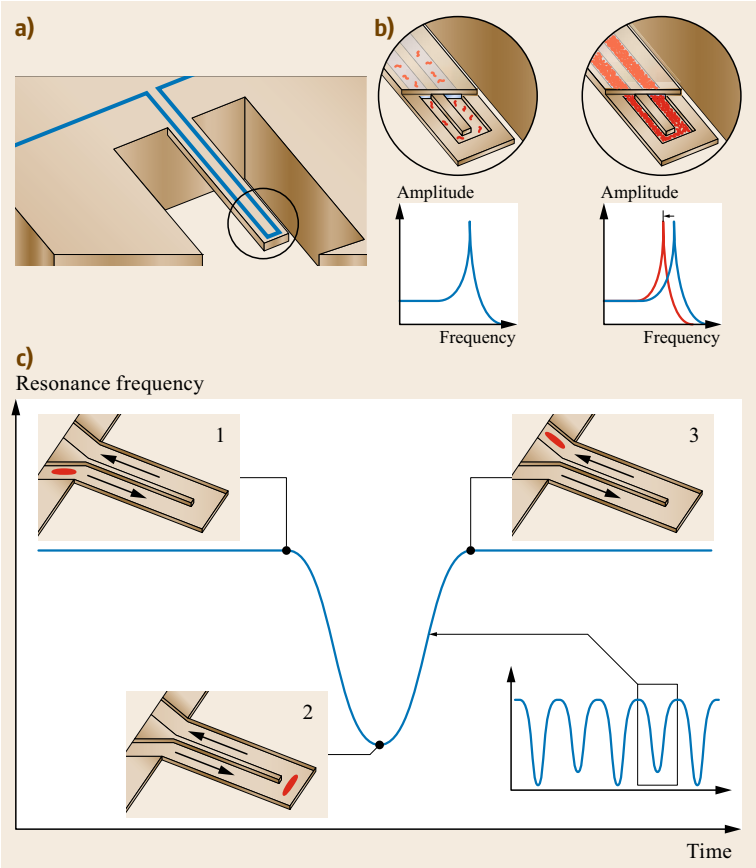

Fig. 19.12a–c Buoyant mass detected by variations in the cantilever resonance frequency. On **(b)** is depicted a schematic representation of a SMR with the cantilever body in *grey* and the hollow tunnel filled with a medium in *blue*. On **(a)** are depicted two conditions in which few or many particles/cells are flowed through the SMR. An increase in buoyant mass is concurrent with a down-shift in the resonance frequency of the cantilever (after [19.164])

and division [19.169]. Taken together, these micromechanical resonators can be employed to determine cell mass by measuring the change in resonance frequency upon immobilization and growth of cells on the resonator.

Another method used to measure cell mass and *instantaneous* growth is to transiently pass cells through the channel of a SMR [19.170]. Compared to the previous methods that measure the total mass of the cell (including the water inside), SMRs measure the buoyant mass. Buoyant mass is described as cell volume multiplied by the difference in cell density and fluid density

$$m_{\text{buoyant}} = V(\rho_{\text{cell}} - \rho_{\text{fluid}}) \, .$$

For the most part, the density of the cell components is greater than water, with the exception of some solubilized small molecules. By measuring the same cell in fluids of various densities, both cell volume and the density of the cell can be calculated [19.171]. The accumulation of buoyant mass was reported to increase exponentially for bacterial cells and eukaryotes alike [19.172]. For yeast cells treated with cell cycle inhibitors, it was observed that the change in the density of the cell occurred predominantly before bud-formation, whereas cell volume and buoyant mass increase throughout the cell cycle [19.173].

Buoyant mass has also been used as a tool to distinguish various species of bacteria [19.174, 175]. In addition, it has been used to distinguish various stages in bacterial cellular differentiation, like the process of sporulation in *Bacillus subtilis* [19.176]. More subtle changes in buoyant mass are also detectable, like the distinction between *E. coli* mini-cells that lack DNA and are the product of highly asymmetric divisions associated with chromosome missegregation [19.177]. Taken together, micromechanical resonators provide powerful tools to study cell growth by measuring cell mass, volume, and cell density. These studies, if combined with optical microscopy studies of cell elongation can provide a powerful and more accurate characterization of the principles underlying cell growth.

19.8 Characterization of Antibiotic Action Using MEMS Devices

Infectious disease imposes a major burden on human society. Treating infectious disease relies heavily on drug therapies whereby antibiotics clear the pathogen in order for the body to repair or replace diseased tissue. Antibiotics are a diverse group of substances aimed at eliminating host diseases or infections. Disease clearance can be measured by pathogen count (mainly measured in colony-forming units (CFU)). The impact of antibiotics on bacterial pathogens can be classified in one of three ways:

1. Bacteriocidal (bacterial killing)
2. Bacteriostatic (bacterial count remains constant)
3. Resistance.

Characterizing the impact of antibiotics on pathogens is a critical field of interest for evaluating drug efficacy. Concurrently, identifying drug targets is important for understanding the mode of action. Estimates suggest that nearly 10% of drugs have no known assigned target [19.178]. Concurrently, $\approx 20\%$ of drugs lack a known mechanism-of-action [19.179]. What remains is simply the knowledge that these drugs possess a positive effect for treating disease [19.180]. Determining how such drugs provide a protective or therapeutic function against infection is an expensive and uncertain endeavor [19.181]. Emerging MEMS-based assays hold much promise in this area.

19.8.1 Characterizing the Impact of Antibiotics

How antibiotics directly affect pathogens is of keen interest in the quest for more potent and effective disease treatments. In microbes, antibiotics target a limited number of cell processes central to life. One major target is cell-wall biosynthesis. A second target is protein biosynthesis by affecting ribosome translation [19.182]. A third is DNA transcription [19.183] or replication [19.184]. These direct effects have historically been identified and characterized in detail using biochemical and molecular biology. Often, antibiotic resistance arises due to mutations in these direct targets. While some mechanisms of bacterial antibiotic resistance have been described recently, these account for only a small portion of the vast numbers of cell–antibiotic interactions. Identifying the responsible factors that lead to antibiotic resistance is a major challenge. Here, the creative use of pre-existent technologies and the development of new MEMS-based techniques could result in substantial advances in our ability to study antibiotic action.

19.8.2 Detecting Fluctuations in the Buoyant Mass of Single Bacteria

As described above, suspended micro-channel resonators (SMR) can detect subtle fluctuations in physiology at the single-cell level [19.164]. One use of such a device is measuring the buoyant mass of bacteria in the presence of an antibiotic. If bacteria are to flow through a SMR containing antibiotics, one can determine physiological changes in the buoyant mass of a cell. The minimum reported detectable limit of transiting mass is 10^{-15} grams (femtograms), which is sensitive enough to detect changes in cell density at the molecular level. Using this method, *Knudsen* et al. were able to distinguish between the pathogenic bacterium *Citrobacter rodentium* known to exhibit resistance to ampicillin (Amp^R) and its ampicillin-sensitive (Amp^S) mutant strain [19.185]. These observations suggest that changes in the buoyant mass can be used as a proxy for determining the antibiotic sensitivity of clinical-bacterial strains or for the diagnosis of antibiotic resistance.

19.8.3 Detecting the Dynamic Motion of Bacteria in Fluid

Another measure used to assess antibiotic efficacy is the dynamic motion of bacterial cells in a fluid. The detection of bacterial viability makes the use of a cantilever as a biosensor of potential interest to the biomedical fields [19.186]. The temporal fluctuations of a cantilever have been monitored over the course of an experiment, wherein bacteria are adhered to the top surface of the cantilever and are subjected to antibiotic stress [19.187]. The fluctuation amplitude increases only when living cells are adhered to the surface of the cantilever (Fig. 19.13). The increase in cantilever fluctuation is attributed to a *nanomotion* of cells [19.189]. What biophysical attribute of living cells is being measured remains unclear, but is currently a topic of keen interest. Experiments done with *Escherichia coli*, treated with ampicillin, revealed a minimum inhibitory concentration (MIC) of about $1.2\pm0.6\,\mu\text{g/ml}$ and a minimum bactericidal concentration of $7.6\pm0.6\,\mu\text{g/ml}$ [19.187]. These values are within the same order of magnitude as values described by conventional biological techniques that entail counting CFUs of bacteria grown on nutrient agar plates containing varying concentrations of an antibiotic. The benefit of the cantilever-based method is that one could potentially detect bacterial resistance of a clinical strain

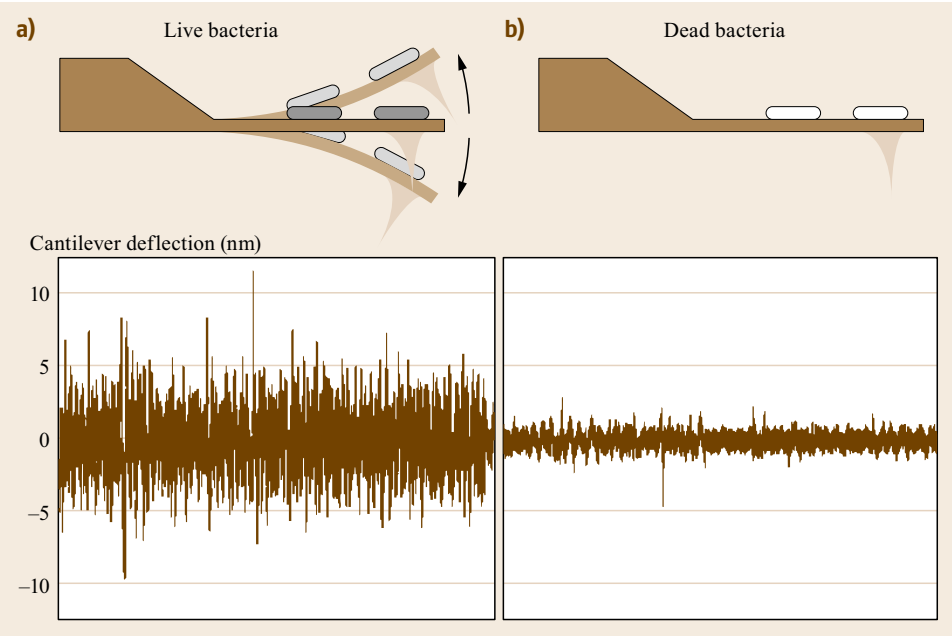

Fig. 19.13a,b Bacterial cell permeability and viability detected by variations in cantilever deflection. Above is depicted a schematic representation of the large variations in cantilever deflection exhibited when living cells **(a)** and dead cells **(b)** are adherent on the surface of the cantilever tip. *Below* is a graphical representation of the range in deflection exhibited by the cantilever in living **(a)** and dead **(b)** cells. A cantilever with adherent live cells has a larger range in cantilever deflection than with dead cells (after [19.188])

more quickly and with a lower titer than needed to perform more conventional techniques currently used in the biomedical field.

19.8.4 Antibiotic Effect on the Bacterial Cell Surface

The biosynthesis of the cell surface is a process directly targeted by multiple first-line antibiotics used for infectious diseases. Antibiotics, like vancomycin, target and inhibit the crosslinking of peptidoglycan, while others block the formation of precursor molecules from which wall components are made. Their impact on bacteria therefore perturbs the physical stability of bacterial cells, making them more fragile, and exhibiting membrane permeability or death. One direct way to assess cell-surface morphology and mechanical properties is to use atomic force microscopy [19.190]. AFM remains to date the only tool to visualize the bacterial-cell surface in time-lapse [19.191]. It is also the only method to directly map changes in mechanical properties along the cell surface, under conditions of growth and stress.

How bacteria are affected morphologically at the cell surface is a central point of interest. AFM can provide unique insights into how cell-surface perturbation leads to cell death. *E. coli* were imaged at high speed and treated with the pore-forming antimicrobial peptide CM15 [19.192]. The cell-surface morphology of *E. coli* appeared to rapidly change from smooth to corrugated over the course of minutes (Fig. 19.14). Curiously, the cells imaged behaved differently in their response to CM15, becoming corrugated on their surfaces at different times in relation to one another. This observation suggests an inherent heterogeneity of single cells in a genetically identical population of bacteria in their ability to tolerate antimicrobial peptide treatment. While the bulging of the *E. coli* cell-surface morphology was visible upon treatment with the peptidoglycan-crosslinking inhibitor, vancomycin, (observable by optical microscopy [19.193]), the emergence of surface corrugations visualized by tapping-mode AFM is undetectable by optical microscopy. Further study into modifications in surface morphology by AFM has been conducted on myocbacteria [19.194], among which *Mycobacterium tuberculosis* is the causative agent of tuberculosis. By following subtle changes in cell morphology, AFM studies have revealed the various ways in which antibiotics and antimicrobial peptides affect cells and offered hypotheses as to how cell death ensues.

It has been suggested that, if the cell-surface morphology is modified by antibiotic treatment, then the

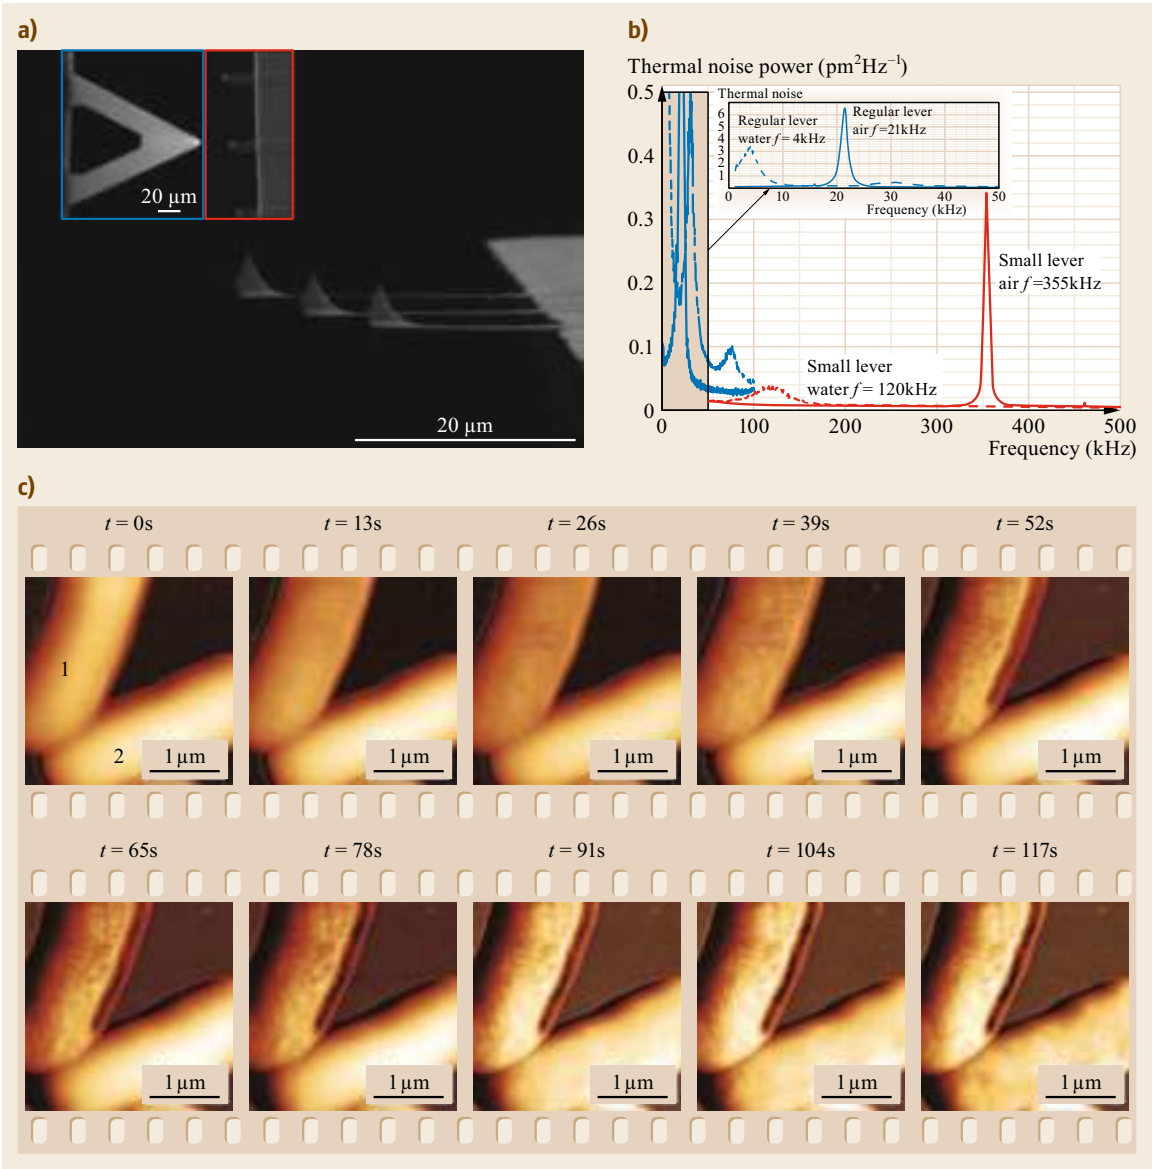

Fig. 19.14a–c Surface-topology fluctuations detected by high-speed AFM using tapping mode. On **(a)** are depicted scanning-electron-micrograph images of small cantilevers. On **(b)** are depicted graphical representations of the resonance frequencies of large (*blue*) and small (*red*) cantilevers. Large cantilevers resonate at ≈ 21 kHz at the first eigenmode whereas small cantilevers resonate at ≈ 355 kHz. **(c)** Graphical film representation of a short time-lapse experiment, wherein cells treated with an antimicrobial peptide exhibit the appearance of cell surface corrugations (after [19.192])

mechanical properties are as well. This could link the surface roughening to the disruption of cell-wall layers composed of arabinogalactan or peptidoglycan crosslinks. These layers are considered to bear the brunt of the architectural load maintaining gross cell morphology [19.195]. Therefore, a second way in which AFM can generally be used to assess the effect of antibiotics on bacterial cells is to quantitatively map surface-mechanical properties [19.186]. By measuring force curves, one can estimate the mechanical properties of the bacteria. Upon treatment of *E. coli* with the β-lactam antibiotic ampicillin regions of greater initial stiffness along the length of the cell undergo the greatest change in mechanical properties following cell death [19.196]. Some studies, however, report a smooth bacterial surface for *E. coli* associated with

homogeneous mechanical properties along that same cell length [19.197, 198].

The ongoing study of how mechanical properties change on the surface of cells treated with antibiotic will reveal the physical principles that are fundamental to our understanding of how cells are formed and how their morphology is maintained. Studies into the repair of the cell surface upon stress will give insights into how cells respond to antibiotics and might lead to ways to prevent the occurrence of antibiotic resistance.

19.9 Conclusions and Outlook

The size scale of MEMS and NEMS make them well-suited for studying biological systems at the single-cell and subcellular level. A myriad of proof-of-concept experiments have demonstrated their potential impact in cell biology. For these techniques to be broadly exploited in the cell biology community, however, some improvements are necessary. To enable wide adoption of these methods requires the development of robust, reproducible, and cost-effective protocols. In addition, to further develop MEMS devices, this will require extensive effort in instrumentation development, sample handling, and ease-of-use improvements.

A second requirement is to correlate the new MEMS-based methods with existing standard cell-biology techniques. Over the most recent decades, a tremendous amount of protocols have been developed and knowledge has been gathered using traditional cell-biology methods. Vast databases have been created, and standardized tests have been established for diagnostic purposes. For new MEMS-based methods to be accepted in the cell-biology community, they must tie in with this existing knowledge base. Firstly, results of the new methods must be validated on reference samples by traditional techniques. Secondly, they need to provide significant advantages in everyday lab use over established technologies. These advantages can be in terms of sensitivity, measurement speed, throughput, or cost. However, great care has to be taken that these advantages don't come at the expense of factors such as standardization, reliability, versatility, or ease-of-use. The successful integration of MEMS technology into cell biology will require an intimate collaboration between engineers and cell biologists.

20. Contact-free Mechanical Manipulation of Biological Materials

Jörg Schnauß, Josef A. Käs, David M. Smith

In biotechnology and medicine, controlled studies on biological material are fundamental for developing new methodologies and therapeutic approaches. To explore the nature of biological processes and to test inherent material properties, it has become increasingly clear that new experimental methods must be developed in order to allow precise manipulations and quantification of biological materials on the microscopic level. Traditional methods often rely on physical contact with the sample, which can induce drastic artifacts in soft biological systems. To bypass this limitation, tools for contact-free manipulation were developed, which even enable the induction of whole-cell deformations to explore their mechanical properties. These approaches facilitate extensive investigations of single molecules, molecular ensembles, cells and even tissues, potentially reducing the need for animal studies. In this rapidly changing field, it is nearly impossible to provide a comprehensive overview of all available techniques since new methods are constantly being developed. In this chapter, we highlight many of the predominant approaches, aiming to investigate cellular as well as subcellular mechanical properties and processes.

Exploring mechanical properties of biological matter or quantifying cellular processes requires controlled manipulations on the microscopic or even nanoscopic scale. Traditional methods such as atomic force microscopy (AFM) are on the forefront of these techniques, but rely on physical contact with the sample. While this approach is sufficient for hard structures, soft biological systems are easily biased by the physical contact and drastic artifacts can be induced. Cells, for instance, are highly heterogeneous structures and results crucially depend on the cellular substructure that is attached to the measurement tool. To reliably quantify biological matter, it has become necessary to use contact-free techniques which are also compatible with the study of biological processes. Several methods have been developed to induce stress-dependent strains on the desired structures. Combined with optical microscopy, deformations can be visualized to derive stress-strain relations, enabling the determination of mechanical properties or the quantification of force-dependent processes.

To controllably manipulate biological structures, methods based on optical effects can induce forces in the pico- and nanonewton range, which even enable whole-cell deformations. Other approaches employ external magnetic or electrical fields to controllably cause strains, while smart designs of microfluidic setups induce large shear deformations of the desired structures at high throughput rates.

20.1 Interaction of Laser Light with Biological Material

Since the days of *van Leeuwenhoek*, the inventor of the microscope, light has been the most powerful and intuitive tool for the investigation of cells. Moreover, light microscopy still remains at the forefront of investigative techniques today. Approaches such as stimulated emission depletion (STED) and statistical optical reconstruction microscopy (STORM) go far beyond the resolution limit of Abbe's criteria and are close to achieving molecular resolution [20.1–4]. The fact that light also carries momentum and angular momentum is less intuitive since it is not on a magnitude that can impact our daily lives, however as described herein, this duality renders light an equally well-suited tool to actively manipulate cells in addition to simply seeing them. The forces exerted on biological matter are in the pico- to nanonewton range and may appear small, however these forces are perfectly suited to noninvasively hold and manipulate individual biological cells. This was already recognized by *Ashkin* [20.5, 6] and *Burns* et al. [20.7] shortly after they discovered the fundamental principles of optical trapping.

Because of their average size of several micrometers, direct physical manipulation of whole biological cells is a challenge. Optical traps have therefore attracted the attention of biologists, providing access from the subnano- to the micrometer scale [20.6, 8].

Compared with other micromanipulation tools such as atomic force microscopes (AFMs) or micropipettes, optical traps are able to generate lower forces, in the pico- to nanonewton range, enabling the holding, moving, orienting, and repositioning of micro- and submicrometer objects as well as dynamic force measurements. Additionally, the manipulation is contact-free, which makes this technique perfectly suited for biophysical applications that need to avoid contamination.

Optical forces become very significant when going to small scales. With a simple *gedankenexperiment*, the highest possible light pressure can be estimated for a given light intensity: consider a ray of light, consisting of single photons that carry a certain momentum, hitting a mirror and getting reflected. According to conservation of momentum, the mirror has to experience a change in momentum twice as high as the momentum of all reflected photons. The force exerted is then given by the momentum change per unit time, resulting in a force of 6.6 nN for a light beam with a power of 1W. Besides the momentum change due to reflection, the momentum change of the photons due to refraction also gives rise to a force. This is the primary effect utilized in optical traps. Forces that arise in this manner are smaller than those arising due to reflection and depend on multiple parameters.

Because of the dual wave–particle nature of light, the particle-like picture of photons is true only within certain limits. The full theoretical explanation for the interaction of small dielectric particles with laser radiation strongly depends on the ratio of the particle diameter d to the wavelength λ of the laser light used. Bead diameters $d \gg \lambda$ are described by the Mie regime of ray optics, whereas for $d \ll \lambda$ the Rayleigh regime applies. The case $d \approx \lambda$ is highly nontrivial and requires the exact solution of the Maxwell equations within the given boundary conditions.

In optical traps, the wavelengths used typically range between 600 and 1300 nm, whereas the minimum diameter of eukaryotic cells is about 10 µm. This falls within the Mie regime, also known as the ray-optics regime, and thus the laser beam can be decomposed into individual rays that propagate in a straight line and are therefore described by geometric optics.

Regardless of the regime applied, laser-based particle trapping works only as long as the refractive index of the particle is higher than that of the surrounding medium, which holds for biological materials since their biomolecular content leads to higher refractive indices than water. Only special beam geometries (a donut-shaped mode, for instance) enable particle trapping with a lower refractive index in the region of lowest intensity, which will not be discussed within the presented framework [20.9].

20.1.1 Conservation of Momentum – Gradient and Scattering Force

In the limit $d \gg \lambda$ (Mie regime), the ability of light to exert forces on matter can be explained by simple transfer of momentum. For a vanishing rest mass, the relativistic energy-momentum relation predicts the momentum $\boldsymbol{p}$ carried by a photon as

$$\boldsymbol{p} = \frac{E}{c}\boldsymbol{e}_r \equiv n\frac{E}{c_0}\boldsymbol{e}_r \,, \tag{20.1}$$

where $E = h\nu$ is the energy of a photon of frequency ν, h is the Planck constant, c is the speed of light in the medium, c_0 the speed of light in vacuum, $n = c_0/c$ is the refractive index, and $\boldsymbol{e}_r$ is the unit vector in the direction of propagation.

As a ray of light, consisting of N photons, hits a particle of low opacity, it gets partially reflected or refracted. These interactions effectively change the momentum of each photon, and conservation of mo-

mentum requires a resulting momentum of

$$\begin{aligned}\boldsymbol{p}_{\text{res}} &= N\boldsymbol{p}_{\text{in}} - N\boldsymbol{p}_{\text{out}} = Nn\frac{E}{c_0}(\boldsymbol{e}_{\text{in}} - \boldsymbol{e}_{\text{out}}) \\ &= Nn\frac{E}{c_0}\boldsymbol{e}_{\text{res}} \end{aligned} \tag{20.2}$$

to be picked up by the particle. Here, the vector $\boldsymbol{e}_{\text{out}}$, is the superposition of the reflected and refracted fractions of the light rays, weighted by their respective intensities. Newton's second law allows the calculation of the resulting force, resulting in

$$\boldsymbol{F}_{\text{res}} = \frac{\mathrm{d}\boldsymbol{p}_{\text{res}}}{\mathrm{d}t} = n\frac{N}{c_0}\frac{\mathrm{d}E}{\mathrm{d}t}\boldsymbol{e}_{\text{res}} = n\frac{P}{c_0}\boldsymbol{e}_{\text{res}}\,, \tag{20.3}$$

where $\boldsymbol{e}_{\text{res}}$ is the vector as defined in (20.2), and P is the power of a ray of light consisting of N photons per unit time.

To describe an extended coherent light source composed of infinite single rays, it is appropriate to switch to an integral formulation of (20.3) using the intensity distribution $I(\boldsymbol{r})$, which represents the number of photons with energy E per unit area and time. The resulting force is then given by

$$\boldsymbol{F}_{\text{res}} = \frac{n}{c_0}\int I(\boldsymbol{r})\boldsymbol{e}_{\text{res}}(\boldsymbol{r})\mathrm{d}A\,. \tag{20.4}$$

The integral has to be performed over the whole illuminated surface of the trapped particle, and it is important to realize that the resulting vector $\boldsymbol{e}_{\text{res}}$ depends on the angle of incidence of the laser. In addition, $\boldsymbol{e}_{\text{res}}$ varies over the surface as does the intensity distribution $I(\boldsymbol{r})$. In general, appropriate expressions for $\boldsymbol{e}_{\text{res}}(\boldsymbol{r})$ and $I(\boldsymbol{r})$ that sufficiently characterize the system physically make the equation easily solvable, but nontrivial, especially for irregularly shaped particles. For many experimental situations, the assumption of a homogeneous, spherical particle is sufficient and largely avoids the need for numerical calculations. In the following discussion of parallel and focused laser intensity distributions, particles are therefore assumed to be spherical and homogeneous.

20.1.2 Quasiparallel Laser Light – Dual-Beam Laser Trap

Optical forces can be utilized to effectively trap particles in a dual-beam laser setup consisting of two counter-propagating, nonfocused Gaussian laser beams, which are slightly divergent. Gaussian beams have a light intensity gradient, with the highest intensity in the beam center (on the optical axis) and a decreasing intensity towards the outer off-axis positions. The beam width w increases with increasing distance z from the optical fiber according to

$$w(z) = w_0\sqrt{1 + \left(\frac{\lambda z}{n_1\pi w_0^2}\right)^2}\,. \tag{20.5}$$

Here, w_0 is the initial beam width (= mean field diameter of the optical fiber), λ is the wavelength of the laser light used, and n_1 is the refractive index of the surrounding medium. In order to understand the effects leading to a stable trapping of particles, one must estimate a bundle of parallel light rays at a distance z.

Consider a sphere of radius ρ located at a distance ρ_0 from the optical axis of a parallel Gaussian laser beam with a beam width w (Fig. 20.1). The intensity distribution $I(\boldsymbol{r}) \equiv I(\theta, \varphi, \rho_0)$ illuminating the particle is then given in spherical coordinates by

$$\begin{aligned} I(\theta, \varphi, \rho_0) &= \frac{2P}{w(z)^2\pi} \\ &\times \exp\left(-\frac{2\rho^2\sin^2(\theta) + \rho_0^2 - 2\rho_0\rho\sin(\theta)\sin(\varphi)}{w(z)^2}\right)\,. \end{aligned} \tag{20.6}$$

Equation (20.6) is the intensity distribution as required in (20.4).

To determine the vector, $\boldsymbol{e}_{\text{res}}$, consider a single ray of power P hitting a sphere at an angle of incidence θ with an incident momentum per second of n_1P/c_0. The

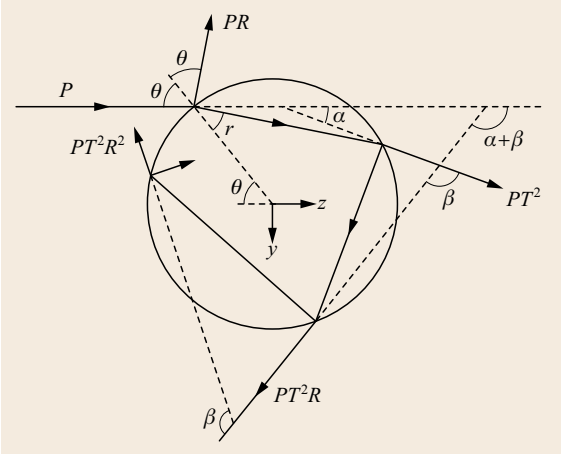

Fig. 20.1 A ray of power P hits a sphere at an angle θ where it partially reflects and partially refracts. These scattered rays make angles relative to the incident forward ray direction of $\pi + 2\theta, \alpha, \alpha + \beta, \ldots, \alpha + n\beta, \ldots$, respectively. Note the geometric relations $\alpha = 2\theta - 2r$ and $\beta = \pi - 2r$

total force on the sphere is the sum of contributions due to the reflected ray of power PR and the infinite number of emergent refracted rays of successively decreasing power $PT^2, PT^2R, \ldots, PT^2R^n, \ldots$, whereas $T(\theta)$ and $R(\theta)$ are the angle-dependent Fresnel coefficients for transmission and reflection.

The subsequent calculation of all appearing forces [20.5] yields a resulting force $\boldsymbol{F}_{\mathrm{res}}$, which is commonly separated into components parallel and perpendicular to the direction of propagation: the scattering force F_{scat} and the gradient force F_{grad}, respectively.

$$\boldsymbol{F}_{\mathrm{res}} = \sum_{\text{all photons}} \frac{\mathrm{d}\boldsymbol{p}_{\mathrm{res}}}{\mathrm{d}t} = \begin{pmatrix} F_{\mathrm{grad}} \\ F_{\mathrm{scat}} \end{pmatrix} , \tag{20.7}$$

where the components F_{grad} and F_{scat} are given by the analytically unsolvable expressions

$$F_{\mathrm{grad}} = \frac{n_1}{c_0} \int_0^{\pi/2} \mathrm{d}\theta \int_0^{2\pi} \mathrm{d}\varphi I(\theta, \varphi, \rho_0) \rho^2 \sin^2(\theta) \sin(\varphi) \times \left(R(\theta) \sin(2\theta) - \frac{T(\theta)^2 [\sin(2\theta - 2r) + R(\theta) \sin(2\theta)]}{1 + R(\theta)^2 + 2R(\theta) \cos(2r)} \right) \tag{20.8}$$

and

$$F_{\mathrm{scat}} = \frac{n_1}{c_0} \int_0^{\pi/2} \mathrm{d}\theta \int_0^{2\pi} \mathrm{d}\varphi I(\theta, \varphi, \rho_0) \rho^2 \sin(\theta) \cos(\varphi) \times \left(1 + R(\theta) \cos(2\theta) - \frac{T(\theta)^2 [\cos(2\theta - 2r) + R(\theta) \cos(2\theta)]}{1 + R(\theta)^2 + 2R(\theta) \cos(2r)} \right) . \tag{20.9}$$

In (20.8) and (20.9), n_1 stands for the refractive index of the surrounding medium, c_0 is the speed of light in vacuum, $R(\theta)$ and $T(\theta) \equiv 1 - R(\theta)$ are Fresnel coefficients describing reflection and transmission, and r is the refraction angle according to Snell's law.

A subsequent analysis of the expressions of the perpendicular components of the resulting force shows that the scattering force arising from a divergent laser beam pushes a trapped sphere away from the laser source, whereas the gradient force pulls it onto the beam axis.

Dual-beam optical traps consist of two counter-propagating laser beams, causing the scattering forces to cancel each other out in the middle. Gradient forces, however, are added up so that the particle is stably trapped on the beam axis.

20.1.3 Focused Laser Light – Optical Tweezers

For beams of complex shape, such as the highly convergent beams used in so-called optical tweezers, the calculation of arising forces becomes more complicated since the angle of incidence on the surface depends on both the polar coordinate θ as well as the relative position of the sphere from the focal point. Nevertheless, the concept of gradient forces and scattering forces can still be applied and at least allows a qualitative understanding of the underlying mechanism of trapping.

Consider a tightly focused laser beam, as illustrated in Fig. 20.2, and a spherical particle near the focal point [20.5]. The trap's underlying working principle for a dielectric sphere can be described in terms of the total force due to a representative pair of rays a and b of the converging beam when neglecting reflection. Using this simplification, the forces F_{a} and F_{b} are caused entirely by refraction and are pointing in the direction of the momentum change due to conservation of momentum (Fig. 20.2a,b).

In experiments, reflection cannot be excluded. Therefore, scattering forces appear in addition to the gradient forces (denoted as F_{a} and F_{b} in Fig. 20.2). For the successful trapping of a particle, the gradient force must exceed the scattering force. Otherwise, the particle will be pushed out of the focus in the direction of light propagation. In order to avoid this, an objective with a high numerical aperture is employed: the higher the aperture is, the tighter the focus, and, therefore, the higher the ratio $F_{\mathrm{grad}}/F_{\mathrm{scat}}$ becomes.

There are several factors influencing the efficiency of a focused laser beam trap. In addition to the laser power, the numerical aperture of the objective and the employed laser mode, the effective refractive index,

$$m = \frac{n_{\mathrm{medium}}}{n_{\mathrm{particle}}} , \tag{20.10}$$

has the greatest effect. Hence, the most convenient way to improve trap efficiency is to increase the effective refractive index.

Because of the complex set of parameters influencing the trapping force, the nontrivial and necessary numerical calculation, and the fact that the particles of interest often don't fulfill the Mie regime criteria $d \gg \lambda$, the real trapping force of optical tweezers has to be determined experimentally. A very common force-calibration method is based on the observation of the Brownian motion of a trapped particle, which assumes

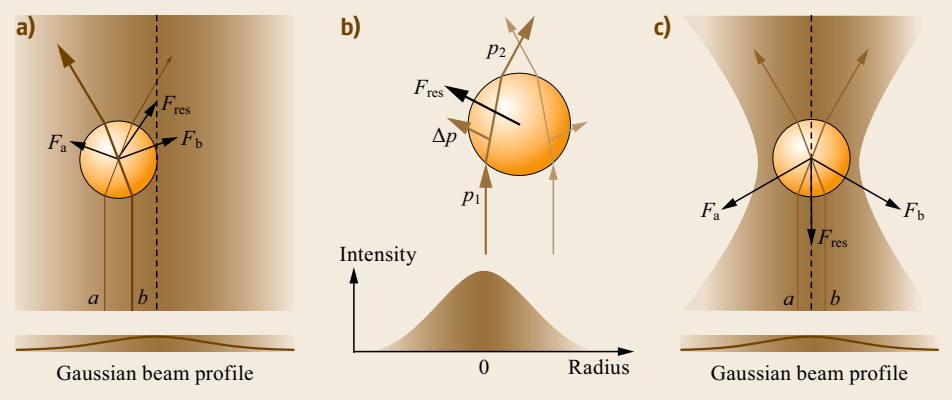

Fig. 20.2 **(a)** In a Gaussian laser beam the rays are refracted when entering and exiting a particle. This change of direction causes a change of momentum resulting in optical forces. In a straight beam these arising forces push the particle down the stream. **(b)** A restoring gradient force towards the beam axis occurs when the particle is off-center. **(c)** In the case of a tightly focused beam this gradient force points towards the beam waist and against the scattering force. These two forces are balanced downstream of the waist causing a stable trapped state (after [20.10])

a harmonic potential generated by the optical tweezers. The fluctuation $x(t)$ of a small particle within a viscous medium satisfies the well-known Langevin equation for the overdamped oscillator,

$$\gamma \frac{\mathrm{d}x}{\mathrm{d}t} + kx = F(t) \,, \tag{20.11}$$

where γ is the hydrodynamic drag coefficient, k is the spring constant of the harmonic potential, and $F(t)$ is the stochastic force experienced by the particle due to the thermal motion of the molecules in the solution. The power spectrum for $x(t)$ can be derived by taking the Fourier transform and the modulus squared, which gives a Lorentzian curve

$$S(f) = \frac{k_\mathrm{B}T}{\gamma\pi^2(f^2 + f_\mathrm{c}^2)} \,, \tag{20.12}$$

where f is the frequency, k_B is the Boltzmann constant, T is the sample temperature, and f_c is the corner frequency. By fitting the power spectrum of the measured positions $x(t)$ to the Lorentzian curve (20.12), the corner frequency f_c provides the desired spring constant k using the relation

$$f_\mathrm{c} = \frac{k}{2\pi\gamma} \,. \tag{20.13}$$

The harmonic potential $V(x)$, generated by optical tweezers, is therefore given by $V(x) = 1/2\,kx^2$, which is a good approximation for small displacements. Once calibrated, the displacement of a bead from the center of the optical trap can be associated with a force, thus allowing the performance of force measurements in the pico- to nanonewton range.

The described procedure has to be understood as a basic recipe for force calibration. The hydrodynamic drag coefficient γ depends on the viscosity of the surrounding medium, which is, in turn, temperature dependent. Because of the heating of the laser, the temperature of the medium varies locally, which has a direct effect on Brownian motion, and, consequently, on the fluctuation of the observed particle. More advanced calibration methods account for this and other errors [20.11, 12].

20.2 Optical and Magnetic Tweezers for Single-Molecule Manipulations

When Kepler looked through his telescope to observe comets roughly 400 years ago, he suggested that the deflection of their tails was caused by solar ray pressure. Although Newton predicted and Bartoli and Maxwell theoretically deduced forces induced by radiation, it was not until 1901 that Lebedev experimentally verified electromagnetic pressure. A few years later, *Debye* presented his dissertation regarding radiation pressure on spheres of different materials [20.13]. However, until the development of lasers as light sources with sufficiently high intensities, this principle could not be used to exert forces on microscopic objects. In 1970, *Ashkin*,

who was working at the Bell Telephone Laboratories, observed that freely suspended particles are accelerated by the forces of radiation pressure from visible laser light [20.8]. In 1986, he published his paper on the *Observation of a single beam gradient force optical trap for dielectric particles*, therein describing the first instance of using light to stably hold micro- and nanoscale objects on the size scale of cells in place [20.14]. This broad concept of manipulating microscopic matter with external fields – whether electromagnetic or magnetic – underpins the techniques that are nowadays known as *optical* and *magnetic tweezers*.

20.2.1 Optical Tweezers

With the invention of optical traps in the 1980s, it became possible to generate and measure forces in the unprecedented range of pico- and nanonewtons. For the first time, microscopic particles such as living cells or bacteria could be individually manipulated. Today, optical tweezers are the most common type of optical traps, and due to their simplicity, they are used in a wide range of different applications.

Their construction essentially only requires a laser and a lens, although applying several lenses and optical devices is useful for controlling the form and position of the laser beam. A conventional optical microscope with a high-aperture objective is sufficient to produce a diffraction-limited focal spot that can act as a trap and already has imaging potential. Furthermore, an important criterion for stable realization of the trap is a minimization of room-temperature variations, acoustic noise, and mechanical vibrations.

For the practical realization of optical tweezers, lasers in the near infrared, e.g., 800 or 1024 nm, are typically used, since biological samples show low absorption at these wavelengths. Currently, diode or fiber lasers are displacing common Nd:YAG or Ti:sapphire lasers due to their lower costs and maintenance needs.

In the simplest setup, the laser beam is broadened by a beam expander, i. e., a telescopic lens system, to fully illuminate the back aperture of the objective before being coupled into the light path of the microscope by a dichroic mirror. Some setups use piezoelectric microscope stages to move the trap with respect to the sample. To facilitate relocation of the trap without moving the stage, beam-steering devices such as acousto-optical deflectors (AODs) or galvanometrically controlled mirrors can be inserted into the beam path. The more common AODs are crystals with a high optical density in which high-frequency acoustic waves are generated and the incoming laser beam is diffracted due to the acousto-optical effect. By tuning the frequency and amplitude of the acoustic waves, the output angle and intensity of the laser beam can be rapidly controlled with great accuracy. Fast switching of the beam deflection angle even allows for simulating multiple traps. Besides controlling the direction of the beam, the amplitude can be attenuated using acousto-optical modulators (AOMs), which work on the same principles as AODs [20.15, 16].

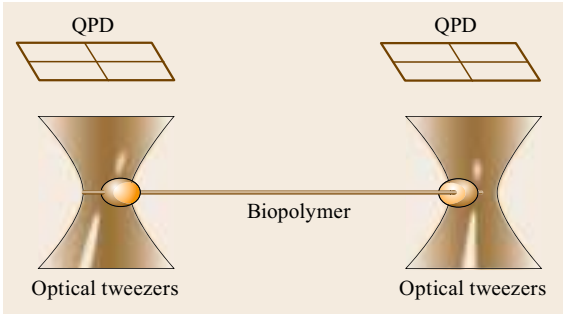

Fig. 20.3 The diffraction pattern of the optical tweezers can be recorded by QPDs and changes if the trapped particle is deflected from the trap center. Force calibrations of the trap allow an attribution of these changes to pulling forces, which can be used to derive stress-strain relations

These additional components allow precise movements of the trapping laser and accordingly the trapped particle, which can be recorded via an external camera. Attaching these particles, for instance to biopolymeric structures, allows an experimenter to controllably deform them in order to investigate their mechanical features and responses against external stimuli [20.17, 18].

If a CCD (charge-coupled device) camera is not sufficient as a position detection system, the setup can be expanded by a quadrant photodiode (QPD) system. After penetrating the sample, the laser light is recollimated by a second objective and projected onto the QPD. A trapped particle causes a diffraction pattern that only depends on its position with respect to the trap center [20.19]. External forces pulling the particle out of the trap center cause a change of the diffraction pattern. Calibrations of the tweezers facilitate the determination of the according forces (Fig. 20.3). Thus, stress-strain profiles for the probed structures (e.g., biopolymers) can be recorded to evaluate their mechanical properties or even monitor dynamic processes [20.18, 20–22].

Trapping of Macromolecules by Dynamic Temperature Fields

Recently, a highly novel trapping design has succeeded in eliminating the direct interaction of the incident light with the probe molecule, instead indirectly inducing the process through the plasmonically driven generation of

thermal fields [20.23–25]. This innovative methodology depends on the coupling of two fundamental physical principles working in unison – thermophoresis and surface plasmon resonance (SPR) – which are dynamically controlled to trap and direct the motions of nanoparticles and macrobiomolecules. Here, the basic trapping chamber is integrated with plasmonically active gold nanostructures using microfabrication techniques. The simplest setup resembles a circular cavity of approximately 5–6 μm in diameter, formed in a 50 nm gold film (Fig. 20.4), via microsphere lithography and thermal evaporation [20.25]. When focused laser light in the visible range (532 nm) is incident upon the edge of the gold structure, localized surface plasmon resonance leads to the conversion of optical energy to heat around the nanoscale ridge structure. This in turn creates a significant, but localized temperature gradient of several 10 K per μm within the surrounding solution. Viewed over the entire trap structure, this gradient can be seen as an inhomogeneous thermal field. For a large nanoparticle such as a 200 nm polystyrene bead [20.24, 25] or a long strand of lambda-DNA (deoxyribonucleic acid) [20.23] in solution, such a field generates a net directional force along one direction of the gradient, an effect termed thermophoresis [20.26]. This arises from a temperature gradient along the surface of the particle inducing an interfacial fluid flow, which acts to move the particle through the solution. In most cases, this leads to particle movement towards the cold region, although in fewer cases, movement in the opposite direction, termed *negative thermophoresis*, is observed.

In this setup, the laser-induced heating of the edges of the chamber leads to a gradient which grows cooler towards its center, causing a particle to become effectively trapped. By altering the laser power, and subsequently the magnitude of the gradient, the diameter of the trap can be controlled [20.25]. A more recent design included a dynamic feedback loop, where the position of the trapped particle is detected with a CCD camera, and the incident laser at the edge of the chamber is steered with the help of an AOD to optimize the thermal gradient [20.23]. This enabled a fast switching of the gradient in response to particle diffusion, leading to a higher trapping efficiency while effectively decreasing the necessary laser power, and the resulting temperature increment at the trapped particle. This ability to precisely tailor the thermal field offers a dual advantage. First, this allowed for smaller particles (with diameters down to 28 nm) and biological macromolecules (here, lambda-DNA) which would normally be difficult to hold in a static thermal gradient, to be stably trapped for long times. Additionally, a dynamic control over the overall thermal field opens the possibility for this methodology to be utilized for on-the-fly manipulation of the trapped objects.

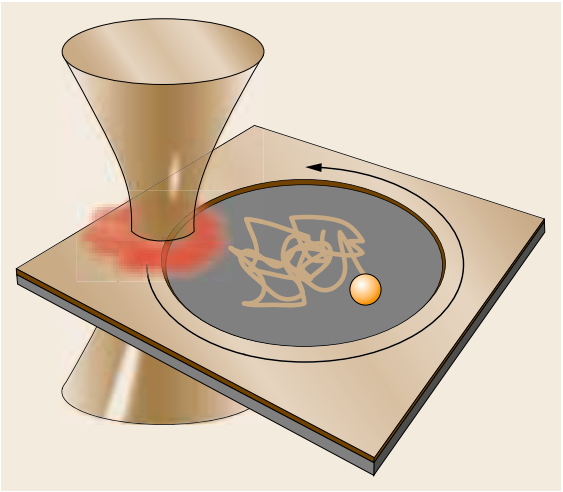

Fig. 20.4 Optically induced thermophoretic trap. A small circular chamber of a few μm in diameter is fabricated into a 50 nm thick gold film. Focused laser light incident upon the nanostructured edge causes local heating due to surface plasmon resonance. The resulting thermal gradient leads to a thermophoretic force on the particle towards the cooler areas. The resulting field from local heating around the edge of the chamber leads to an effective trapping of the particle

20.2.2 Magnetic Tweezers

Optical tweezers have some inherent limitations when used to probe biological samples. The laser light that heats the sample – possibly even to biologically incompatible temperatures which can lead to denaturation of proteins or biopolymers – may interact with other particles within the sample, or cause photodamage. A different, contact-free method for single-molecule or whole-cell experiments consists of so-called magnetic tweezers. Experiments involve attaching magnetic particles, e.g., beads comprised of paramagnetic nanoparticles, to the structures which are tested (Fig. 20.5). These particles can be manipulated by a setup exposing them to an external magnetic field $\boldsymbol{B}$, which induces a magnetic momentum $\boldsymbol{m}(\boldsymbol{B})$ proportional to the magnetic field $\boldsymbol{m}(\boldsymbol{B}) = V\chi\boldsymbol{B}/\mu_0$ with μ_0 being the vacuum permeability, V the volume of the particle, and χ the magnetic susceptibility. An induced magnetic moment saturates at a material-dependent value $\boldsymbol{m}_{\text{saturation}}$ in strong magnetic fields, and induced forces $\boldsymbol{F}$ can be derived from the potential $U = -1/2\,\boldsymbol{m}(\boldsymbol{B})\cdot\boldsymbol{B}$ for the according magnetic momentum [20.27].

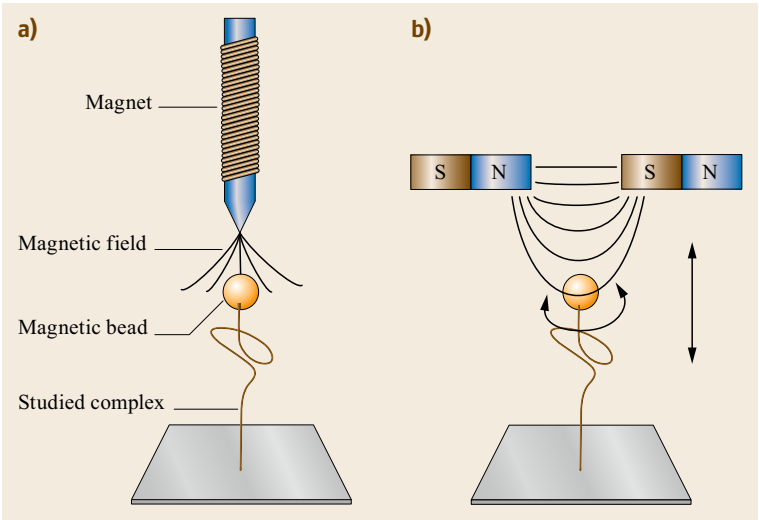

Fig. 20.5a,b Magnetic fields can be used to effectively manipulate magnetic particles. **(a)** A single magnet is sufficient to pull on a magnet bead inducing a stress-dependent strain in the studied structure. **(b)** Using at least two magnets allows not only a pull but also induction of torques on structures

Because of the highly specific interaction of the particle with the magnetic field, stresses are applied solely at the test structure (Fig. 20.5) leaving the rest of the sample practically unaffected.

Forces in the pico- and nanonewton range can be exerted to induce strains in the sample. Measurements are conducted via visual inspection and image acquisition to monitor the displacement of the bead as a response to the imposed magnetic field. Thus, the spatial and temporal resolution of the bead position depend highly on the properties of the recording camera. To evaluate not only the x- and y-position of the bead but also its vertical deflection or z-position, the diffraction rings around beads can be analyzed. These rings occur as an optical effect if the bead moves out of the focal plane of the objective. To precisely determine the z-position, the diffraction pattern has to be compared and normalized to a reference bead with known distances from the focal plane. During this calibration, the bead is fixed while moving the objective by defined distances, which later allows an attribution of specific diffraction patterns to an according z-position with a precision of a few nanometers [20.28]. When using an electromagnet-based setup, the field strength and its direction can be precisely adjusted by the amplitude and phase of the current for the magnets, which can be controlled by a feedback loop depending on the coordinates of the bead. Thus, the bead can be either held at a specific position or precisely moved by alterations of the magnetic field.

Monitoring and evaluating the exact position of the bead at a given time can be used to derive stress-strain relations. These facilitate the determination of the mechanical properties of the structure and further enable, for instance, the evaluation of binding events between subdomains. In addition to stretching forces, magnetic tweezers are also able to induce torsional strains. The magnetic particles themselves gain their special characteristics from embedded paramagnetic nanoparticles. Since the distribution of these nanoparticles within the bead inherently develops anisotropies, the arising magnetic moment is never perfectly aligned with the external magnetic field. Thus, torsional forces arise, aiming to align $\boldsymbol{m}$ and $\boldsymbol{B}$, which are usually sufficient to twist the tested molecule. Exerting torques is also possible with optical tweezers employing a circularly polarized laser beam and birefringent beads. However, magnetic tweezers are able to measure a multitude of the molecules in parallel since they are not limited to one focal spot.

20.2.3 Mechanical Measurements of Biomolecular Ensembles

The ability for optical and magnetic tweezers to accurately measure forces on the magnitude relevant to single biomolecules has made them invaluable tools for the quantitative characterization of the fundamental mechanisms and machinery underpinning the vast complexity of cells. Active force generation as well as processes driven by entropic or enthalpic mechanisms, respectively, can be readily quantified to complement the existing picture of cellular processes [20.29].

Measurement of Passive Force Generation

The predominant picture of biologically generated forces relies on active, energy-dissipating processes based on molecular motors. However, a series of studies employing optical tweezers has revealed that biomolecular ensembles can generate biologically relevant forces

without the need to convert energy into mechanical work. Experiments with pairs of microtubules or actin filaments, respectively, have proven that these biopolymers contract in crowded environments by entropic means – so-called depletion forces – to achieve a maximized overlap of their contours [20.21]. These biopolymers were each attached to a bead one micrometer in size, which were trapped by optical tweezers, similar to the configuration shown in Fig. 20.3. Emergent retraction forces deflected the beads off the trap center, corresponding to the magnitude of the contractile force on the order of 0.1 pN, independent of the overlap lengths of the biopolymers. Upon addition of a third rod, forces have been shown to be pairwise additive. Scaling up this additivity to a multifilament scale, like in the case of actin bundles, revealed very different dynamics within the contractile process when compared to the pairwise case. The magnitude of the contractile forces has not been reported to be constant as in the pair-wise case, but decayed exponentially during contraction, depending on the overlap of the constituting filaments. In this bundled case, maximal forces even reached up to 3.5 pN, a regime which corresponds to the activity of single molecular motors [20.18].

Besides depletion force-induced contractions, recent studies emphasize the role of crosslinking proteins for force generation. These proteins interconnect biopolymers and utilize their parallel alignment at high concentrations to maximize available binding sites. If several of these crosslinking proteins are confined, for instance between two axially shifted microtubules, their thermal motion leads to the generation of force aiming to drive the microtubules to a maximized overlap, i. e., to maximally available binding sites. When intentionally deflecting these rods by optical tweezers, available binding sites are reduced and the system exerts restoring forces similarly to a gas spring [20.22]. These forces are even sufficient to stall active molecular motors, a scenario which might explain the interplay of antiparallel microtubules in the midzone of the mitotic spindle forming during cell division [20.30].

Crosslinkers can also alter properties of biopolymer arrangements drastically and even add their own contributions to the system. An inherent property of most naturally occurring crosslinking proteins is that they constantly bind and unbind to the according biopolymer with discrete on- and off-rates. This so-called transient binding leads to rearranging effects and facilitates time-dependent responses of the entire structure. Actin bundles crosslinked by alpha-actinin and attached to a polystyrene bead, for instance, predominantly show elastic responses when deformed on a short time scale via optical tweezers. Deforming these bundles on longer time scales, however, reveals plasticity effects due to crosslinker rearrangements stabilizing the deformed configuration over time [20.17]. At the point of deformation, the bead is deflected off the trap center, since the stressed bundle aims to restore its equilibrium position. The involved crosslinkers rearrange in a time-dependent manner and stabilize the deformed configuration, which in turn slowly releases the stress, allowing the bead to slowly relax into the trap center again.

Optical tweezers-based experiments can be used to probe the mechanical properties of a wide range of biopolymers in reconstituted systems. So far, only studies on cytoskeletal proteins have been described, but this versatile tool is also widely employed to investigate DNA structures and DNA-related processes. Attaching the desired DNA structure to beads enables optical-tweezers-assisted force-clamp measurements or stretching experiments to quantify the according mechanical properties of the probe molecule. Force-clamp measurements are especially suitable to determine forces for DNA condensation processes. An inherently important process is the compacting of DNA via histones in order to condense this carrier of genetic information into the tiny space inside the nucleus. These histones are protein complexes able to exert sufficiently high forces to fold DNA appropriately in order to achieve a high packing density. Force-clamp measurements have revealed that histone activity is stalled only for relatively high forces around 40 pN and that two characteristic force regimes arise for the histone-like protein from *Thermotoga maritima* [20.31].

Measurement and Manipulation of Actively Driven Molecular Motors

Classically, the initial groundbreaking work for single-molecule characterization of biological materials with optical tweezers was based on the study of individual molecular motors such as kinesin [20.32, 33] and myosin [20.34, 35]. These translocate along microtubules or actin filaments, respectively, while converting chemical energy in the form of adenosine triphosphate (ATP) to kinetic motion. In early studies, motor proteins were attached to the surface of microscopic beads consisting of either silica or polystyrene, which could be manipulated by an optical trap during the course of translocation along the corresponding filament type (Fig. 20.6). By applying an optical force against the direction of motion until the bead-motor complex stalled [20.33], or conversely by reducing the force until motors were able to escape the trap [20.34], the force generated by single motors could be deter-

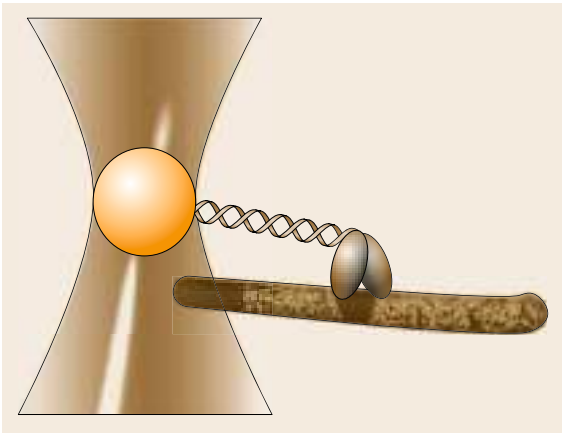

Fig. 20.6 Manipulation of a translocating molecular motor with an optical tweezers setup. A molecular motor (e.g., kinesin or myosin) undergoes directed motion along its corresponding filament type (microtubule or actin, respectively). The motor is physically tethered to a bead, which can be actively manipulated in order to determine physical properties of the motors such as stalling force

mined with single pN resolution. Measurements revealed that individual kinesin motors are capable of exerting roughly 5−6 pN of force during translocation along a microtubule, while motile subunits of myosin II generate between 1−5 pN of force along actin filaments [20.35].

Similarly, the ATP-dependent translocation of DNA-specific motors has been heavily investigated with the help of magnetic tweezers. One set of studies in particular focused on the DNA enzyme EcoR124I [20.36, 37]. This is a multisubunit motor where a core unit recognizes and binds a specific DNA sequence, then the two flanking subunits translocate in a unidirectional manner along the DNA strand. This draws the DNA towards the central unit, thereby creating pairs of DNA loops. The result is an overall decrease in the end-to-end distance, which can be analyzed with the help of a standard magnetic tweezers setup. Here, the translocation of a single flanking subunit along a DNA strand was investigated in order to determine properties such as the translocation rate, dependence on ATP concentration and generation of helical torque [20.36] as well as step size and ATP coupling efficiency [20.37]. A long DNA segment was anchored on one end to the surface and bound on the other end to a magnetic bead, which was used to stretch and supercoil the DNA molecule with the help of two external magnets. By monitoring the end-to-end distance during single translocation events, a translocation speed of 550±30 DNA base pairs per second was found at a saturating ATP concentration of 4 mM, and the quantification of supercoil unwinding demonstrated a helical pitch for the motor, matching that of the DNA double-helix. Later studies confirmed a basic step-size of one base with approximately one ATP molecule consumed during each step.

The ability to apply torsional forces to beads in a magnetic trap has also been instrumental in uncovering the chemical details of molecular motors exhibiting a rotational motion rather than directed linear translocation. Most famously, the coupling of mechanical work to the chemical synthesis of ATP molecules by the rotary F1-ATPase molecular motor has been determined on the single-molecule level [20.38, 39]. This motor is part of the ATP synthase complex responsible for generating ATP in biological systems, by coupling proton gradients to chemical synthesis. When isolated in vitro, the F1 fragment hydrolyzes ATP molecules at the rate of three catalytic events per full counterclockwise (viewed from above) turn. By attaching a magnetic bead to the central rotary γ subunit, it was shown that rotations in the reverse (clockwise) direction, mechanically driven by magnetic forces, led to the generation of ATP with up to 77% mechanochemical coupling efficiency [20.39].

Measurement of Specific Ligand Recognition

Specific receptor-ligand recognition events can also be characterized on a single-molecule level through dynamic force spectroscopy enabled by optical tweezers. In particular, the specificity of monoclonal antibodies (mAb) to their target ligand can be investigated by optical tweezers-enabled dynamic force spectroscopy in order to precisely determine binding kinetics and determine possible off-target cross-reactions [20.40]. This was carried out for the mAb HPT-101, which is known to bind to specific markers on proteins that are potential early indicators for Alzheimer's disease. Previous studies in steady-state, equilibrium conditions using the enzyme-linked immunosorbent assay (ELISA) have indicated that HPT-101 binds exclusively to the double-phosphorylated tau-proteins. While no indication of off-target binding to the corresponding mono-phosphorylated variant has been seen in ELISA, this does not reveal quantitative details of the dynamic binding process where all cross-reactions would be evident.

Here, a two-bead setup was used, where one is trapped in optical tweezers, while the other is fixed on the tip of a micropipette and can be spatially manipulated, e.g., retracted with a known velocity. The mAb is immobilized on the bead in the laser trap, and the target region of the tau-protein – either the double- or one of the two mono-phosphorylated derivatives – is immobilized on the pipette-fixed bead (Fig. 20.7).

By initially bringing the beads into contact to establish mAb-peptide binding and then retracting the pipette-bound bead from the trap until rupture is observed, the frequency of binding events was measured. This unexpectedly revealed that off-target binding to the two mono-phosphorylated derivatives does indeed occur at a comparable frequency (0.20 ± 0.12 and 0.15 ± 0.04) to the standard double-phosphorylated target (0.31 ± 0.08). The apparent discrepancy to earlier ELISA results was resolved by determining the average bond lifetime through force-induced unbinding events. By measuring the average force required to rupture the mAb-peptide bond through the application of a force ramp (with an applied loading rate of $56 \pm 7\,\mathrm{pNs}^{-1}$), the average bond lifetime was calculated. This showed that the bond between the mAb and double-phosphorylated target has a lifetime of approximately 10 and 40 times that of the two off-target mono-phosphorylated variants, explaining the lack of observed binding at steady-state conditions. A further study utilized the same range of tweezers-based techniques to scan the sequence of the target region and identify distinct amino acids that were essential to the specific binding of the mAb [20.41]. Such a precise kinetic analysis is not possible with equilibrium conditions in standard ELISA assays, and offers important information that can be used to selectively optimize antibody specificity in a deterministic manner.

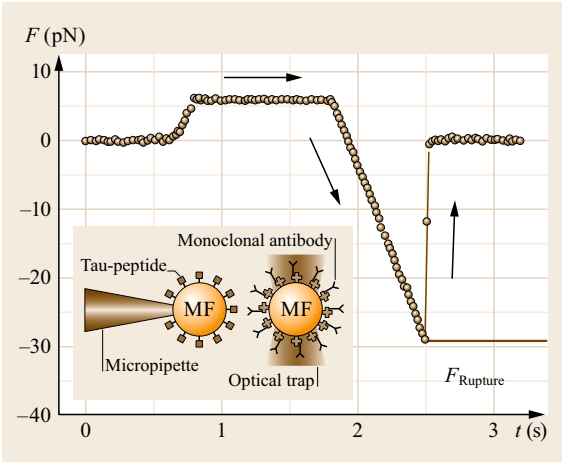

Fig. 20.7 Specific ligand recognition characterized by an optical tweezers setup. (*Inset*) The ligand of interest is immobilized on a micropipette-bound bead which can be freely manipulated, while the receptor, in this case an antibody, is on a separate bead held by a force-calibrated optical trap. Bringing the beads into contact induces ligand-receptor binding, and subsequent retraction to the point of bond rupture allows the quantitative examination of bond kinetics [20.40]

Bottom-Up Construction of Tools for Micromechanical Characterization

More recently, advances made in the last decade for the bottom-up, structural and mechanical programming of materials, starting from the single-molecule level, have facilitated a new range of complementary tools to enrich these micromechanical techniques. Most prominent amongst these is the advent of structural DNA nanotechnology, which enables the construction of discrete objects of defined size and shape, with molecular precision. Approaches such as DNA origami [20.43] or tile-based DNA construction [20.44, 45] are based on the self-assembly of sequence-defined sets consisting of anywhere from a few to several hundred synthetically produced DNA oligonucleotides. Through the hybridization of strands with complementary sequences based on the Watson-Crick nucleobase pairing of adenine to thymine and guanine to cytosine, complex objects can be designed and constructed with structural and functional resolution on the size scale of a single base-pair (3.4 Å). Beyond their potential for biomedical applications [20.46], these hold a particular importance for the micromechanical techniques described in this chapter, since their underlying structural properties, e.g.,

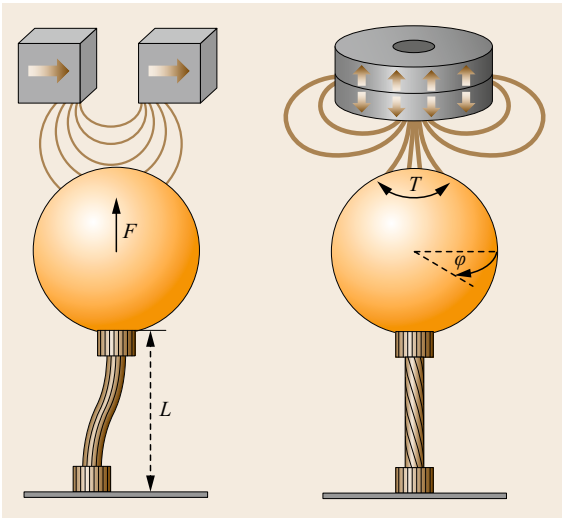

Fig. 20.8 Probing the bending and torsional rigidity of a rod-like DNA nanostructure with magnetic tweezers. Rod-like DNA origami structures are fixed on one end to a surface and on the other to a magnetic bead. By applying shear or torsional force from external magnets, the bending ($l_{p,b}$) and torsional ($l_{p,t}$) persistence lengths can be determined [20.42]

bending [20.47, 48] or torsional rigidity [20.42], can be deterministically controlled, opening possibilities for

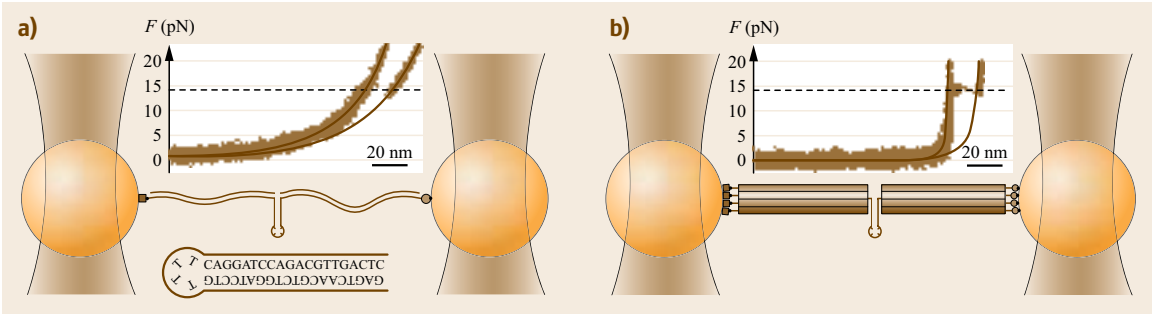

Fig. 20.9a,b Rigid DNA-based beams for noise suppression in optical tweezers-assisted single-molecule force spectroscopy. **(a)** Flexible double-stranded DNA linkers between optically manipulated beads and a macromolecule of interest (here, 20-base-pair DNA hairpin) lead to a high amount of noise and inability to precisely determine conformational transitions in the low-force (single-pN) regime. **(b)** By contrast, rigid beam connectors constructed from DNA origami suppress Brownian fluctuations, thereby increasing the resolution of observed transitions [20.49]

their use as mechanical standards or thermal noise suppressors.

One recent study [20.42] points towards the ability to use these bottom-up methods for fabricating precisely tailored mechanical calibration standards. Semi-flexible, rod-like structures were formed using the DNA origami method, consisting of parallel bundles of double-stranded DNA (dsDNA) arranged in a tube-like configuration. Two such structures were characterized in this study: a so-called six-helix bundle (6HB of six parallel helices, measuring 371 nm long and approximately 8 nm in diameter, and a four-helix bundle (4HB) with a length of 478 nm and a diameter of 5 nm. The bending and torsional rigidity of each species was determined by magnetic tweezers (Fig. 20.8), and compared to the standard of a dsDNA segment with a length of 428 nm. Compared to dsDNA, both rod-like DNA origami *n*HBs (n = number of helices) showed a significant increase in rigidity. Bending rigidity was seen to approximately scale with n^2, with the persistence length $l_{p,b}$ increasing from 50 nm for dsDNA to 740 ± 140 nm for 4HBs and 1880 ± 270 nm for 6HBs. The torsional rigidity had a weaker scaling proportional to n, with $l_{p,t}$ increasing from 97 ± 4 nm for dsDNA to 390 ± 30 nm for 4HBs and 530 ± 20 nm for 6HBs. This ability to deterministically *program* the material properties of discrete objects can be applied to craft mechanical rulers for the precise calibration of magnetic and optical tweezers systems.

Rigid DNA structures can also be utilized to suppress inherent thermal noise in single-molecule force measurements by optical tweezers. Measuring conformational transitions in single proteins or other macromolecules often involves the necessity to measure small length changes on the order of single nanometers, and force regimes less than 10 pN. Usually, the molecules of interest are attached at a distance to the trapped beads by dsDNA segments or some other predominantly flexible linker. Measurements at this high resolution are limited in the case of conventional force spectroscopy by optical or magnetic tweezers due to inherent thermal noise arising from Brownian fluctuations of beads and linkers. A recent study [20.49] showed that rigid beam-like structures from DNA could suppress noise in this low-force regime (Fig. 20.9). 250 nm beams consisting of 10 parallel double helices (10HB) in a roughly block-like configuration were constructed using the DNA origami method, and found to be completely rigid. As a proof of concept, a 20-base DNA hairpin, known to have an unzipping force of approximately 15 pN, was used as a standard probe molecule. Force-extension curves for the unzipping transition were compared for both the rigid beam linkers as well as for more flexible dsDNA linkers (modeled as a worm-like chain with $l_p = 50$ nm). Noise suppression by the rigid DNA origami linker at loads of 14 pN provided greater detail of information about the energy landscape of the hairpin transition. This included transiently populated substrates and sharper barriers which were masked with the flexible DNA linkers. This highlights the ability of these bottom-up methods to not only give cleaner, less noisy data, but also enable the acquisition of basic physical information which is otherwise unavailable through conventional means.

Novel DNA-based architectures can also be designed for assisting in mechanochemical analysis of molecules, where chemical processes are coupled to mechanical changes detectible by force spectroscopy methods. In one such study, an interconnected chain of seven DNA origami segments was used as a means to improve upon not only the detection limit and time resolution of mechanochemical sensing events, but also

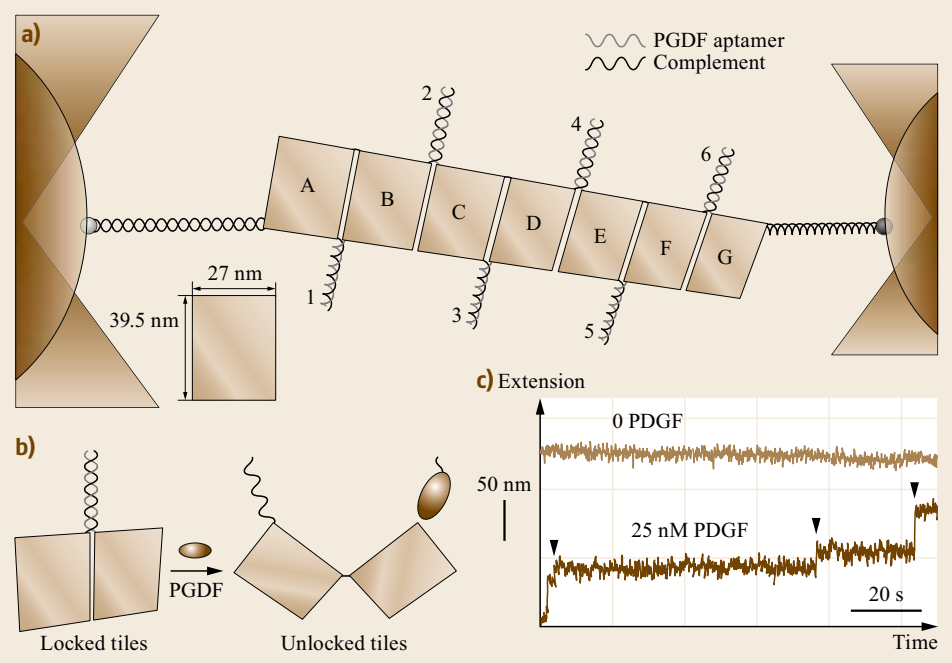

Fig. 20.10a–c Enhanced mechanochemical sensing with the aid of DNA origami. **(a)** A DNA origami structure with seven interconnected segments is maintained in a *closed* conformation by aptamer-based locks for a target molecule while held at a constant force by a dual-trap optical tweezers setup. **(b)** Upon attachment of the target molecule (here, PDGF) to the aptamer, the lock is opened, creating an outstretched configuration which **(c)** can be detected as jumps in the relative force-distance curves of the two beads [20.50]

enable simultaneous multiplexed sensing of multiple targets [20.50]. Aptamer-based recognition elements for platelet-derived growth factor (PDGF) were integrated as locking elements between neighboring segments in such a way that binding of the molecule would release the lock, thereby inducing a mechanical change (Fig. 20.10a,b). When tethered between two beads held at a constant force of 8 pN in an optical tweezers setup, this associated elongation of the overall structure could be detected by distinct jumps of approximately 40 nm in the force-extension curves (Fig. 20.10c). Compared to a mechanochemical sensor with only a single recognition element, the integration of six parallel elements on the DNA origami-based backbone reduced the lower detection limit by a factor of 10 from 100 pM to 10 pM, while simultaneously reducing the necessary measurement time from 30 to 10 min. The same approach was additionally used to enable multiplexed sensing of multiple targets. In this case, PGDF recognition elements and an additional element unlocked by the hybridization of a complementary DNA sequence were coupled into the segmented DNA origami structure in a way so that each conferred a distinguishable elongation of either 40 or 15 nm, respectively. With this variation, the simultaneous detection of PDGF at 25 nM and the target DNA sequence at 5 μM in the solution was possible.

20.3 Optical and Electric Forces for the Manipulation of Whole Cells

Moving beyond single molecules and biomolecular ensembles, the contact-free interaction of external fields – in particular the aforementioned electromagnetic and inhomogeneous electric fields – offers unique opportunities for manipulating discrete biological objects such as whole cells with unprecedented precision. This has been responsible for carving out cutting-edge breakthroughs for rheological characterization of biomaterials beyond the bulk scale, and down to the single-cell or even subcellular level of detail.

20.3.1 The Optical Stretcher

While *Ashkin* is known for the invention of the single-beam gradient force laser trap, he also proposed a two-beam laser trap using divergent laser light [20.8]. Since the momentum of a photon is changed not only by the particle as a whole, but at each transition from one medium to another (Fig. 20.11), forces actually act on the surface of a trapped particle according to (20.3). The transition of a ray of light from a medium of refractive index n_1 to the particle of refractive index n_2 is accom-

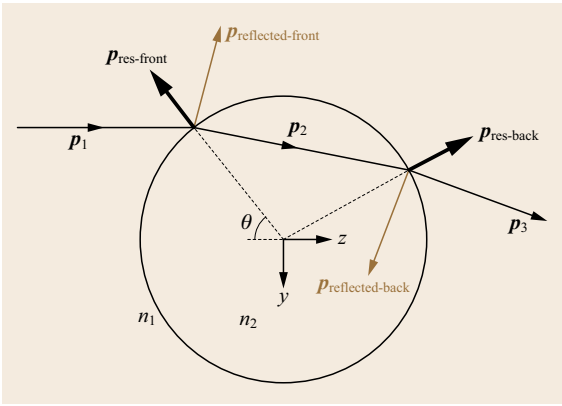

Fig. 20.11 Surface forces exerted by the transition of a single ray passing a spherical particle. By using Snell's law, it can be shown that the resulting momenta are always perpendicularly oriented to the transmitted surfaces, from higher to lower refractive index, independent of the particle's shape

panied by a resulting momentum of

$$\boldsymbol{p}_{\text{res-front}} = N(\boldsymbol{p}_1 - T\boldsymbol{p}_2 - R\boldsymbol{p}_{\text{reflected-front}}) \qquad (20.14)$$

and as the ray exits, another resulting momentum of

$$\boldsymbol{p}_{\text{res-back}} = TN(\boldsymbol{p}_2 - T\boldsymbol{p}_3 - R\boldsymbol{p}_{\text{reflected-back}}) \qquad (20.15)$$

occurs, where the influence of reflection on the front and on the back side is included by $\boldsymbol{p}_{\text{reflected}}$.

In these terms, the resulting force in (20.7), acting on the whole particle, has to be understood as the sum over all infinitesimal surface forces, (20.14) and (20.15).

In 2000, *Guck* et al. presented their two-beam laser trap – dubbed the Optical Stretcher (OS) – which realized that a two-beam laser trap could not only trap cells but also deform them thereby probing their biomechanical properties [20.51].

Two counter-propagating, divergent laser beams induce surface forces on a spherical object (as illustrated in Fig. 20.12) and give rise to a stress profile as shown in Fig. 20.13a. Scattering and gradient forces act in such a way that a cell entering the vicinity of the counter-propagating beams is centered and stably held in the middle of the trap. Once stably trapped, the resulting force acting on the whole particle is zero even though surface forces still act upon it [20.52]. Generally, whenever light enters or exits a dielectric medium it exerts a force pointing away from the optically denser medium normal to its surface. These surface forces depend on various parameters such as the applied laser power, the refractive indices of the cell and the surrounding medium, the cell size, the beam width at the center of the trap, and the wavelength of the laser beam.

Using appropriate laser powers yields surface forces, which are sufficient to effectively stretch a cell (Fig. 20.13b) [20.53]. This effect enables contact-free, whole-cell elasticity measurements and allows a determination of the mechanical properties of suspended, biological material in general [20.54, 55]. Once a cell is trapped, the magnitude of the stretch stress can be varied simply by tuning the intensity of the laser beam. Captured by a CCD camera, the deformation is analyzed using edge-detection software, thereby permitting the extraction of numerical data and the calculation of the cells' mechanical properties. The extent of a cell's deformation at a certain applied stress is known as its deformability. More specifically, the term *optical deformability* describes the elongation of the cell along the laser axis, normalized by the acting maximal forces. This deformability gives information not only about the cell's overall mechanical properties but also its underlying, cytoskeletal cellular structures, which can be used to compare different cells. Assuming similar refractive indices and sizes, a cell that deforms more at a given applied stress is softer than a cell that deforms less.

Compared to focused laser-beam traps, divergent laser-beam traps have a great advantage of exposing the trapped biological material to lower laser intensities, and therefore avoiding radiation-induced damage of living samples. The typical light intensities of optical

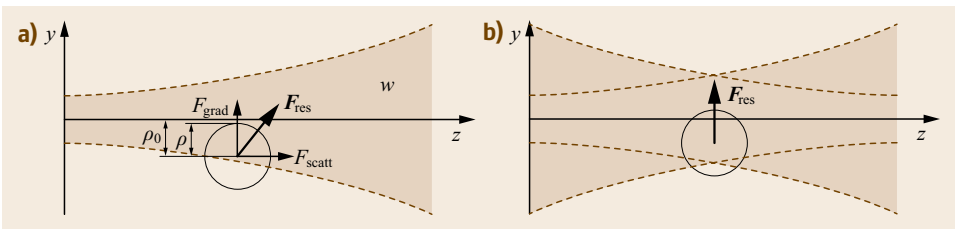

Fig. 20.12 **(a)** Forces exerted by a single Gaussian laser beam. The gradient force pulls the sphere onto the beam axis, whereas the scattering force pushes it away from the laser source. **(b)** A sphere in a divergent, dual-beam trap. The scattering forces of the two lasers cancel each other out in the middle, whereas the gradient forces are summed up, leading to stable trapping

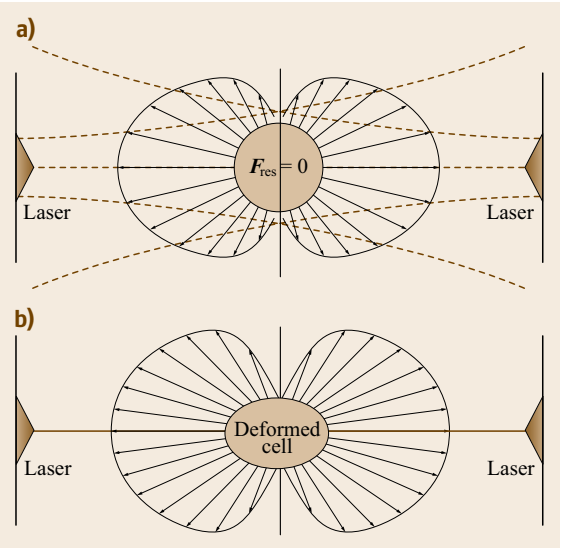

Fig. 20.13 **(a)** Numerical calculation of the stress profile of a spherical particle centered on the optical axis inside the optical stretcher, assuming parallel light beams. When light enters a dielectric medium, forces are induced normal to the surface and pointing away from the optically denser medium. In spite of a vanishing resulting force, stretch forces are applied on the surface. **(b)** At appropriate laser powers, exerted surface forces yield a stretch deformation of the trapped cell along the direction of the laser axis, with the highest stretching forces on the beam axis and virtually no forces near the poles (after [20.53])

tweezers, which would not lead to damage of biological samples, can be sufficiently used to trap particles, but induced forces are too weak to lead to deformations as the basis for rheology experiments. As compared with other techniques for single-cell elasticity measurements such as AFM, the OS allows one to measure up to 250 cells per hour, providing better statistical results.

Contact-Free Cell Rheology with the OS

Structural changes of the cytoskeleton cause changes in the viscoelastic response of the cell. This can be used to investigate diverse characteristics, as previously mentioned. Optical deformability is, however, an OS-specific quantity. To make it comparable with results obtained from other elasticity measurement techniques, a model for calculating the complex shear modulus was developed.

When a deforming force is applied to a material, it will respond elastically, viscously, or viscoelastically. The latter is an intermediate form between purely elastic or viscous behavior, and is observed in cells. The different responses are illustrated in Fig. 20.14.

For linear elastic deformations, the tensile creep compliance $D(t)$ can be described in terms of stress $\sigma(t)$ and the relative deformation (strain) $\gamma(t) = \Delta x/x$

$$\sigma(t) = E\gamma(t) = \frac{1}{D(t)} , \tag{20.16}$$

where $E(t)$ is the Young's Modulus. Linear viscous deformation is given by

$$\sigma(t) = \eta \frac{\mathrm{d}\gamma(t)}{\mathrm{d}t} . \tag{20.17}$$

There are various models for viscoelastic behavior. The general relationship between stress and strain can be expressed by

$$\sum_{i=0}^{n} a_i \partial_t^i \gamma(t) = \sum_{j=0}^{m} b_j \partial_t^j \sigma(t) . \tag{20.18}$$

In typical stretch experiments, cells are exposed to a step stress and the time-dependent strain is recorded. Terminating (20.18) at the second-order expansion of the strain and at first-order expansion of the stress and neglecting zeroth-order strain terms leads to

$$a_1 \partial_t \gamma(t) + a_2 \partial_t^2 \gamma(t) = \sigma(t) + b_1 \partial_t \sigma(t) , \tag{20.19}$$

which has been found to be sufficient to fit the typical response of a cell to a temporal stress [20.56]. A temporal step stress can be described by

$$\sigma(t) = F_\mathrm{G} \sigma_0 \theta(t)\theta(t_1 - t) , \tag{20.20}$$

where F_G is a geometric correction factor that takes into account the geometry of the cell and the shape of the applied stress field with respect to the peak stress σ_0 [20.57]. Here, t is the time from the initiation of the step stress, and t_1 is the duration of the applied stress. The deformation behavior of a cell is primarily determined by its actin network, which is assembled as an isotropic cortex in suspended cells and can therefore be modeled as a thick shell [20.57]. Combining (20.19) and (20.20), the strain becomes

$$\gamma(t) = F_\mathrm{G}\sigma_0 \left(\frac{b_1}{a_1} - \frac{a_2}{a_1^2}\right)\left[1 - \exp\left(-\frac{a_1}{a_2}t\right)\right] + \frac{F_\mathrm{G}\sigma_0}{a_1}t \tag{20.21}$$

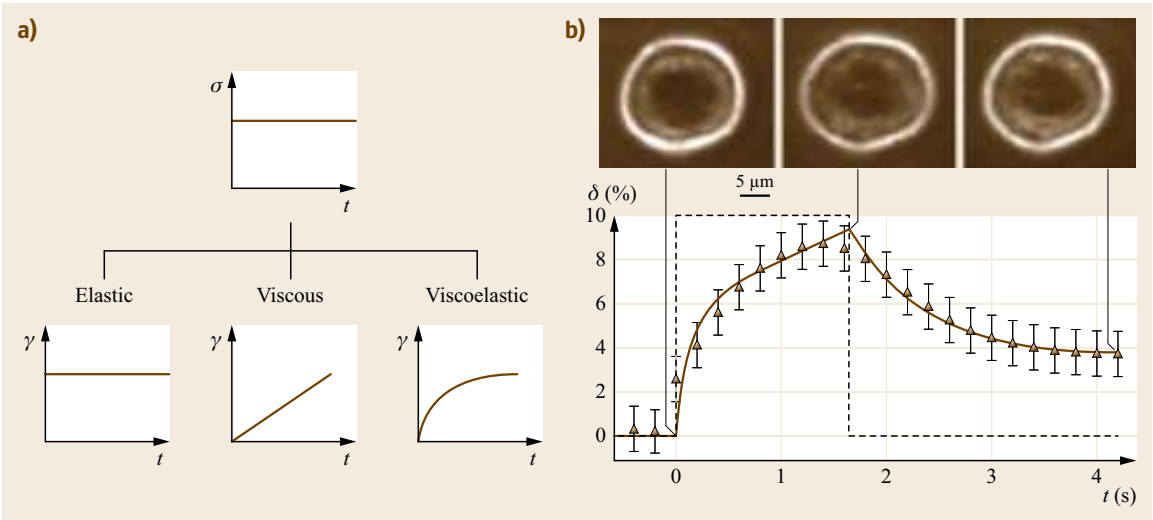

Fig. 20.14 **(a)** Different responses to a constant stress σ. Elastic materials show an immediate response while viscous materials expand in proportion to time. Viscoelasticity, as a combination of elastic and viscous behavior, displays a retardation of the response to the applied stress. **(b)** Typical deformation behavior of a cell when a step stress is applied. After increase of the laser power from 0.1 to 1.7 W at $t = 0$ s, an instantaneous deformation of the cell is observed, followed by a slower increase to a maximum strain value. Reducing the power back to trapping levels, the strain decreases but does not completely relax back to the initial value. The solid line shows a fit of the strain function ((20.21)–(20.22)) to the deformation data and the dashed line represents the laser power signature. Data points were binned to five points per second. The three phase contrast images show the cell prior (0 s), during (until 1.7 s), and after application (up to 4.2 s) of the step stress

for $0 < t < t_1$, the interval over which the stress is applied, and

$$\gamma(t) = F_G\sigma_0\left(\frac{b_1}{a_1} - \frac{a_2}{a_1^2}\right)\left[1 - \exp\left(-\frac{a_1}{a_2}t\right)\right] \times \exp\left[-\frac{a_1}{a_2}(t - t_1)\right] + \frac{F_G\sigma_0}{a_1}t_1 \tag{20.22}$$

for $t > t_1$.

In order to obtain the constants a_1, a_2 and b_1, the function is fitted to the measured data of the time-dependent strain. The time-dependent shear modulus, $G(t)$, is defined by the ratio of mean stress to mean strain. The strain behavior, $G(t)$, is given by

$$G(t) = \frac{1}{2(1+\mu)}\left[\frac{a_1b_1 - a_2}{b_1^2}\exp\left(-\frac{t}{b_1}\right) + \frac{a_2}{b_1}\delta(t)\right], \tag{20.23}$$

where μ is the Poisson's ratio and considered to be $\mu = 0.45$ for a shell-like actin cortex [20.58]. $G(t)$ can be converted via Fourier transformation into a frequency-dependent complex shear modulus $G^*(\omega) = G'(\omega) + \mathrm{i}G''(\omega)$ with

$$G'(\omega) = \frac{1}{2(1+\mu)}\left(\frac{\omega^2(a_1b_1 - a_2)}{1 + \omega^2b_1^2}\right), \tag{20.24}$$

and

$$G''(\omega) = \frac{1}{2(1+\mu)}\left(\frac{\omega a_1 + \omega^3a_2b_1}{1 + \omega^2b_1^2}\right). \tag{20.25}$$

The storage modulus, $G'(\omega)$, yields the elastic component of the cell's response to the applied stress. The loss modulus, $G''(\omega)$, gives the viscous component. From these functions, one can obtain characteristic material constants [20.56] such as the so-called rubber plateau,

$$G_{\mathrm{Plateau}} = \lim_{\omega\to\infty} G'(\omega) = \frac{1}{2(1+\mu)}\frac{a_1b_1 - a_2}{b_1^2}, \tag{20.26}$$

the fluid-to-solid transition frequency,

$$\omega_{\mathrm{f\text{-}s}} = \frac{1}{2}\left(\frac{a_1}{a_2} - \frac{1}{b_1}\right) - \sqrt{\frac{1}{4}\left(\frac{a_1}{a_2} - \frac{1}{b_1}\right) - \frac{a_1}{a_2b_1}}, \tag{20.27}$$

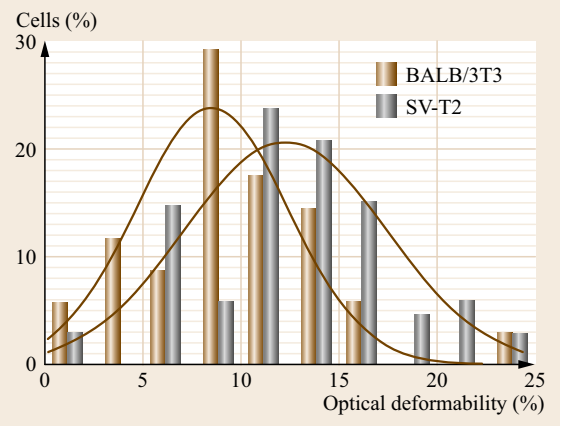

Fig. 20.15 The deformation of fibroblasts in an Optical Stretcher. A BALB/3T3 fibroblast deforms by 6.48 ± 0.36% along the laser axis, as determined by image analysis, when the light power is increased from 0.1 to 1.7 W in both beams. Measuring large numbers of cells reveals that the optical deformability of malignantly transformed SV-T2 fibroblasts is significantly shifted to higher values compared to normal BALB/3T3 fibroblasts (after [20.61])

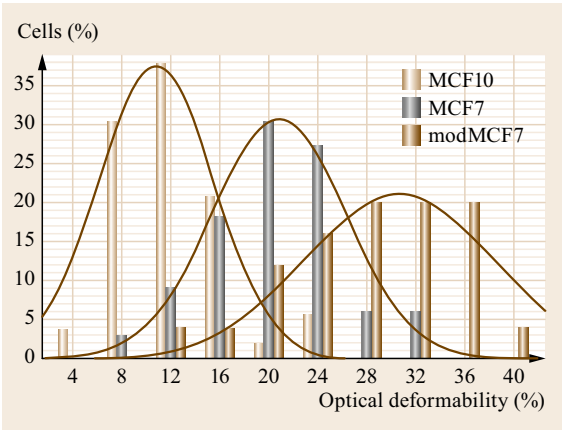

Fig. 20.16 Optical deformability of normal, cancerous, and metastatic breast epithelial cells. The three populations of the MCF cell lines are clearly distinguishable in the histograms of the measured optical deformability (after [20.61])

and the inner-dynamical transition frequency,

$$\omega_t = \frac{1}{2}\left(\frac{a_1}{a_2} - \frac{1}{b_1}\right) + \sqrt{\frac{1}{4}\left(\frac{a_1}{a_2} - \frac{1}{b_1}\right) - \frac{a_1}{a_2 b_1}}\,. \tag{20.28}$$

High-throughput biomechanical measurements became increasingly important when the mechanical properties of cells were found to be a very sensitive cell marker. A relatively low number of cells is sufficient to distinguish different populations without the use of molecular markers. In addition, subcellular structures such as the nucleus or the cell membrane can be targeted individually [20.59, 60].

The OS has been used, for instance, to identify differences in the biomechanical properties of normal and cancerous primary tissue as well as cell lines. Differences in optical deformability of benign fibroblasts (BALB/3T3) and malignantly transformed fibroblasts (SV-T2), for instance, clearly show that SV-T2 cells have a higher deformation and are therefore softer than the BALB/3T3 cells (Fig. 20.15) [20.50]. This finding corresponds to measurements of the cytoskeletons of these two cell lines, showing a reduced actin cortex for the cancerous SV-T2 cells, which accounts for the softer behavior.

Regarding human cancer types, breast cancer is the most common form of this disease in women. Using cell models, measurements with the OS have shown that breast cancer cells in different states of aggressiveness can be distinguished by their optical deformability, as illustrated in Fig. 20.16. More importantly, this trend is persistent for primary samples extracted from breast cancer patients, which give rise to a wide range of medical applications, including diagnosis and drug screening.

Since mechanical properties are well-defined quantities, this opens a wide field of applications. In the future, the OS might be used for tumor staging and might help to develop individual chemotherapies for cancer patients. A reasonable addition would be the monitoring of the cellular optical properties, since refractive index distributions can strongly vary between cell populations. This extra information is rather necessary in particular for experiments with primary cells due to the lack of literature values [20.62].

Thermorheology of Living Cells

Using laser light to trap and stretch biological matter also leads to a significant temperature increase within the sample, which nearly instantaneously influences the biomechanical responses of cells [20.63, 64]. Laser-induced heating from absorption is an inherent property of optical traps and optically driven cell deformations change about 10% per Kelvin. These changes are mainly caused by temperature-induced viscosity variations as known for polymeric solutions in general. Thus, the cellular, viscoelastic components, which determine the overall mechanical parameters, are highly sensitive to temperature changes.

More information on the temperature dependence of the cell's cytoskeletal components and its regulating processes are needed to be able to precisely attribute

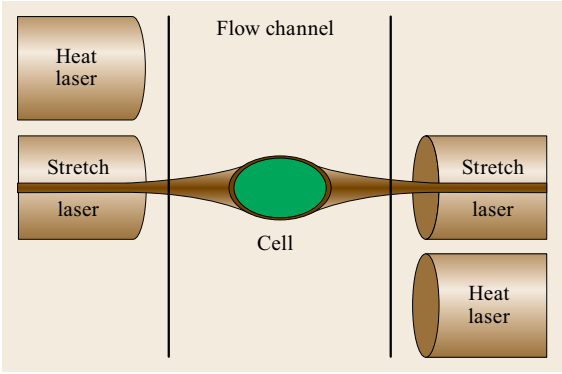

Fig. 20.17 The OS can be equipped with additional heating lasers, which allow the temperature of the medium around the cell to be tuned, thereby facilitating thermorheological measurements. Cells are delivered via a microfluidic system pumping cells in suspension through a capillary. Once the software recognizes a cell, the flow is stopped and the cell is subsequently trapped and stretched. The deformation is recorded via optical microscopy and afterwards the flow is switched on again to position the next cell to be measured (after [20.35])

experimental findings to specific effects. To achieve a decoupling of temperature-induced effects and purely rheological properties, the OS setup can be extended with two additional heating lasers (Fig. 20.17). It is very reasonable to use the OS instead of single-beam optical traps since its nonfocused beams drastically decrease local heating compared to strongly focused laser beams (about a factor of 400). By tuning the power of the heating lasers, the medium around the cell can be precisely adjusted before measuring. Randomizing the heating pattern for the measurement of an entire cell population yields unbiased, temperature-dependent deformation curves, which allow a distinction between temperature and rheological effects.

First experiments illustrated that time-temperature superposition (TTS) principles are applicable to creep compliance curves to create a master curve for MCF-10A cells [20.65]. In the consideration that cells are highly heterogeneous structures based on different types of polymers, it is rather surprising that deformation curves can be matched by this fundamental model. However, other cell lines have proven to have more complex properties and cannot be described by simple thermorheological behavior [20.66]. These effects can arise, for instance, due to a thermally activated process or active cellular responses and more complex thermorheological descriptions have to be applied.

In general, simple as well as complex thermorheology are new approaches for contact-free cell rheology. Differences in the applicability of the TTS give rise to new insights of biomechanical measurements without any assumptions for underlying models. Results for various cell lines have proven that the creep deformation of suspended cells strongly depends on temperature and that there are qualitative differences between cell types. Potentially, this concept can even be extended to determine whether effects are based on passive, stochastic processes or active, directed mechanisms since they behave in a contrary manner upon temperature changes.

Dielectrophoretic Cell Stretching

Optical stretching is an ideal technique to induce whole-cell deformations at a relatively high throughput without the need for extensive preparation for each cell. However, some experiments might require stable temperatures, which cannot be achieved with the OS since the stretch lasers will always lead to a temperature increase during the measurement.

A potential workaround is provided by a technique that uses forces induced in a dielectrophoretic field to stretch whole cells and also allows a characterization of their mechanical properties by stress-strain relations. Here, stretching is based on the fact that cells are dielectric particles that are polarized in an electric field established by an alternating current. Within this field, cells develop a dipole moment and interact with the inhomogeneous electric field. Depending on the external field and the induced dipoles, cells can either experience translational motion (dielectrophoresis), rotation, or stretch deformation [20.67]. The amplitude of the stretching depends on the size of the cell and its dielectric properties in regard to the medium. By carefully choosing the same experimental conditions, the induced deformations can be used to determine and compare mechanical properties of different cell types. However, since deformations are taking place on different time scales than in the OS, results can be hardly compared and potentially even display discordant trends [20.68].

20.3.2 Cell Deformation via Optical Tweezers

Optical tweezers are used for an increasing number of biological experiments and are now an appropriate technique for cell manipulation and characterization. The most common applications cover the deformation of whole cells in conjunction with force measurements as well as the manipulation of subcellular components, probing of the cell interior via microrheology, or the positioning of cells in combination with spectroscopy techniques in order to follow processes within single cells.

To study the mechanical behavior of a cell using optical tweezers, beads can be attached to the cell membrane diametrically on each side. If one of the beads is

attached to the substrate and the second is held by optical tweezers, constant force or constant-deformation measurements can be realized. *Suresh* et al. used such a setup to measure the shear modulus of red blood cells (RBCs) during the development of the malaria parasite *Plasmodium falciparum* and discovered a tenfold increase in the rigidity of infected RBCs compared with noninfected cells [20.69, 70]. However, one can also optically trap both attached beads and use them to quantify forces generated by cells. With this geometry, both the mechanical properties of the cells as well as their force fluctuations can be investigated in parallel. Additionally, the influences of cytoskeletal drugs such as blebbistatin (inhibiting myosin activity) or nocodazole (depolymerizes microtubules) on the cell stiffness can be readily tested and evaluated [20.71].

The use of optical tweezers is not limited to studying cells as a whole, but also allows for the manipulation of subcellular components. Kress et al. attached beads to filopodia, thin finger-like protrusions from the cell body, of macrophages. Amongst others, filopodia are implicated in a process called endocytosis, where they attach to objects and retract them to the cell membrane to be engulfed and taken up into the cell. Upon measuring step sizes and forces of filopodial retraction, it could be inferred that molecular motors are involved in this process [20.72].

However, even without beads being attached to the cell membrane, optical tweezers can be used to measure the cortical tension by monitoring the position of the membrane as well as recording the dynamics of bleb growth [20.73]. By automating this technique, optical tweezers can even be used as scanning devices monitoring, for instance, the fluctuation of membranes. This allows the employment of active and passive microrheology to directly compare membrane responses and thermal fluctuations on a single cell level [20.74].

By increasing the laser power to relatively high values compared to trapping conditions, the shape of cells can even be manipulated and processes such as protrusion can be guided, as shown for neuronal cells. More precisely, the intracellular processes are affected by highly focused laser light on the leading edge of a growth cone, which results in growth of the nerve cell towards the laser focus. The induced growth has been verified experimentally for wavelengths in the range of 800–900 nm [20.75].

Another method dubbed laser tracking microrheology (LTM) makes use of the QPD position detection system of an optical tweezers setup. In the passive mode, the Brownian motion of a tracer particle, for instance, a micrometer-sized bead or an intracellular granule, is monitored with subnanometer resolution and sampling rates in the range of 100 kHz at low laser powers [20.76, 77]. At higher powers, tracer particles can be trapped and moved such that out-of-equilibrium viscoelastic properties can be inferred.

Using optical tweezers to hold individual cells in place and combining the measurement with Raman spectroscopy employing the same laser facilitates noninvasive characterization. This technique yields highly reproducible biomolecular fingerprints representing DNA, protein and lipid content along with conformational information [20.78] and can be used, for instance, to distinguish neoplastic from normal lymphocytes [20.79]. Laser (or optical) tweezers Raman spectroscopy (LTRS/OTRS) even allows for marker-free kinetic studies of biochemical processes inside a single cell. Singh et al. monitored the response of single yeast cells to heat treatment and hyperosmotic stress caused by high glucose concentrations. The examined yeast, *Saccharomyces cerevisiae*, then switches to fermentation mode, and the products of which (glycerol and ethanol) could be observed in real time [20.80].

These examples underline the wide use of optical tweezers to characterize individual cells or even subcellular components and processes. Both mechanical properties as well as chemical composition can be measured and monitored in a contact-free, noninvasive way in order to study the effect of drugs on the intracellular processes of living cells, which also allows for the separation of cells based on these characteristics.

The possibility to hold and manipulate several objects at the same time opens the door for a large number of new applications such as the study of the collective behavior of trapped objects. However, time-sharing or splitting and recombining the laser beam poses limits on the number and power of trap centers.

In 1997 Grier and Dufresne pursued the idea of creating multiple traps using phase holograms and patented their invention as holographic optical tweezers (HOT). With holographic optical tweezers, a novel device had been developed, allowing for the creation of an array of optical tweezers for synchronous trapping of particles in arbitrary geometric patterns [20.81]. The basis of holographic optical tweezers are holograms that modify the collimated laser beam. In general, the hologram would affect both the amplitude and the phase. However, since changing the amplitude would diminish the power available for trapping, algorithms have been developed that produce an equivalent phase-shift pattern, a so-called kinoform. When being focused through the objective, the pattern is Fourier-transformed into a pattern of multiple traps.

The first HOTs were realized using microstructured diffractive optical elements. However, because of their lack of flexibility, they have been succeeded in research applications by computer-addressed spatial light

modulators. These are liquid-crystal devices where the orientation of the molecules can be locally controlled, varying the optical path length and resulting in the desired phase shift [20.82–84]. The technique of holographic optical tweezers is a relatively new technology that opens the door to a number of new applications by parallelization of particle trapping. Whereas a single-beam trap is only able to hold a single or very few cells, the application of HOTs allows for the positioning and organization of many cells into a desired pattern.

In this way, it is possible to create a stable three-dimensional (3-D) configuration of cells where each object is located at a predefined position. *Jordan* et al. placed *E. coli* in a gelatin matrix, switched off the lasers after the positioning of the objects and provided appropriate nutrients such that single cells were able to survive for several days [20.85, 86]. This demonstration of cellular positioning using multiple beams included observation of the effects of both the position and number of neighboring cells upon one another and points to the wide range of future biological applications. These include the possibility of organizing specific cell lines such as stem cells into a novel or complex geometry, e.g., so-called stem cell niches. These geometric arrangements of cells may facilitate the study of the collective behavior of many-body structures and act as motifs for promoting tissue differentiation.

While trapping cells in suspension with conventional optical tweezers might prove difficult for cells much larger than the focal spot, HOTs offer the possibility to create a more stable trap configuration by using multiple beams around the periphery of the object. By applying Raman spectroscopy the samples can be scanned back and forth across the focus of the stationary excitation laser beam, resulting in space-resolved Raman spectra of an entire cell [20.87].

20.4 Hydrodynamic Shear Forces for the Manipulation of Single Cells

Optical forces are a versatile tool to investigate cellular properties on a single cell level. They allow a quantification of biological processes by scanning parts of the cell or even facilitate the induction of whole-cell deformations to record the stress-strain relation thereby determining a cell's mechanical properties. However, optical forces also inherently induce a temperature increase in the sample, which has to be accounted for in the analysis. Furthermore, these measurements are too slow for a wide range of applications in biology or medicine and cannot compete with throughput rates of standard flow cytometers. Rates of 250 cells per hour – as achieved with an automated OS setup – are sufficient to probe concepts such as marker-free, mechanical phenotyping of cell populations [20.88]. A major advantage of this approach is that cells do not have to be treated before being measured, but to transfer this concept into a clinical frame, higher throughput rates are needed to gain sufficient statistics in a reasonable time frame.

To achieve these clinically relevant rates, new techniques were developed inducing whole-cell deformation by shear flows facilitating rates up to 2000 cells per second [20.89] with a real-time analysis possible at slower rates of up to 500 cells per second [20.90]. This throughput is sufficient for flow cytometry, which is independent of additional markers. In contrast to experiments based on optical forces, only one deformation mode is tested neglecting possible time and frequency dependencies of the cellular mechanical properties. Thus, these techniques nicely complement each other facilitating a further advancement of the concept of marker-free, mechanical phenotyping of cells.

20.4.1 Flow-Induced Shear Deformation of Cells

Within microfluidic systems, cells can be carried by the surrounding fluid. Under laminar flows they migrate in a predictable manner across streamlines, which can ultimately lead to an ordering effect in longitudinal direction driving the cells to the axial center of the channel [20.89]. This ordering and initial focusing can be used to deliver suspended cells uniformly to a chamber where they are deformed in contact-free manner by an additional, opposing flow (Fig. 20.18a). Resulting high strains induce large whole-cell deformations allowing a derivation of stress-strain relations reflecting the cellular mechanical properties. The uniform delivery is crucial to preserve the uniformity in hydrodynamic stresses, which enables a comparison of the deformed cells. Furthermore, cells never come into contact with the channel itself, thereby bypassing any adherence or clogging effects. Furthermore, this principle has the advantage that measurements are independent of heterogeneities of subcellular structures since the whole cell is deformed. These heterogeneities can cause severe reproducibility issues for methods relying on physical contact such as AFM.

After a cell has entered the chamber where the opposing flows meet, its deformation is recorded via an optical microscope equipped with a high-speed camera. Depending on the camera, throughputs up to 2000 cells per second can be achieved, which allows the user to acquire statistically significant data. Subsequently, automated image analysis routines can be employed

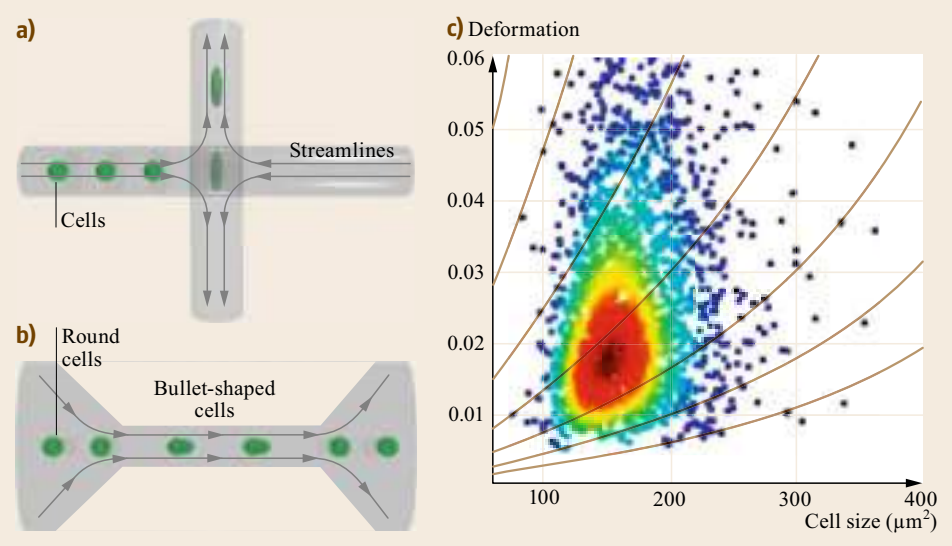

Fig. 20.18a–c Shear forces induced by flows can cause cell deformations detectable via standard microscopy techniques at high throughput rates. **(a)** A flow transports cells through a channel and aligns them in the middle region. At the intersection, an opposing flow leads to a detectable deformation attributable to the cells' mechanical properties. Stretched cells are subsequently transported through the release channels (after [20.89]). **(b)** The RT-DC setup employs geometrical constrictions in the flow channel leading to substantial shear forces. Cells are deformed into a bullet-shape profile, which can be analyzed and attributed to cell deformability (after [20.90]). **(c)** Flow-induced cell deformations can be recorded in the form of scatter plots similar to data illustrations of other standard types of flow cytometers

to identify the cell boundaries to quantify the according deformability, usually presented in the form of scatter plots similar to those also used for standard flow cytometers (representative example shown in Fig. 20.18c). Since measurements can be completely automated, user bias is minimized and experiments are quickly repeatable. This illustrates the translational possibility of mechanical phenotyping for diagnostic tools.

Microfluidic approaches, in general, allow a tuning of the magnitude of the induced deformation by altering the hydrodynamic stresses. This variability is important to probe cells under different conditions in order to investigate, for instance, time-dependent deformabilities necessary to gain a complete rheological profile. For slow deformations, optical stretching can be used to complement the rather fast hydrodynamic measurement techniques.

20.4.2 High-Throughput Mechanical Phenotyping of Cell Populations in Real Time

The previously described methods have one major drawback, which still impedes their clinical use. Although data acquisition can be relatively fast due to high throughput rates, their evaluation has to be performed off-line due to the enormous amount of data, which even limits the total number of analyzed cells.

A new technique called real-time deformability cytometry (RT-DC) resolves this issue by analyzing the data on-the-fly [20.90]. Within this setup, high shear stresses are induced by constricting the channel geometry (Fig. 20.18b). Arising pressure gradients are sufficient to deform even relatively stiff cells into a bullet-like shape, which facilitates the extraction of Young's modulus while also considering different initial cell sizes [20.91]. The underlying analytical model decouples cell deformation and size, which is infeasible for methods based on inertial forces.

Data is acquired by a high-speed camera synchronized with a light source for illumination and directly analyzed by an image-processing algorithm, which detects and determines the contour of a cell in real time [20.90]. Using these values, the cell deformation and size can be quantified and displayed in form of a scatter plot (representative example shown in Fig. 20.18c). This method allows a continuous analysis of cells at rather high rates ($>$ 1000 cells/s) and enables measurements of more than 100 000 cells per run.

RT-DC readily enables the measurement of, for instance, the influence of cytoskeletal drugs [20.92] or the progression in the cell cycle [20.90]. Furthermore, even cell mixtures such as blood can be analyzed showing

a typical fingerprint when decomposing the different cell populations. This fingerprint has been reported to change upon infections, which can be potentially used as a marker-free diagnostic tool for diseases [20.90]. Essentially, all bodily fluids are easily experimentally accessible since cells are already in the suspended state and do not require extensive preparations. The high throughput rates potentially even allow the user to sort the different cell populations in sufficient quantities after the deformation measurement.

20.5 Conclusion and Outlook

Methods for contact-free measurements of biological materials have greatly advanced during the last decade and now enable the exploration of the biological microcosmos with high precision. Manipulations and quantifications have been reduced down to the molecular level and can readily identify nanoscopic details of biopolymeric structures. However, not only has the high resolution led to significant new insights, but modern techniques have also attained high accuracy in measuring whole-cell deformability to determine according mechanical properties. These recent advances have promoted the concept of using cell mechanics as a potential marker-free method for mechanical phenotyping. Pathological as well as physiological changes are reflected in an alteration of cell mechanics and potentially allow the application of this principle as a diagnostic tool, a concept which has been already initially proven for blood analysis [20.90, 93], cancer diagnostics [20.61, 94, 95], and the tracking of stem cell differentiation [20.93]. Because of the increasing throughput, some methods are rather close to translation to clinical frames, and furthermore have the potential to drastically reduce animal studies by shifting the focus towards cell-based assays as a first approach.

21.1 Overview

Nanoparticles (NPs) are extremely small particulates with an average size that ranges from a micron or less to a few nanometers [21.1–5]. This is not an operational or functional definition and in the present interpretation the sole condition for an object to be considered a nanoparticle is its size. Notice that the radius of the first electron orbit in the hydrogen atom is $\approx 0.5\,\text{Å} = 0.05\,\text{nm}$ [21.6] and the atomic radius of unstrained silicon is $\approx 1\,\text{Å} = 0.1\,\text{nm}$ [21.6], thus smaller NPs in the low nanometer range comprise a finite and generally low number of atoms and are obtained using bottom-up techniques including supramolecular assembly techniques [21.7, 8], and chemical [21.9, 10] or electrochemical [21.11, 12] deposition techniques. Larger micrometric or submicrometric NPs are produced using top-down methods in which the intended structures are obtained from a bulk constituent that is shaped into its final form using patterning, lithography or imprinting techniques, or a combination of these [21.13], or by conveniently removing the excess of material using wet or dry etching methods or porosification techniques [21.14]. In some cases, bottom-up and top-down techniques may be used in cooperation to attain the maximum control over the size and shape of the NPs, and this is described below. Thus, despite not being a strict requisite, the vast majority of NPs necessitate nanotechnology/nanofabrication methods. There are a few exceptions, such as diatoms, which are unicellular organisms with a porous silica (SiO_2) skeleton that is regular in size with an average length scale of some microns, and a spherical, spheroidal or ellipsoidal shape, depending on the family. Diatoms resemble micro/nanovectors and in fact most of the diatoms are used as sponges or molecular filters [21.15, 16]. But, even in this case, nanotechnology methods are necessary to image and verify the structures and assess their efficacy.

The size of NPs may vary over a significant range, and in this resides their scientific potential in that NPs may help cross the bridge between bulk materials and atomic or molecular structures. More importantly, NPs are nanotechnology products, thus, in contrast to biological/natural systems, they can be designed and engineered. NPs are not really particles; they are more akin to engineering systems in which size, shape, material, physical and chemical properties, structure and level of hierarchy can be precisely tailored or tuned to obtain systems with an elevated technology content. The complexity of these systems may depend less on their individual constituents taken in isolation and more on the fact that many of these constituents cooperate in a complex system. Interactions among these elements at the nanoscale yield collective phenomena with improved abilities in contrast to isolated components of those systems at conventional continuum scales. Consider a very practical example. For spherical metal particles, the surface-to-volume ratio (SVR) scales with $3/r$, where r is the radius of the particles. Thus, for a 50 nm particle, $SVR = 0.06\,\text{nm}$, which means that one has $0.06\,\text{nm}^2$ of surface per nm^3 of volume. For a 50 mm particle, $SVR = 6\times10^{-5}\,\text{nm}$, with a thousand-fold decrease. Thus smaller nanometric particles have larger surface-to-volume ratios and larger surface energy reactivity. The increasing proportion of surface atoms with decreasing particle size compared with bulk metals makes small metal particles highly reactive catalysts, as surface atoms possess more energy than bulk atoms. This in turn translates into a decrease of melting point that for nanomaterials may be two to three times lower compared to macromaterials. Moreover, it is widely reported [21.17] and very well understood [21.18–20] that metal nanoparticles with an average particle size of 50 mm interact with an electromagnetic field to yield site-specific increments of that field, which in cascade yields an amplification of the Raman spectroscopy signal of molecules adsorbed to those particles, in an effect that is called surface-enhanced Raman spectroscopy. Thus metal nanoparticles are preferable to bulk metal materials in at least two aspects. In general, the scale-dependent properties of nanomaterials are:

1. Chemical properties, including reactivity and catalysis [21.21]
2. Thermal properties, i. e., melting temperature and heat amplification/attenuation [21.22, 23]
3. Mechanical properties, i. e., adhesion, capillary forces, and increased mechanical strength at the nanoscale [21.24, 25]
4. Optical properties, i. e., absorption and scattering of light at the nanoscale
5. Electrical properties [21.26, 27]
6. Magnetic properties and superparamagnetic effects [21.28].

Consider now the case of biology, biomedicine and life sciences. The aims and scopes of such disciplines are various and diverse in nature and range from understanding the chemical/biological mechanisms of life [21.29]; to deepening the knowledge of anatomy, pathology and physiology of the body system; to studying the human body and how it is affected by disease, including studying at cellular and molecular levels; to the development of systems that may prevent or alter the

course of a disease or treat it, either by improving the diagnosis efficiency of conventional analytical/imaging techniques or the methods of administration and the therapeutic efficacy and the methods and timing of administration of drugs in the systemic circulation. Very roughly, cells have a size of ten microns, biomarkers (proteins and molecules involved in cellular activity) or viruses have a size of few nanometers or less [21.30–32], and the circuits involved in the cardiovascular system, the pulmonary circulation and systemic circulation, have cross-sections that range from several microns to few nanometers [21.33]. Thus, most of the items in biology have a characteristic length scale that falls in the same dimensional range as nanotechnology, and much of nanotechnology can be applied to biology and medicine. On directly interacting with cells, including the structures of cells, their machinery and their waste products, NPs represent an unprecedented tool for addressing specific biological problems. Excellent properties associated with nanoparticles of controlled geometry have opened up exciting opportunities for new material designs and will potentially revolutionize current biology and medicine practice. Following this motivation, nanomedicine originated at the intersection between biomedicine, nanotechnology and nanoparticles.

Nanomedicine can be defined as the design of diagnostics and/or therapeutics on the nanoscale, which provides advantages due to the high degree of coincident transport and delivery of the active species with mediation of their navigation within the biological systems for the treatment, prevention and diagnosis of diseases [21.34]. The biological transport processes, anatomically and down to the cellular and subcellular levels, are affected by the physical attributes of the nanocarriers, including their size, shape, and flexibility, as well as their chemical characteristics, including for instance the incorporation of active ligands for recognition by and triggering of biological receptors. Therefore, it is of critical importance to utilize procedures that prepare nanostructures with high degrees of uniformity, and with control over their physical and chemical traits. Nanoparticles can be constructed from various materials (e.g., polymers, lipids, metals) and can host a wide range of active components, including chemotherapeutics, contrast agents, proteins and nucleic acids, for various biomedical applications. Incorporation of certain functionalities can modulate the responsiveness (assembly/disassembly) of the nanoparticles in biological environments under different pH, enzymatic, oxidative, and reductive conditions, etc., or in response to external stimuli, such as variation in temperature, irradiation with near-infrared (IR) or ultraviolet-visible (UV-Vis) light, activation with magnetic fields, and application of ultrasound vibrations, etc.

In the remaining part of this section, we will briefly review some recent advances rather than classical results in nanoparticle research for biomedical applications, spanning mesoporous silicon particles, gold and silver nanoparticles, magnetic rather than paramagnetic effects, and polymeric nanocarriers for therapeutic, diagnosis, or theranostic (therapeutics + diagnosis) applications. This will provide the background necessary to understand and locate the paragraphs that form the present chapter.

Although intravenous injection is the main route of administration for nanoparticles, there are other ways to deliver them via less invasive ways, such as dermal/transdermal, oral and mucosal delivery. In all cases, these nanoparticles have to be equipped with smart components to allow their delivery beyond the different biological barriers, such as skin, mucus, blood, and extracellular matrix, in addition to the cellular and subcellular barriers. In the activity led by *Mauro Ferrari* [21.35, 36], mesoporous silicon particles were used for the delivery of different types of nanoparticles into primary endothelial cells, where the avoidance of biological barriers is left to a multistage strategy, whereby larger mesoporous particles are transported with a certain efficiency in close proximity to the endothelium, and a second generation of smaller nanoparticles is released from the pores to traverse easily, due to their small size, the endothelium barrier with their therapeutic payload. In [21.37], the same team used biomimetic leukolike vectors, i. e., nanoporous silicon particles coated with cellular membranes purified from leukocytes, to deliver drugs in the systemic circulation with no or minimum clearance by the immune system.

In the described applications, Ferrari et al. used mesoporous or nanoporous silicon as the main constituent for their carriers, principally because a similar porosified material is biocompatible, biodegradable [21.38], and offers a system of pores to load/unload therapeutics drugs rather than imaging contrast agents as in [21.39].

In contrast to porous silicon, gold nanoparticles are stable over time, can be easily functionalized, and may interact with an external electromagnetic (EM) radiation field to produce localized surface plasmon resonance and an amplification of that field [21.40, 41]. Gold nanoparticles (GNPs) with controlled geometrical, optical, and surface chemical properties are the subject of intensive studies of applications in biology and medicine. GNPs have been demonstrated in a variety

of applications, including genomics and biosensorics, immunoassays and clinical chemistry, photothermolysis of cancer cells and tumors, targeted delivery of drugs and antigens, and optical bioimaging of cells and tissues with state-of-the-art nanophotonic detection systems. In similar applications, gold nanoparticles have been produced in a variety of different, sometimes exotic shapes, including nanospheres, nanorods, sharpened nanorods, nanoshells, nanocages/frames, hollow nanospheres, tetrahedra/octahedra/cubes/icosahedra, rhombic dodecahedra, octahedra, concave nanocubes, tetrahexahedra, rhombic dodecahedra, obtuse triangular bipyramids, trisoctahedra, and nanoprisms. A similar diversity is justified by different EM amplification factors, transport properties in biological fluids and drug-loading capacities associated with different shapes. Similarly to gold NPs, silver NPs are used in diagnostic applications and therapeutic applications. The high antimicrobial activity of silver NPs has attracted much interest from scientists and technologists who want to develop nanosilver-based disinfectant products [21.42, 43]. Thus, in most of the therapeutic applications, it is the antimicrobial property that is being intensely explored. In a recent approach, the advantages of gold and silver have been united in bimetallic nanoparticles, as for example in [21.44].

Magnetic and superparamagnetic NPs have also been heavily investigated as sensitive probes for magnetic resonance imaging and therapeutic applications, tissue repair, immunoassay, detoxification of biological fluids, hyperthermia, drug delivery, and cell separation [21.45, 46]. In some cases, magnetic nanoparticles have been used to convert electromagnetic energy into heat [21.47] for applications such as disease treatment and remote control of single-cell functions. Recently, an approach based on magnetic particles and protein-assisted functionalization of graphene has been proposed for the production of hierarchical composites of functionalized graphene in polymeric matrices, exhibiting transparency and electron conductivity [21.48]. This shows that while materials science methods are effective in bionanotechnology, the opposite may be also true, and biology methods may be used to obtain supramolecular structures in which the organization of the structures depends on a biological driver, such as DNA assembly [21.49] in an approach that reconsiders the interactions of nanostructure with biological systems and highlights new directions in the design of biodegradable and multifunctional nanomedicine. Hybridization between organic and inorganic systems at the nanoscale is perhaps the new frontier in nanomedicine.

Polymeric nanoparticles have received great interest due to the versatility in which their structures can be modified to package and deliver their cargoes to the desired site of action or to respond to specific physiological or external stimuli [21.34, 50]. Polymeric nanoparticle-based therapeutics show great promise in the treatment of a wide range of diseases, due to the flexibility in which their structures can be modified. Advances in polymerization chemistries and the application of reactive, efficient and orthogonal chemical modification reactions have enabled the engineering of multifunctional polymeric nanoparticles with precise control over the architectures of the individual polymer components, to direct their assembly and subsequent transformations into nanoparticles of selective overall shapes, sizes, internal morphologies, external surface charges and functionalizations [21.34].

In what follows, we will cover specific nanoparticle-based systems for drug delivery and diagnosis, where the reported cases are thoroughly analyzed to offer a description of how, at the present state of technology advancement, a nanomedicine platform is realized, from a concept to a working prototype, passing through its design and fabrication.

21.2 Rational Design of Nanoconstructs

The intravenous administration of nanoconstructs for the precise delivery of imaging and therapeutic agents holds potential for the detection and treatment of deadly diseases, such as cancer and cardiovascular and neurodegenerative diseases [21.51, 52]. Nanoconstructs are man-made nanoscale objects that can be loaded with multiple different drug molecules as well as contrast agents. They are made out of biocompatible and biodegradable materials, such as lipids, polymers, and combinations thereof [21.53], and when transported by the blood flow can reach any location within the circulatory system and release their cargo [21.54, 55].

Over the last decade, a plethora of nanoconstructs have been demonstrated exhibiting different sizes, shapes, surface properties and, more recently, mechanical stiffnesses [21.13, 56, 57]. The characteristic size of a nanoconstruct can vary from a few tens of nanometers, as in the case of dendrimers and micelles, up to several hundreds of nanometers, as in the case of

large polymeric nanoparticles. Furthermore, although most nanoconstructs exhibit a spherical shape, multiple approaches have been developed for fabricating nanoparticles with discoidal, cylindrical, elliptical, stellar and other shapes. As for the surface properties, nanoconstructs with positive, neutral and negative electrostatic charges have been proposed. Also, multiple chemical moieties have been conjugated on the surfaces of nanoparticles to provide specific targeting properties. Finally, a few laboratories have recently started manipulating the mechanical stiffness of nanoconstructs leading to nanoparticles as soft as cells or as rigid as silica beads.

These four parameters – size, shape, surface and stiffness – have been shown to significantly affect the vascular and extravascular behavior of systemically injected nanoconstructs [21.13, 57]. However, a complete understanding of their effects on vascular margination and adhesion, crossing of the fenestrated endothelium, and diffusion into the diseased tissue of nanoconstructs is still missing. Indeed, given the range of variability for the design parameters, the number of possible combinations to be experimentally explored is impractically large. Consequently, the rational design of nanoconstructs requires the integration of experimental research activities with computational modeling, as schematically depicted in Fig. 21.1. The integration of in silico, in vitro and in vivo research modules, which is known as the integrated approach for the rational design, aims at identifying ideal combinations of the four design parameters – 4S parameters – that would maximize accumulation within the diseased tissue while minimizing the nonspecific sequestration by filtering organs, such as the liver, spleen and lungs [21.56].

Multiple computational techniques have been proposed for modeling transport problems including direct numerical simulations (DNS) [21.58], immersed finite element methods (IFEM) [21.59, 60], immersed boundary methods (IBM) [21.61], and isogeometric analysis (IA) [21.62, 63]. These approaches are all based on the numerical integration of the Navier–Stokes equations and their direct applications to modeling the vascular transport of multiple particles with complex shapes and mechanical properties is still challenging. However, particle-based techniques, such as the lattice Boltzmann method (LBM), provide simpler implementation schemes, higher flexibility and can be readily translated into parallel computing, allowing for a more efficient analysis of complex, multiparticle flows [21.64–66]. LBM uses the mesoscopic Boltzmann equation to determine macroscopic fluid dynamics and mass transport and has already been employed for modeling the vascular transport of particle suspensions and deformable cells [21.67, 68].

21.2.1 A Hierarchical Multiscale Approach for Vascular Transport of Nanoconstructs

A combined immersed boundary (IB) and lattice Boltzmann (LB) model has been developed for solving the transport of nanoparticles into vascular flows [21.68]. As an example, this computational framework allows for precise elucidation of the mechanisms that regulate the transport of particles in moderate Reynolds planar Couette flows. Under this condition, three forces govern the problem:

1. Inertial drift due to shear slip
2. Inertial drift due to rotational slip
3. Lubrication effect due to the presence of the wall.

Through direct numerical simulation, it has been shown that the difference between the actual particle horizontal velocity and the local undisturbed flow velocity (shear slip velocity, u_{Slip}) is responsible for the generation of a lateral force aimed at reducing such a difference. This force drives the particle towards flow regions where $u_{\text{Slip}} = 0$. Specifically, a particle would move towards a flow region of higher (slower) velocities if it lags (leads) the flow or, in other words, if $u_{\text{Slip}} < 0\ (> 0)$.

Such a behavior is depicted in Fig. 21.2a, where the linear slip velocity is plotted for particles in a planar Couette flow at Reynolds (Re) equal to 20. One particle is released at a quarter of the channel height, $y/H_{t=0} = 0.25$, and the other particle is released at three quarters of the channel height, $y/H_{t=0} = 0.75$.

The second contribution to the particle lateral drift, given by inertial drift due to rotational slip and described by *Joseph* and *Ocando* [21.58], shows that the rotational slip velocity is responsible for a lateral force. In particular, the angular slip velocity, $\omega_{\text{Slip}} = \omega + 1/2\gamma$, where ω is the angular velocity and γ is the local shear rate. Notice that $-1/2\gamma$ is the fluid angular velocity so that the nonzero angular slip velocity at the equilibrium implies a nonzero component of the lateral force generated by the rotational slip; see Fig. 21.2a.

Finally, the lubrication effect generates a lateral force pushing the particle away from the wall. The flow through the small meniscus at the particle-wall interface is strongly reduced as compared to the flow above the particle. Figure 21.3 demonstrates this mechanism, showing the profiles of a local slip velocity obtained at $tU_{\text{Max}}/L_{\text{ref}} = 10, 50$, and 500 along the line passing by the centroid of the particle. This local slip velocity is evaluated as the difference between the undisturbed linear Couette velocity profile and the computed horizontal velocity profile, namely $u_{\text{Shear}} - u$. Once the equilibrium position is reached, the local slip velocity

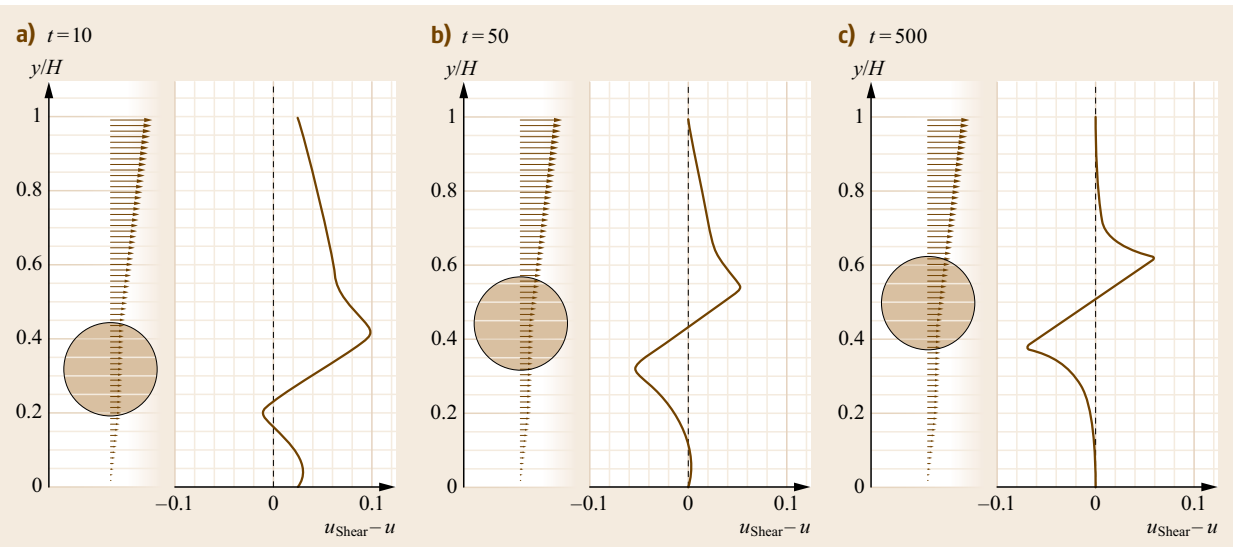

Fig. 21.3a–c Local slip velocity profile taken at the axis passing by the centroid and parallel to y at three different times for the particle released in $y/H = 0.25$ (after [21.68])

profile almost symmetrizes (never becoming symmetrical) and so the repulsive force from the wall becomes small (never becoming null).

In summary, the combination of immersed boundary methods based on continuum mechanics approaches, and lattice Boltzmann methods, allows one to define a computational framework for precisely elucidating the transport mechanics of nanoconstructs. Future efforts are needed to perform systematic analyses varying the Reynolds numbers, the shape and deformability of nanoconstructs, and including the adhesive interaction with vascular and other circulating cells.

21.3 Multifunctional Polymeric Nanoconstructs

The enhanced permeability and retention effect (EPR) has been extensively exploited for facilitating the accumulation of systemically injected nanoparticles within the tumor tissue [21.69]. This effect relies on the occurrence of openings – fenestrations – within the tumor vasculature, which can be passively crossed by long circulating nanoparticles with a diameter on the average of 100 nm. However, the size of fenestrations depends on tumor type, location and stage, and its high variability often limits the efficacy of EPR-based delivery strategies. Moreover, the occurrence of fenestrations in human patients seems to be far less common than in preclinical models of the same disease [21.69]. This has pushed scientists to identify novel and complementary strategies for enhancing nanoparticle accumulation within neoplastic masses. The rapid and uncontrolled development of cancerous tissues is generally associated with high tortuosity and permeability of the tumor vasculature and minimal activity of the lymphatic system [21.70]. This is often responsible for lower blood perfusion and mean blood velocity in tumor capillaries as well as higher interstitial fluid pressure compared to healthy tissues. Nanoconstructs can be designed to take advantage of such differences and specifically lodge within the tumor vasculature. In the following subsections, examples are given of nanoconstructs targeting tumors via the EPR effect (spherical polymeric nanoconstructs – SPNs) and by exploiting specific features of tumor vasculature (discoidal polymeric nanoconstructs – DPNs).

21.3.1 Spherical Polymeric Nanoconstructs (SPNs) for Combination Therapy and Biomedical Imaging

Two different polymeric nanoconstructs will be presented here for the systemic delivery of multiple drug molecules and contrast agents for imaging. The two nanoconstructs are spherical in shape with a diameter of about 100 nm and are composed of the same constituents: poly(lactic-co-glycolic acid) (PLGA), and DPPC (1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine) and DSPE-PEG (1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-N-[amino(polyethyleneglycol)-2000] (Carboxylic acid)) lipid chains. Due to these features, these nanoconstructs are referred to as spherical polymeric nanoconstructs (SPNs).

In one configuration, SPNs are synthesized by nanoprecipitation. PLGA polymeric chains and two therapeutic agents – docetaxel (DTXL), a potent anticancer molecule, and curcumin (CURC), an anti-inflammatory molecule – are dissolved in acetonitrile (oil phase) (Fig. 21.4a). The lipid chains are dissolved in 4% ethanol at 65 °C and added dropwise into the oil phase while heating. Water is added to reduce the temperature while the mixture is gently stirred. The SPNs' size and surface zeta potential are estimated by dynamic light scattering, whereas electron microscopy imaging analyses are employed to confirm sphericity and size homogeneity (Fig. 21.4b). The same nanoconstructs can be readily labeled with ^{64}Cu for the development of a positron emission tomography (PET) imaging nanoagent. Specifically, the radioactive ^{64}Cu can be entrapped within a DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) cage conjugated directly to the lipid chains constituting the nanoconstruct surface. For this, SPNs are resuspended in acetate buffer (pH 5.5) and incubated with ^{64}Cu for 1 h. Details methods can be found in previous works by the authors [21.71]. The efficacy of combination therapy derived by coloading DTXL and CURC within the same nanoconstruct is demonstrated in vitro and in vivo, using xenograft mouse models of a brain tumor. The systemic administration of SPNs – every two days for 20 days – is responsible for complete tumor regression within 40 days from the treatment initiation (Fig. 21.4c). The same SPNs are also labeled with ^{64}Cu(DOTA) to follow up on the progression of the disease and nanoconstruct accumulation within the neoplastic mass via PET imaging; Fig. 21.4d.

In a second configuration, SPNs are prepared via a sonication-emulsion method. In this case, PLGA, DPPC, and the two drug molecules – DTXL and diclofenac (DICL), a potent anti-inflammatory drug – are dissolved in chloroform (oil phase). DSPE-PEG is dissolved in 4% ethanol (aqueous phase). Then, the oil phase is added dropwise to the aqueous phase under ultrasonication. The resulting emulsion is placed in a low-pressure environment under magnetic stirring. A schematic representation and electron microscopy images of the resulting nanoconstructs are presented in Fig. 21.5a,b. The synergistic effect of the therapeutic combination is tested in vitro (Fig. 21.5c,d) and in vivo (Fig. 21.5e,f), in xenograft mouse models of brain tumor. Tumor response curves suggest that the combination of DTXL and DICL constitutes a potent strategy for inhibiting tumor growth (Fig. 21.5e,f) [21.72].

21.3.2 Discoidal Polymeric Nanoconstructs (DPNs) for Maximizing Accumulation Within Tumor Vasculature

Discoidal polymeric nanoconstructs (DPNs) are designed to firmly adhere to endothelial cells lin-

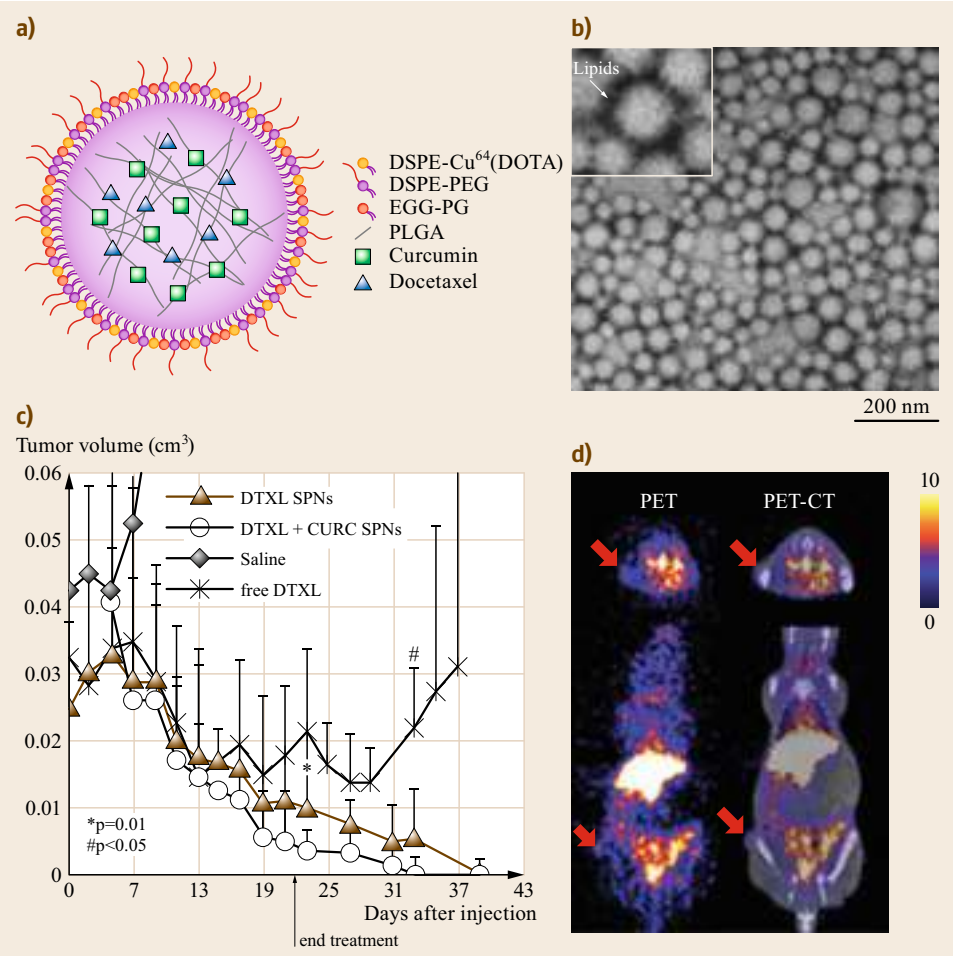

Fig. 21.4a–d *SPNs coloaded with DTXL and CURC for brain tumor therapy* (after [21.71]). **(a)** Schematic representation of SPNs. **(b)** Electron microscopy images of SPNs. **(c)** Brain tumor response to SPN combination therapy in xenograft mouse models. **(d)** Nuclear imaging of SPN accumulation in brain tumors over the course of treatment

ing the diseased vasculature in tumors [21.13]. It has already been shown that nonspherical submicron-sized nanoconstructs can efficiently navigate the circulatory system and sense vascular abnormalities by moving within the *cell-free layer*, behaving like platelets [21.73–76]. While nanoparticles smaller than 200 nm are mainly made through a bottom-up approaches based on emulsification and nanoprecipitation, DPNs are obtained via a modified hydrogel-template strategy [21.13]. The advantage in using a top-down approach rests in the ability to finely tune the size, shape, surface properties and mechanical stiffness (*4S parameters*) of nanoconstructs simultaneously and independently. DPNs' fabrication process starts with the preparation of a silicon master template via electron beam lithography (EBL). In one configuration, this master template comprises arrays of cylindrical holes with a 1 μm diameter and 400 nm depth. This structure is replicated into a polydimethylsiloxane (PDMS) template from which, eventually, several sacrificial poly(vinyl alcohol) (PVA) templates are fabricated. The PVA templates reproduce precisely the same structure as the original Si template. At this point, a polymeric paste is uniformly deposited on the sacrificial PVA template to fill up the wells. UV-light exposure polymerizes the polymers, which after dissolution in water of the sacrificial PVA template, returns the discoidal nanoconstructs [21.13].

DPNs present a highly porous and spongy matrix composed of the two main polymers entangled together: the hydrophobic PLGA and the hydrophilic PEG. Within this polymeric matrix, different therapeutic and imaging payloads can be dispersed depending on the biological applications. For instance, iron oxide nanocubes (NCs) with an edge size of ≈ 20 nm for magnetic resonance imaging, ablation therapy and magnetic guidance [21.13]; ^{64}Cu(DOTA) radioactive molecules for nuclear imaging [21.13]; and red fluorescent dyes (Rhodamine B or cy5) for optical imaging [21.13] can be directly incorporated in the polymeric matrix.

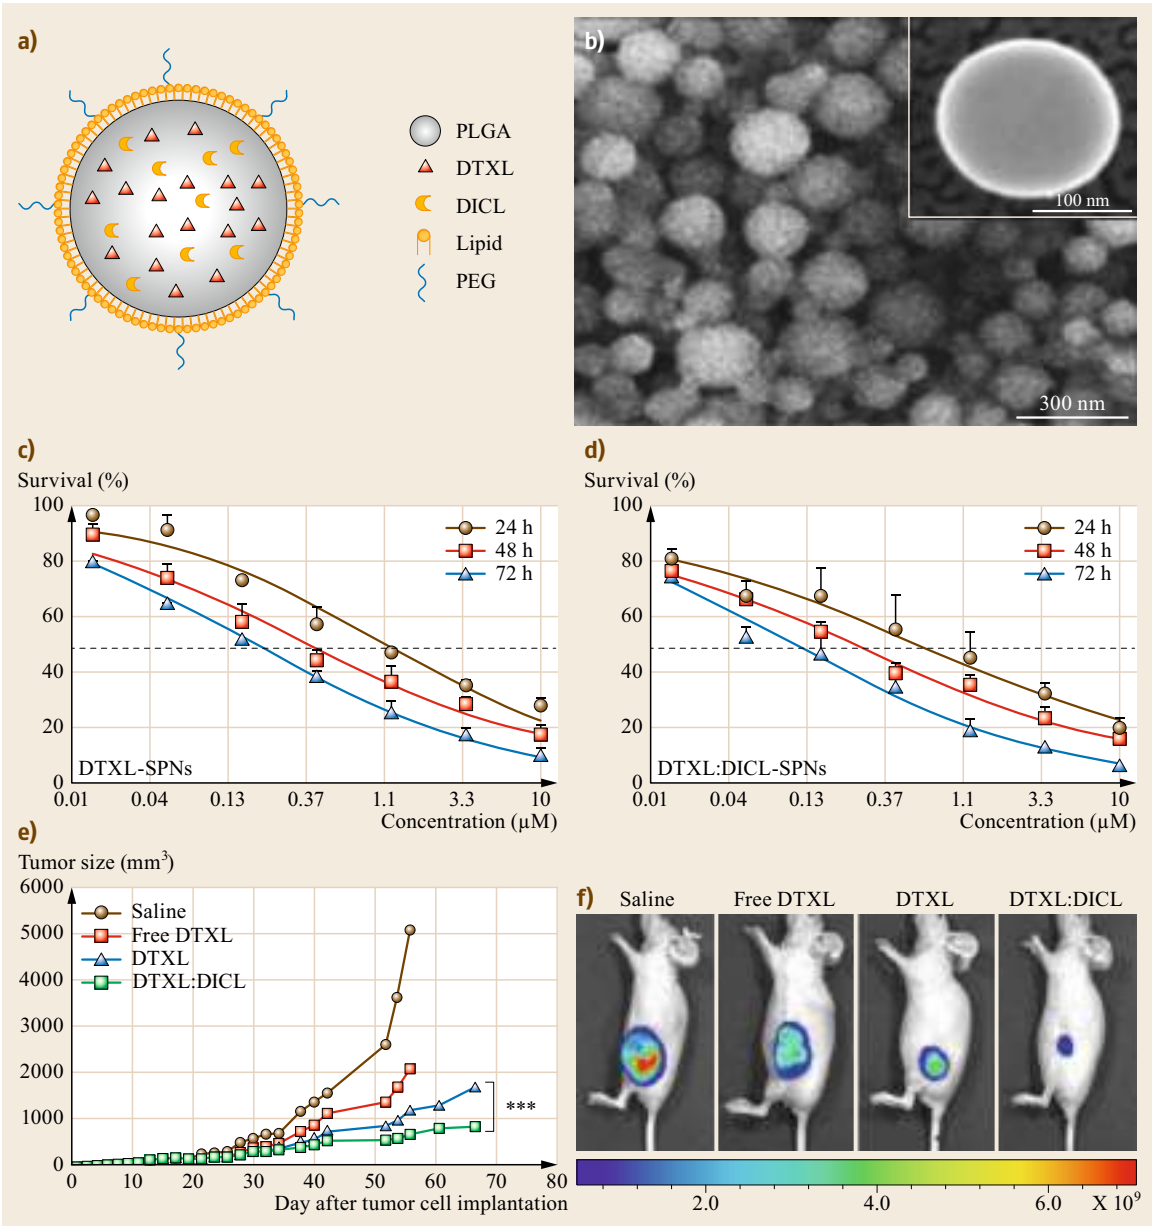

Fig. 21.5a–f *SPNs coloaded with DTXL and DICL for brain tumor therapy* (after [21.72]). **(a)** Schematic representation of SPNs. **(b)** Electron microscopy images of SPNs. **(c,d)** U87-MG brain tumor cell response to SPN combination therapy. **(e,f)** In vivo tumor response to SPN therapy and bioluminescence data for assessing tumor extension (after [21.72], with permission from Elsevier). *** indicates $P < 0.001$

As shown in Fig. 21.6a–d, the geometry of DPNs is characterized via scanning electron microscopy (SEM) and atomic force microscopy (AFM) before removal from the template, and optical microscopy in solution after dissolution of the PVA template. DPNs appear as disks with a circular base of ≈ 1000 nm and height of ≈ 400 nm. The Multisizer data presented in Fig. 21.6d show a size distribution with a peak at ≈ 800 nm, which results from averaging the two characteristic sizes (diameter and height). DPNs present a slightly negative surface electrostatic charge (−14 mV) due to the PLGA terminal carboxylic groups.

Besides controlling the size, shape and surface charge, the top-down fabrication process also allows

the modulation of DPN mechanical properties. Specifically, DPNs with different Young's moduli (soft DPNs and rigid DPNs) are synthesized by changing the concentration of polymers within the original paste. This allows the production of nanoconstructs whose mechanical stiffness can vary from a cell-like Young's modulus (1.5 kPa) to more rigid structures ($\approx$ 20 kPa).

The effect of mechanical stiffness on the in vivo performance of DPNs – blood longevity, biodistribution and macrophage uptake – is assessed in mouse models of brain and melanoma tumors. Specifically, biodistribution studies are performed by injecting DPNs labeled with ^{64}Cu(DOTA) into mice and following the progressive accumulation of DPNs via PET/CT imaging. Figure 21.7a presents transversal and coronal sections of PET/CT images, converted into percentage of injected dose per gram tissue (%ID/g), taken at one, six, 24 and 48 h postinjection of DPNs. These images show, for the initial time points, a significant signal from the

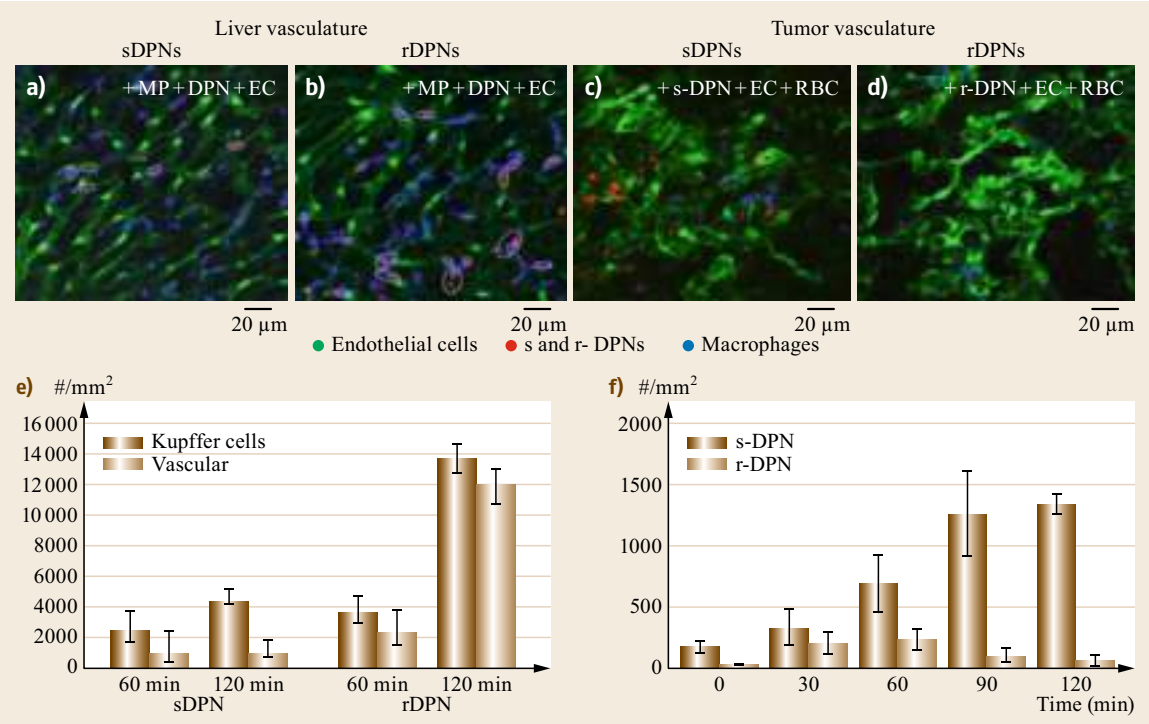

Fig. 21.8a–f *Intravital microscopy studies on soft and rigid DPNs.* **(a–d)** A set of representative liver and tumor images. Differential liver **(e)** and tumor **(f)** accumulation for the two different DPNs. Adapted with permission from [21.13], copyright 2015 American Chemical Society

liver and the abdominal cavity, which tends to reduce over time. Conversely, the signal within the tumor mass grows with time peaking at 24 and 48 h post-DPN injection via the tail vein. Tumor uptake of the soft DPNs reaches almost 20% ID/g tumor at 48 h postinjection (Fig. 21.7b). Note that this accumulation is much higher than what has been observed in similar tumors with SPNs. Figure 21.7c shows data on the blood concentration of DPNs demonstrating that a circulation half-life for the soft DPNs of ≈ 24 is estimated.

A direct comparison between soft and rigid DPNs is performed via intravital microscopy analysis (Fig. 21.8). This technique is used to quantify DPN differential accumulation in the liver and tumor mass. DPNs are systemically injected in tie-2 mice bearing a skin cancer model. These mice are genetically engineered to express green fluorescent proteins in the endothelial cells, so that the vasculature lights up in green under the microscope. As depicted by representative microscopy images (Fig. 21.8a–d), soft DPNs are less prone to sequestration by Kupffer cells in the liver while tending to more avidly deposit within the tumor vasculature as compared to rigid DPNs.

In summary, these examples continue to demonstrate that the size, shape, surface properties and mechanical stiffness of polymeric nanoconstructs should be properly designed and tailored during the fabrication process to maximize tumor accumulation and minimize sequestration by filtering organs, such as the liver, spleen and lungs.

21.4 Sensing and Drug Delivery with Porous Silicon Nanomaterials

Porous silicon (pSi) has been extensively researched and developed as a biomedical material since the first report of its biodegradability and bioactivity in the early 1990s [21.77]. Although pSi is a relatively new biomaterial, it benefits from advanced and established manufacturing, functionalization and characterization processes developed for silicon over several decades by the semiconductor, energy and electrochemistry industries, which accelerates its translation. In the last two-and-a-half decades of research, pSi has

proven simple and versatile to fabricate and functionalize, has displayed favorable interactions with biological systems, and was effective for drug delivery and biosensing.

21.4.1 Fabrication

Of the many top-down [21.82], bottom-up [21.83] and natural-source [21.84] approaches to obtain porous silicon, two main routes have taken center stage in biomedical applications: anodic etching [21.85] and metal-assisted chemical etching (MACE) [21.86]. In these approaches porous silicon forms by etching crystalline silicon wafers in hydrofluoric acid (HF) under conditions leading to local anisotropic oxidation of the silicon surface, which induces porosification. Anodic etching is the most widely documented route for generating porous silicon. During anodic etching, porous silicon forms by applying an anodic current through the wafer in an electrochemical cell with a HF electrolyte. Local injection of holes sustains oxidation at defects sites, followed by the dissolution of oxidized silicon in HF. Following an initial formation of pits at the site of surface defects, the pores propagate along crystalline axes [21.87] or current lines [21.88]. The porosification occurs mainly at the interface between the formed porous layer and the underlying pristine silicon [21.82]. In this way, porous silicon forms as a layer originating from the wafer surface and increasing in thickness as the etch progresses. It is possible to control pore diameter and porosity over wide ranges. The resistivity of the substrate, its doping type, the composition of the etching solution and the density of anodic current influence pore size [21.89]. Higher current density leads to larger pores and higher porosity, up to the limit where electropolishing of the surface occurs [21.82]. Since porosification occurs at the bottom of the porous layer, by modulating the current over time it is possible to vary pore morphology along the axis of etching. This variation can either generate pores with continuously variable size, or distinct discontinuous layers [21.90]. Ultimately, by repeating set cycles of current variation it is possible to generate periodic porous silicon structures (Fig. 21.9a). Due to the spatial variations in the dielectric constant associated with porosity, such periodic structures act as photonic crystals, which find extensive use in biosensing [21.91].

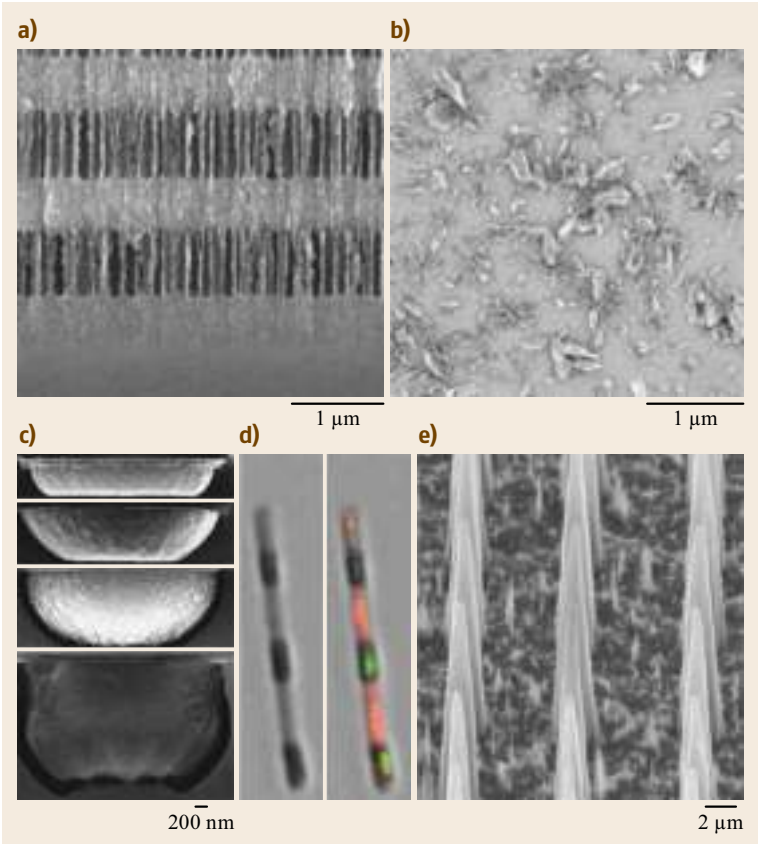

Fig. 21.9a–e *Porous silicon nanostructures.* **(a)** Photonic crystals of pSi obtained with periodic variation of anodic current (after [21.78], courtesy of Wiley). **(b)** Polydisperse pSi nanoparticles obtained from sonication of anodically generated freestanding porous silicon layers (after [21.79], copyright 2011 American Chemical Society). **(c)** Tailored particles obtained from photolithography combined with anodic etching (after [21.80], courtesy of Wiley). **(d)** Nanobarcodes obtained from multilayer metal-assisted chemical etching through variation of oxidant concentration (after [21.80], courtesy of Wiley). **(e)** Nanoneedles obtained from photolithography combined with metal-assisted chemical etching (after [21.81])

Crushing freestanding porous silicon layers forms particles. Forming an electropolishing layer using high anodic currents detaches a pSi layer from the substrate [21.92]. Ultrasonication [21.93] or ball milling [21.94] then crushes the layer into micro- or nanoparticles (Fig. 21.9b). Particles are then size-selected by differential sedimentation in a centrifuge [21.95] or by filtering [21.96]. This strategy is rapid and high yield but grants only limited control over particle size, and no control over particle shape. Controlling size and shape of a nanoparticle influences its behavior as a drug delivery system by determining its biodistribution [21.74, 97], degradation profile and biointerface [21.98]. Combining photolithographic patterning with anodic etching provides tight control over size and shape of the resulting particles (Fig. 21.9c). This strategy forms discoidal, quasihemispherical and tubular nanoparticles, with aspect ratios between two and six and base axes between 400 nm and 3.2 µm [21.99–101]. Modulating the etching forms multilayer nanoparticles. This approach can form a thin layer at the top of the particle to guarantee structural stability, followed by a layer with porosity over 80% and pores larger than 60 nm that would not otherwise be stable by itself [21.100]. Particles with such large pores and high porosity can improve drug loading efficiency and can load large *second-stage* nanoparticles in a *multistage* drug delivery approach [21.101]. Microfabrication combined with anodic etching increases the production yield for tailored porous silicon nanoparticles. This approach first forms porous silicon pillars by deep reactive ion etching, and then selectively porosifies such pillars into stacks of discoidal or quasihemispherical particles.

MACE is more versatile than anodic etching, since it combines anisotropic silicon etching and porosification in a single process [21.99, 102]. In MACE, a metal nanostructure (thin film, nanoparticle, dendrite) catalyzes charge injection into silicon from an oxidizing solution of hydrofluoric acid [21.103]. The charge injection is localized at the silicon–metal interface and the hydrofluoric acid dissolves the oxidized silicon. The speed and extent of silicon oxidation depends on the density and mobility of injected charges [21.104]. This in turn controls the etching rate, the profile and the porosification of the silicon [21.80]. Combining and controlling lithography, metal deposition and MACE yields a wide variety of silicon nanostructures, both porous and nonporous. By tuning silicon resistivity and the etchant composition it is possible to finely tailor pore size and porosity during MACE [21.80]. Etch duration controls the size of the nanostructure along the etching axis, with the etching rate depending on the resistivity of the silicon and the etching solution [21.80, 105]. MACE can modulate pore size and porosity along the etching axis by varying oxidant concentration over time [21.80]. Combining MACE with anodic etching varies the porosity of the nanostructures by controlling the anodic current applied over time [21.106]. These nanostructures are lifted off the substrate either by creating an electropolishing layer as the last process step [21.106] or by mechanical removal [21.80]. The resulting structures are freestanding high-aspect-ratio photonic crystals (nanobarcodes) (Fig. 21.9d). Tailoring metal deposition controls the geometry of the resulting nanostructure. Electroless deposition of noble metal nanoparticles from solution or the deposition of discontinuous metal films (subpercolation threshold) yields vertically aligned, randomly ordered nanowires [21.102]. Patterning the location of the metal deposition with photoresist [21.107], nanospheres [21.108] or a dielectric layer [21.80, 81] creates arbitrary base patterns for the nanostructures, for the formation of nanopillars [21.80, 108], nanofins [21.80] and nanoparticles [21.109]. The typical diameter of MACE nanowires obtained ranges from 10−100 nm; nanopillars and nanofins have typical dimensions in the 300−2000 nm range; and nanoparticles can be as small as 400 nm. Post-MACE plasma etching of the nanopillars shapes them into nanoneedles, with a tailored tip diameter down to less than 50 nm (Fig. 21.9e) [21.81]. Multiple cycles of electroless metal deposition and MACE on nanopillars yield a selective etch of the rim, shaping them into nanorods, nanocones or nanopencils depending on the details of the procedure [21.110]. MACE combined with deep silicon etching forms solid pillars with a thin porous silicon film at the top [21.111].

21.4.2 Surface Chemistry

The surface of a material is a primary determinant of its performance for drug delivery and sensing, as the interaction with biological systems occurs at the interface. Also, the overall properties of porous silicon strongly depend on its surface, due to the high surface-to-volume ratio. The native surface of porous silicon is hydrogen terminated [21.112]. In this native form, porous silicon is photoluminescent, electroluminescent and chemoluminescent [21.113]. The porous structure and the resistivity of the silicon controls the position of the emission band, ranging from the blue to the near-infrared. Although not extremely efficient, thanks to this luminescence pSi nanomaterials can combine imaging alongside their primary delivery and/or sensing task [21.96]. The hydrogen termination of silicon is thermodynamically unstable and in ambient conditions it progressively forms a nonstoichiometric *native* oxide layer [21.114]. The surface defects within this ox-

ide layer affect the luminescence and quench it to levels unsuitable for any application [21.115]. In pursuit of passivation strategies that preserve this valuable optoelectronic behavior, several surface derivatizations were developed [21.116]. Thermal, plasma or wet oxidation yield a thicker and more stoichiometric oxide [21.81, 117]. This silicon oxide surface provides simple and extremely versatile routes of functionalization through silane chemistry [21.118]. Organofunctional alkoxysilanes form covalent Si–O–Si bonds with the hydroxyl groups on the silicon oxide surface, creating a self-assembled mono- or multilayer depending on the details of the process. One of the four arms of the alkoxysilanes can carry a functional group that acts either as the starting point for bioconjugation strategies, or provides functionality at the biointerface. Typical silanization processes yield amine, sulfhydryl and aldehyde groups, which serve as the starting point for many bioconjugation strategies and biological interactions [21.119].

Thermal carbonization in the presence of acetylene yields a silicon carbide surface, either C or CH_2 terminated, depending on the process conditions [21.120]. The CH_2 surfaces can be oxidized to form hydroxyl groups for silane functionalization, or the surface hydrogens can mediate hydrosilylation with undecylenic acid. The pristine hydrogen surface can also be directly hydrosilylated through thermal, photochemical or lewis acid mediated reactions [21.85]. The undecylated surface provides a carboxylic acid for biological interaction and functionalization.

21.4.3 Biointerface

Porous silicon is biodegradable, with a degradation kinetic influenced by its porous structure, its surface chemistry and the environment. Oxidized porous silicon readily undergoes hydrolysis and dissolution by attack of OH^- ions (Fig. 21.10a) [21.121].

The kinetic of this dissolution depends on the surface-to-volume ratio (i. e., on the porosity and wall thickness size) and on the concentration of OH^- ions in solution [21.124]. Surface functionalization by silanization [21.80] or with polyethylene glycol [21.125] slows the degradation kinetic of porous silicon particles in a chain-length-dependent fashion, likely by hampering the diffusion of nucleophilic moieties and that of the dissolved silicon to and from the particle surface. Porous silicon surfaces that degrade very slowly due to their low porosity can catalyze the deposition of minerals from biological buffers and contribute to the mineral formation process necessary for osteogenesis [21.77, 126]. Surface carbonization improves the stability of porous silicon in aqueous solutions, significantly slowing the degradation kinetics and the ability of alkaline solutions to attack the porous structure [21.127]. There is strong evidence that intravenously injected porous silicon particles degrade in vivo [21.99, 128–130], and that their degradation kinetics strongly depends on their microenvironment [21.128]. The changes in their photonic properties that occur with degradation allow monitoring of the process in vivo [21.131].

Passivated porous silicon is a highly biocompatible material. Although the native hydrogen termination can generate reactive oxygen species [21.132], its oxidized form is safe at the concentrations relevant for biomedical applications [21.95, 123]. Porous silicon as a cell culture substrate [21.126, 133, 134] and in nanoparticle form [21.35, 95] interacting with a wide range of mammalian cells does not exhibit significant toxic effects. The carbonized surface is less cytocompatible than the oxidized one, in a dose- and size-dependent fashion [21.95]. Animal models prove the safety of multiple pSi administration routes, including oral [21.135], intravenous [21.129], intraocular [21.136] and intratumoral [21.137]. Intratumoral administration is safe in humans [21.137]. Orally administered porous silicon particles are not absorbed through the intestine [21.135], while their intravenous injection does not modulate cytokines, indicating a favorable immune response profile [21.129].

Phagocytic and nonphagocytic cells internalize porous silicon micro- and nanoparticles in a surface chemistry-dependent fashion [21.95, 138]. Positively and negatively charged particles are readily opsonized and internalized by cells, while particles functionalized with polyethylene glycol moieties are more resistant to opsonization and internalization [21.123]. Coating the particles with a leukocyte-derived membrane also delays their recognition and internalization by phagocytic cells [21.37]. These *leukolike* particles cross epithelial layers more efficiently than *naked* pSi ones and injected intravenously they display prolonged circulation times. The particles are internalized by endocytotic pathways and trafficked through the endolysosomal system to the perinuclear region of cells [21.56, 139]. A nanoparticle payload loaded within the pores can be sorted within the endolysosomal system and follow a different fate, which can ultimately lead to exocytosis (Fig. 21.10b) [21.123].

Flatter, discoidal nanoparticles marginate and interact with epithelial layers more efficiently than hemispherical ones [21.74]. In vivo, the size and aspect ratio of the particles affects their biodistribution (Fig. 21.10c) [21.74, 99]. Smaller particles more efficiently negotiate the organs of the mononuclear phagocytic system and the small capillaries of the alveoli, accumulating more efficiently at a tumor target site [21.74, 99]. Flat, discoidal particles accumulate

preferentially in the lungs and heart, while cylindrical ones accumulate in the liver. Live imaging of injectable pSi particles tracks their biodistribution in real time [21.96, 130, 140]. Time-resolved fluorescence imaging enhances the signal originating from pSi over the fluorescence tissue background, improving the limit of detection [21.130].

21.4.4 Drug Delivery

Porous silicon particles efficiently load a variety of payloads. They load small-molecule drugs across a wide range of solubilities with differences in acid/base character and lipophilicity, and from multiple biopharmaceutical classifications [21.94]. They modulate the solubility of the payload as a function of pH [21.94]. In general pSi encapsulation enhances the solubility of poorly soluble drugs and reduces that of highly soluble ones [21.94]. Porous silicon particles efficiently load biological payloads, including proteins [21.141], peptides [21.142] and nucleic acids [21.81, 108], while mediating their sustained release over several hours and days. The mesoporous structure provides a harvesting effect thereby concentrating the biological payload with respect to the loading solution [21.81, 100]. Capping the porous structure with pH-responsive moieties, such as pH-responsive polymers [21.123] or nanovalves [21.143], enables triggered or smart drug delivery. A polymeric coating protects biological payloads from degradation [21.141]. An agarose coating prevents access of proteolytic enzymes within the porous structure, increasing the stability of a protein payload. This coating does not affect the degradation profile of the particle, nor the release profile of the payload.

Porous silicon particles also load and release nanoparticles in a dose-dependent fashion (Fig. 21.11a) [21.35]. The loading efficiency depends on the relative pore-to-particle size, with a pore size twice that of the particle providing ideal loading [21.100]. Particles larger than the pores do not load due to size exclusion [21.80]. Sequentially loading nanoparticles from the largest diameter to the smallest achieves compartmentalized loading into porous silicon structures (Fig. 21.11b) [21.35, 80].

Porous silicon nanoparticles mediate light absorption and photothermal therapy by conjugation with porphyrins [21.145]. The delivery of antibiotics from pSi particles sustains antibacterial activity over several weeks [21.146]. The particles release chemotherapeutic agents to kill cancer cells both in untargeted and targeted fashions. The *leukolike* system can effectively cross an endothelial barrier and deliver doxorubicin to the far side of it, causing the death of cancer cells while preserving the viability of the endothelium (Fig. 21.11c) [21.56]. Intraperitoneal delivery of a pSi multistage system delivers siRNA for sustained silencing of target genes, inducing ovarian tumor regression in mouse models [21.129]. Similarly, intravenous injection of polymeric doxorubicin

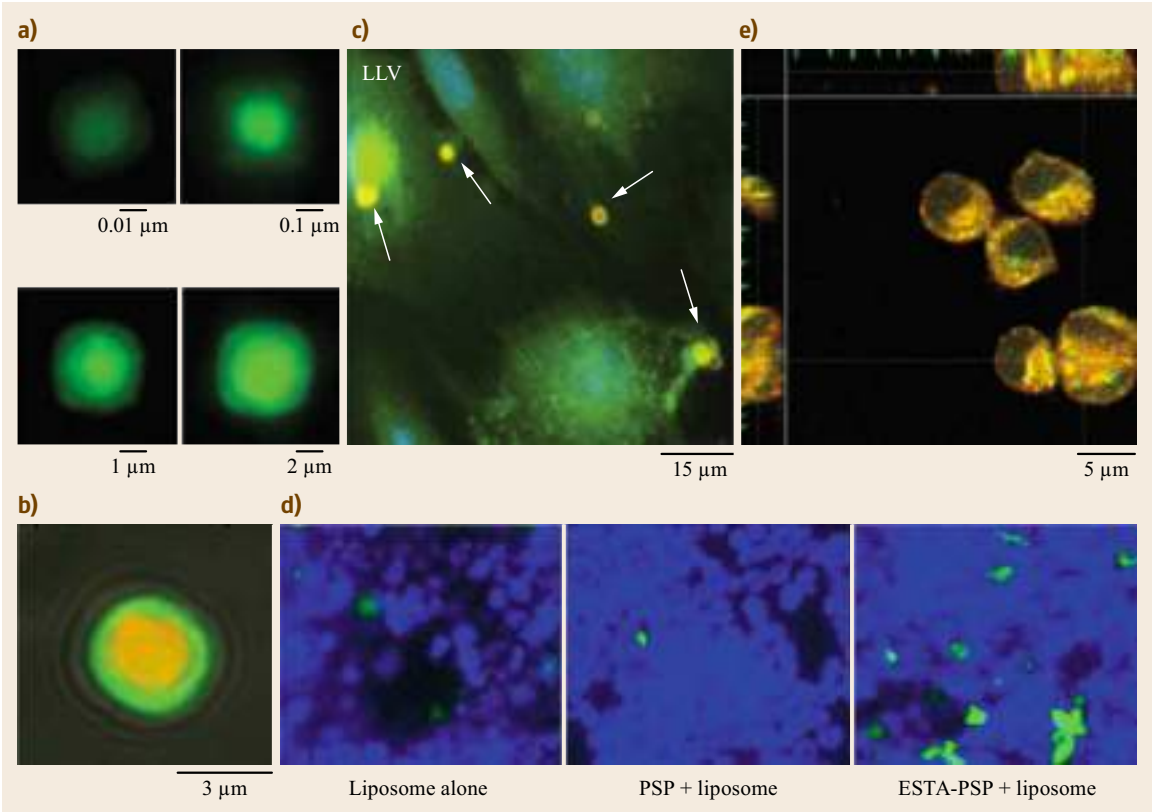

Fig. 21.11a–e *Porous silicon for drug delivery.* **(a)** Dose-dependent loading of quantum dots (*green*) into a porous silicon particle (after [21.35]). **(b)** Size-dependent compartmentalized loading of carbon nanotubes (*green*) and quantum dots (*red*) into a porous silicon particle (after [21.35]). **(c)** In vitro delivery of nucleic acids from porous silicon nanoneedles. Targeting efficiency is compared between delivery of payload alone (liposome alone), delivery with pSi particles (PSP + liposome) and delivery with targeted pSi particles (ESTA-PSP + liposome). Cell nuclei are in *blue*, liposomes are in *green* (after [21.144], courtesy of Wiley)

nanoparticles loaded within the porous silicon matrix accumulates doxorubicin at metastatic liver sites inducing their regression, and improving overall survival in a mouse model [21.147]. Porous silicon functionalized with bioactive molecules to actively recognize tumors effectively localizes at the tumor site and improves therapeutic efficacy over untargeted approaches (Fig. 21.11d) [21.54, 144, 148]. Porous silicon particles can deliver immunostimulators eliciting a host response in the context of immunotherapy [21.149].

Porous silicon nanoneedles are efficient delivery systems for nucleic acids [21.81] and nanoparticles [21.150]. They interface tightly with the cell and deliver their payload directly to the cytosol, bypassing the endolysosomal system (Fig. 21.11e) [21.150]. Nanoneedles interfacing with cells (nanoinjection) modulate expression of target genes following delivery of siRNA or plasmid DNA for up to 92% of the cells in culture [21.81]. Nanoinjection in vivo is safe and does not elicit detectable immune reactions [21.81]. In the first example of nanoneedle-mediated in vivo gene therapy, nanoinjection localized delivery to a defined area within the muscle of a mouse and delivered a plasmid encoding for the human vascular endothelial growth factor (VEGF) [21.81]. The nanoinjection induced localized expression of the target protein and the formation of new blood vessels connected to the vasculature of the host [21.81].

Human trials with pSi particles proved their safety, and the efficacy of locally delivered brachytherapy through intratumoral injection of neutron-activated porous silicon nanoparticles [21.137].

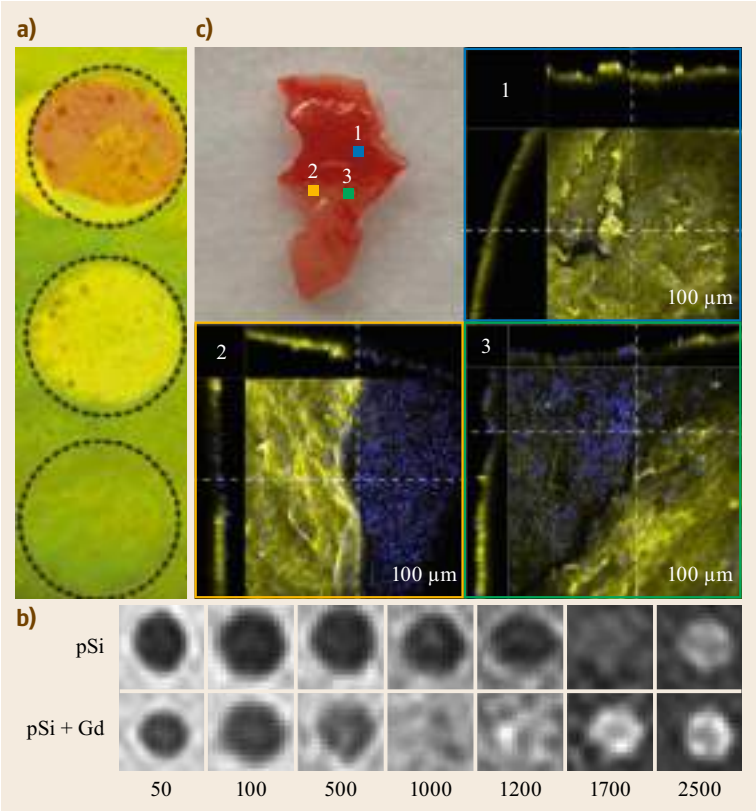

Fig. 21.12a–c *Sensing with porous silicon.* **(a)** Colorimetric detection of protease activity on a porous silicon photonic crystal. Protease activity is detected by intracellular fluorescent signals in three locations across the margin. Cell nuclei are in *blue*, fluorescent signal is in *yellow* (after [21.152], courtesy of Wiley)

21.4.5 Sensing

Biosensors can leverage the photonic properties of porous silicon to detect small molecules [21.153], proteins [21.151], nucleic acids [21.154] and pathogens [21.155]. The general principle of operation relies on the adsorption of biomolecules inducing a shift in the transmittance or reflectance spectrum of a porous silicon photonic crystal (Fig. 21.12a) [21.156]. The adsorption process can be made specific for a target analyte through a selective enzymatic substrate [21.157] or the bioconjugation of a complementary biomolecule that selectively recognizes it. Ligand–receptor interactions [21.158], base-pair complementarity [21.154] and antibody/aptamer–target interactions [21.159] are among the most common strategies developed to generate porous silicon biosensors. Most of these biosensors are thin films developed for use ex vivo, but can be formulated as particles [21.93]. While optical reporting is the most common strategy, electrochemical [21.159] reporting strategies are employed when advantageous.

Porous silicon nanostructures are efficient Raman substrates. The porous structure can host metal nanoparticles mediating surface-enhanced Raman scattering to achieve ultralow limits of analyte detection in biologically relevant buffers [21.111].

The natural photoluminescence of porous silicon makes it an ideal candidate for near-infrared imaging. The organ distribution and clearance of pSi particles can be imaged live [21.96, 130, 140]. Porous silicon particles absorb ultrasound, mediating both imaging and thermal therapy [21.160]. The confinement of gadolinium nanoparticles within the porous silicon structure enhances their longitudinal relaxivity, improving their performance as MRI (magnetic resonance imaging) contrast agents (Fig. 21.12b) [21.39, 161].

Porous silicon nanoneedles, thanks to their tight interaction with cells, can detect enzymatic activity within the cell cytosol. A fluorescently labeled peptide cleavable by Cathepsin B and bioconjugated to the nanoneedles can discriminate cancer cells from healthy ones in coculture, thanks to their cytosolic enzymatic activity [21.152]. The same sensor can discriminate tumor clinical samples of tissue from healthy ones, and image the intracellular activity of Cathepsin B across a tumor margin region (Fig. 21.12c).

21.5 Nanomedicine Synthesis by Microfluidics Technology

In drug development the poor water solubility of drugs is one of the major problems. Thus, for the last decades, the pharmacological properties of free drugs have been improved using different strategies [21.162–165]. For example, drugs can be integrated into carriers for protection from acidic pH or enzymes that may degrade them, with tunable release properties for increasing their bioavailability [21.166–168]. This is particularly important for chemotherapeutic agents, which usually have low solubility and stability, leading to deleterious off-target side effects and poor therapeutic efficacy. Targeted therapy in cancer is very important, and different nanocarriers have been extensively used as nanomedicine tools for the treatment of solid tumors [21.96, 169–171]. For example, porous silicon (pSi) materials [21.89, 165, 172] have been extensively used in drug delivery and biomedicine due to their properties, which can overcome some of the challenges in the field of drug delivery [21.142, 165, 173]. However, like in many drug delivery systems, these materials per se do not provide fully controlled drug delivery of the payloads. To overcome this hurdle different fabrication strategies of nanomaterials have been reported, including microfluidics technology [21.13, 174].

In general, this technique can be used to precisely manipulate fluids in the micrometric scale in a highly reproducible way [21.176], using droplet-based methods [21.176] for carriers in the micrometric range or mixing-based microfluidics based on the nanoprecipitation principle for preparing nanorange delivery systems [21.81, 178]. This technique allows the production of drug delivery systems with high encapsulation efficiency, and a precise control of the size and dispersity of the carrier. This is particularly important for the co-delivery of multiple therapeutics using the same carrier, allowing for the precise control over the drug loading and release for simultaneously encapsulated cargoes and facilitating combination therapy, especially if hydrophobic and hydrophilic payloads are codelivered, and minimizing the batch-to-batch variability.

In this section, the microfluidics technique for preparing nanomedicines and its applications in cancer are presented and discussed with practical examples of our most recent research on this topic, focusing on the fabrication of multiple therapeutics loaded into multicomponent platform systems with precisely controlled drug loading and release prepared by microfluidic-based platforms.

21.5.1 Why Microfluidics for the Synthesis of Nanomedicines?

During the last years, microfluidics has impacted the fields of biological analysis, chemical synthesis, tissue engineering, colloid generation, and cell encapsulation [21.179–182]. Microfluidics offers great possibilities, such as the capacity to use tiny amounts of samples and reagents, detection and separation of compounds with high resolution and sensitivity, and exploitation of the laminar flow occurring at the microchannels at a reduced cost [21.183]. The manipulation of multiphase flows in microfluidics can be used to produce lipidic and polymeric particles by single emulsion-templating [21.184, 185], double emulsion-

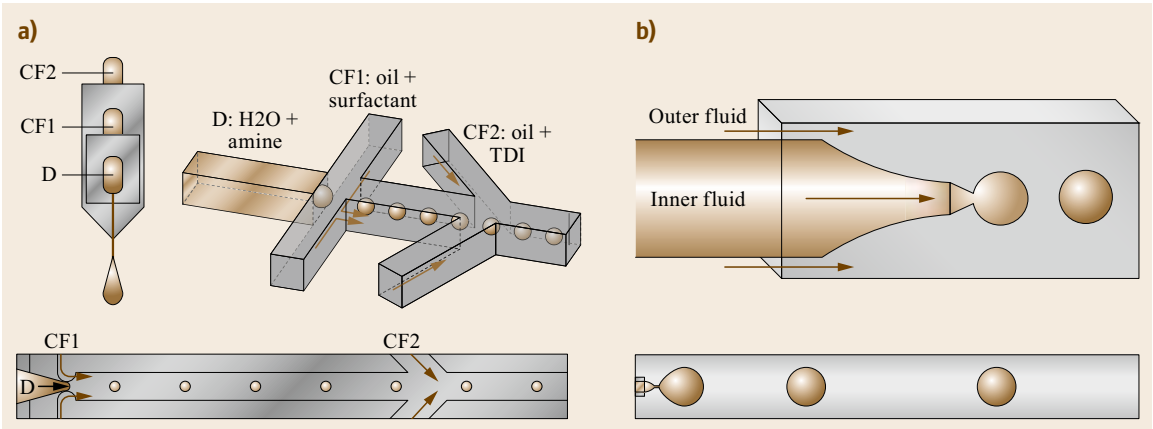

Fig. 21.13 **(a)** Schematics of the geometry of droplet formations in a PDMS microfluidic device; *D*: dispersed fluid, *CF*: continuous fluid for emulsification, *CF*2: continuous fluid for encapsulation (after [21.175], copyright 2015 American Chemical Society). **(b)** Glass capillary flow-focusing microfluidic device; a truly 3-D flow can be achieved, as compared to the PDMS device (after [21.176, 177], reproduced with permission)

templating [21.186], and rapid mixing [21.81]. The size of the droplets and nanoparticles can be finely tuned by controlling the flow rates of the fluids pumped inside the capillaries, where the viscosity and interfacial tension of the fluids, and the type and concentration of the polymers or lipids used, stabilizes the droplets or forms the nanoparticles, which are highly monodisperse and have high encapsulation efficiencies [21.81, 187–189].

The production of particles can be achieved by using microchannels etched primarily on a Si rubber of poly(dimethylsiloxane) (PDMS) using soft lithography [21.190], by chemical attachment to a glass slide, or by a circular capillary (or a series of them) inserted concentrically into another capillary and coaxially aligned and glued to a glass slide [21.47]. In the case of glass capillary, the production of truly three-dimensional (3-D) flows can be achieved [21.176], and they are very robust and compatible with a wide variety of solvents [21.59], as compared to the PDMS ones (Fig. 21.13). However, a high production efficiency in the assembly can be achieved with microchannels in PDMS platforms. The fluid flow manipulation offered by the microfluidics technique allows for the control of the material formation dynamics, thus facilitating the fabrication of many advanced drug delivery systems, e.g., double and higher-order emulsions, microcapsules, nanoparticles and other colloidal delivery systems [21.13, 174, 176, 177, 179, 191–193]. In addition, this technology further offers precise control over the shape, size, and geometry of the carriers, as well as the loading of different cargoes [21.174, 179, 194–196].

The fabrication of nanocarriers using the microfluidics technique [21.81, 198], based on the nanoprecipitation approach [21.199] and the formation of nanoparticles (Fig. 21.14), has been suggested to be triggered by the *Ouzo effect* [21.157, 200]. In this case, the mixing process in microfluidic channels can be laminar or turbulent. The former is achieved through hydrodynamic flow-focusing, in which an inner stream is narrowed and focused enabling the rapid diffusion of solvents and nonsolvents inside and outside the stream, and thus the nanoprecipitation of the solute [21.197]. Thus, the size, polydispersity, and the drug loading and release of nanoparticles can be controlled by varying the flow rates, the polymer composition, and the polymer concentration [21.197]. When increasing the viscosity of the liquids or the flow rate or when decreasing the density of the fluids, a higher Reynolds number (Re) can be achieved [21.81, 178]. The transition from low to high Re dictates changes in the mixing patterns of the fluids inside a microfluidic device from laminar flow to microvortices and unsteady jetting [21.81]. In this case, nanoparticles can be prepared with smaller sizes at higher Re [21.81, 178]. Furthermore, the size of the nanoparticle has been shown to be more sensitive to Re than to the solute composition, demonstrating the importance of the mixing speed in the formation of nanoparticles [21.178].

Recently, micro- and nanoparticles have been produced with microfluidics for excellent control of size, defined composition and morphology, as well as size distribution [21.81, 142, 201–205]. Santos' group and collaborators have used microfluidic devices consisting of an assembly of borosilicate glass capillaries on a glass slide to develop advanced micro- and nanocarriers to encapsulate and deliver different cargoes (e.g., small drug molecules and peptides) [21.81, 142, 202, 203]. For example, a microfluidic platform for synthesizing diverse types of homogeneous nanoparticles with mass production rates up to 242.8 g/day was reported [21.81]. Microfluidics was also successfully used to fabricate a pH-responsive multistage system based on polymeric–inorganic nanoparticles for simul-

taneous delivery of fluorouracil and celecoxib for colon cancer combined therapy [21.203]. In addition, pSi nanoparticles have been assembled in giant liposomes on a microfluidic chip for coloading and codelivery of multidrugs combined with synthesized DNA nanostructures, gold nanorods, and magnetic nanoparticles for overcoming the multidrug resistance in cancer cells [21.201]. Similarly, a multifunctional composite consisting of chitosan and cell-penetrating peptide-modified poly(lactide-co-glycolide) (PLGA) and pSi nanoparticles was prepared by microfluidics, specifically designed for simultaneous codelivery of peptide (glucagon-like peptide-1) and an enzymatic inhibitor (dipeptidyl peptidase 4) for therapy of diabetes [21.202].

21.5.2 Microfluidic Production of Nanocarriers Using PDMS Microfluidic Devices

As a result of the advantages of the microfluidic technology, diffusion, emulsification, and mixing approaches have been employed for the continuous preparation of a variety of nanocarriers, including liposomes [21.206], lipid–polymer hybrid nanoparticles [21.207], polymeric nanoparticles [21.208], and polymeric micelles [21.197]. The majority of these nanocarriers have been fabricated with PDMS microfluidic devices, and more recently also with glass capillaries by Santos' group. A few examples of these nanocarriers produced by PDMS are discussed below.

Nanoliposomes and Polymersomes

Using a microfluidic flow-focusing method, *Jahn* et al. fabricated nanoliposomes by employing a central flow of a phospholipid-containing ethanol solution focused at a microchannel cross-junction between two aqueous buffer streams [21.209]. As a result of the dilution of ethanol above a critical concentration, the lipids spontaneously self-assembled into nanoliposomes, which depending on the flow rates, were monodisperse carriers with sizes of 50−150 nm [21.206, 209]. Block copolymer vesicles or *polymersomes* have also been fabricated using a microflow-focusing device (MFFD) for the control of their size [21.210]. The polymersome size was tuned from 40 nm to 2 μm with a narrow size distributions and excellent reproducibility by changing the flow rate ratio in the water and ethanolic inlet channels, thus forming the polymersomes at the ethanol–water interface.

Polymeric Nanoparticles

A very limited number of studies have been reported for the preparation of polymeric nanoparticles using the microfluidic approach, and the majority of these studies rely on the diffusion-governed mixing processes to induce the self-assembly of polymers for cancer treatment. For example, *Kolishetti* et al. developed dual-drug-loaded nanoparticles with precise control over the ratio of payloads with varying physicochemical properties [21.208]. To achieve this, a water-soluble Pt(IV) prodrug was conjugated with the polylactic acid (PLA) polymer backbone, and then a blend of Pt(IV)-conjugated PLA and carboxyl-terminated PLGA-*block*-poly(ethylene glycol) copolymer (PLGA-PEG-COOH) together with docetaxel was pumped into the microfluidic channels (Fig. 21.15a–c). As a result, a great drug encapsulation efficiency and high loading of both hydrophilic and hydrophobic drugs was achieved, further enabling the ratio control over these two drugs. Taking advantage of the functional groups of the PLGA-PEG-COOH polymer, an A10 aptamer was further conjugated onto the nanoparticles' surface for specific targeting of the prostate cancer cells [21.211]. A sustained release for both drugs over a period of 48−72 h was also observed (Fig. 21.15d), independent of the drugs' solubility.

Majedi et al. have also used solvent-free microfluidics for the production of paclitaxel (PTX)-loaded chitosan nanoparticles with fine-tuned physicochemical properties [21.212]. With this method the formation of nanoparticles was driven by changing the pH conditions in an aqueous environment. The avoidance of the organic solvent contamination and the mixing time during the nanoprecipitation process fixed the size and surface potential of the nanoparticles. Consequently, the obtained nanoparticles showed pH-dependent drug release profiles (Fig. 21.15e), as a result of the different solubility of the chitosan at different pH conditions.

Hybrid Nanocarriers

Recently, polymer and lipid hybrid nanocarriers have also been fabricated using microfluidics [21.207, 213]. These complex lipid–polymeric hybrid nanoparticles combine the unique features of both liposomes and polymeric nanoparticles, possessing high drug encapsulation efficiency, high stability in physiological fluids and relatively slow drug release kinetics. The fabrication of the hybrid nanoparticles can be done in a single mixing step by controlling the microscale mixing processes (microvortex), thus achieving hybrid nanoparticles production rates as high as 3 g/h with excellent reproducibility [21.207]. By changing the flow rates in the microvortex platform, the particle size can be tuned (30−170 nm).

In another example, a PDMS-based microfluidic mixer consisting of Tesla structures was also demon-

strated to be effective in the production of lipid–polymeric hybrid nanoparticles (monodisperse of sizes of 40 nm) by enhancing the mixing of fluids in transverse dispersion [21.214]. This technique has also been used to fabricate hybrid lipid–quantum dot (QD) nanocomposites with a homogeneous size distribution of 60 nm, where the nanocomposite contained on average four QDs encapsulated per nanocomposite.

21.5.3 Microfluidic Production of Nanocarriers Using Glass Capillary Microfluidic Devices

Microfluidic glass capillary devices are not yet as common as the PDMS ones. However, a few studies have been reported in the literature and two examples are discussed next.

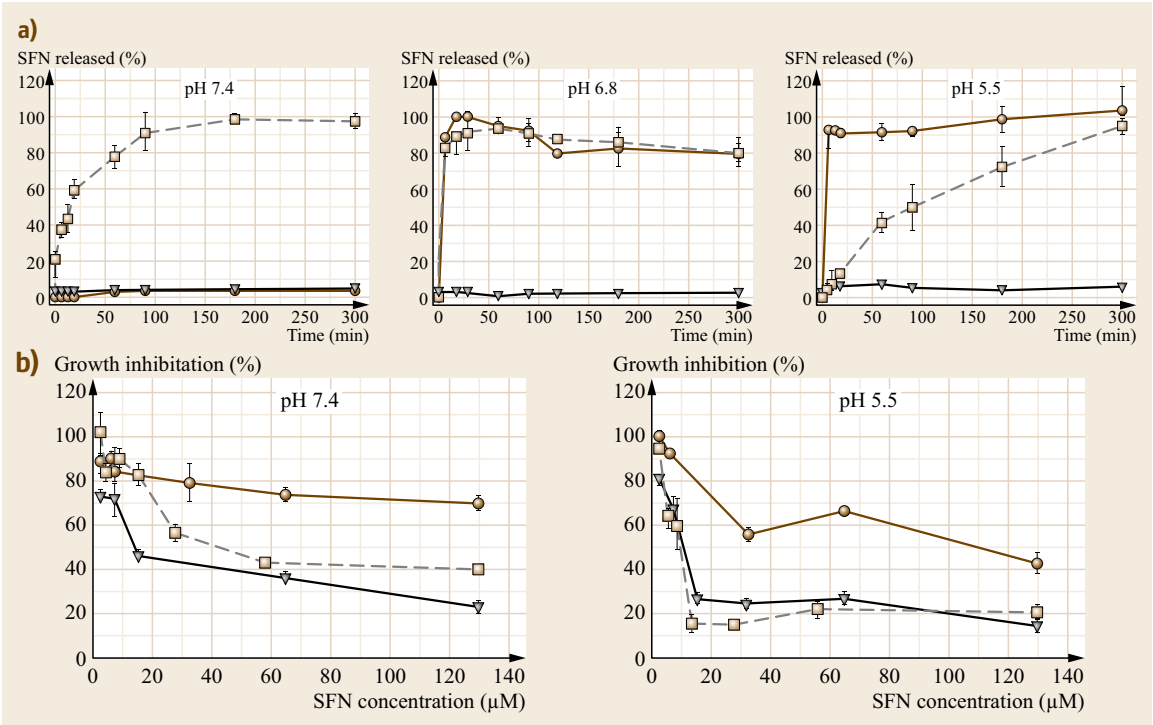

Fig. 21.16 **(a)** Dissolution and drug release profiles of SFN (*solid brown line*), SFN-loaded nanoparticles (*dashed black line*) and nanocomposite (*solid gray line*) in plasma pH 7.4 and PBS enriched with 10% serum at pH 6.8 and 5.5. **(b)** Growth inhibition of PC3MM2 cells incubated with SFN (*black solid line*), SFN-loaded nanoparticles (*dashed gray line*) and the nanocomposite (*solid line*) at pH 7.4 and 5.5 for 24 h (after [21.142])

In order to overcome some of the challenges of the drug nanocarriers for the treatment of tumors, such as the poor water solubility of certain anticancer drugs, fast clearance from the bloodstream and lack of controlled drug delivery at the tumor site [21.215, 216], a smart hybrid nanocomposite was developed consisting of a blend of PEG-*block*-poly(L-histidine) (PEG-PHIS) and PEG-PLA assembled on the surface of sorafenib (SFN)-loaded pSi nanoparticles (circa 130 nm), spontaneously formed by nanoprecipitation in a flow-focusing microfluidic chip [21.142]. The final nanocomposite had a size of 260 nm and a surface charge of −5 mV. This nanocomposite was designed for controlled drug delivery upon acidification of the environment triggered by the tumor extracellular microenvironment or the intracellular endosomes or lysosomes (typical pH values of 5–6.8 [21.217, 218]). PEG-PHIS possessed a pH-responsive behavior due to the presence of an imidazole ring in each histidine unit of the polypeptide bearing a protonable nitrogen, thus a pH-triggered drug release from the pores of the pSi nanoparticles upon the rupture of the polymeric structure assembled on its surface could be achieved. SFN, a cytotoxic drug that inhibits cell proliferation and angiogenesis, was loaded into the pores of the pSi nanoparticles and further encapsulated into the polymeric structure, with a final drug loading degree of 4.9% [21.142]. The SFN release profiles from pSi nanoparticles and the nanocomposite at different conditions, in order to mimic the physiological tumor microenvironment and the intracellular conditions, are shown in Fig. 21.16a. This same system was the used to assess how the pH could trigger the release of SFN from the nanocomposite in order to inhibit the growth of prostate cancer cells, PC3MM2, in different experimental conditions (Fig. 21.16b) [21.142]. It was observed that the concentration of SFN needed to inhibit the cell population to half (IC_{50}) at both pH values was lower than 15 μM, with an IC_{50} of ≈ 27 μM and 130 μM at pH 7.4 for the pure drug and the nanocomposite respectively. At pH 5.5, the IC_{50} of the nanocomposite was reduced to 32 μM, showing that the acidic conditions triggered the release, and thus the drug effectively inhibited the proliferation of PC3MM2 cells.

Increasingly sophisticated strategies are required for combination cancer therapy with co-administration of multiple drugs for synergistic benefits. Combination therapy can be accomplished by coloading multiple

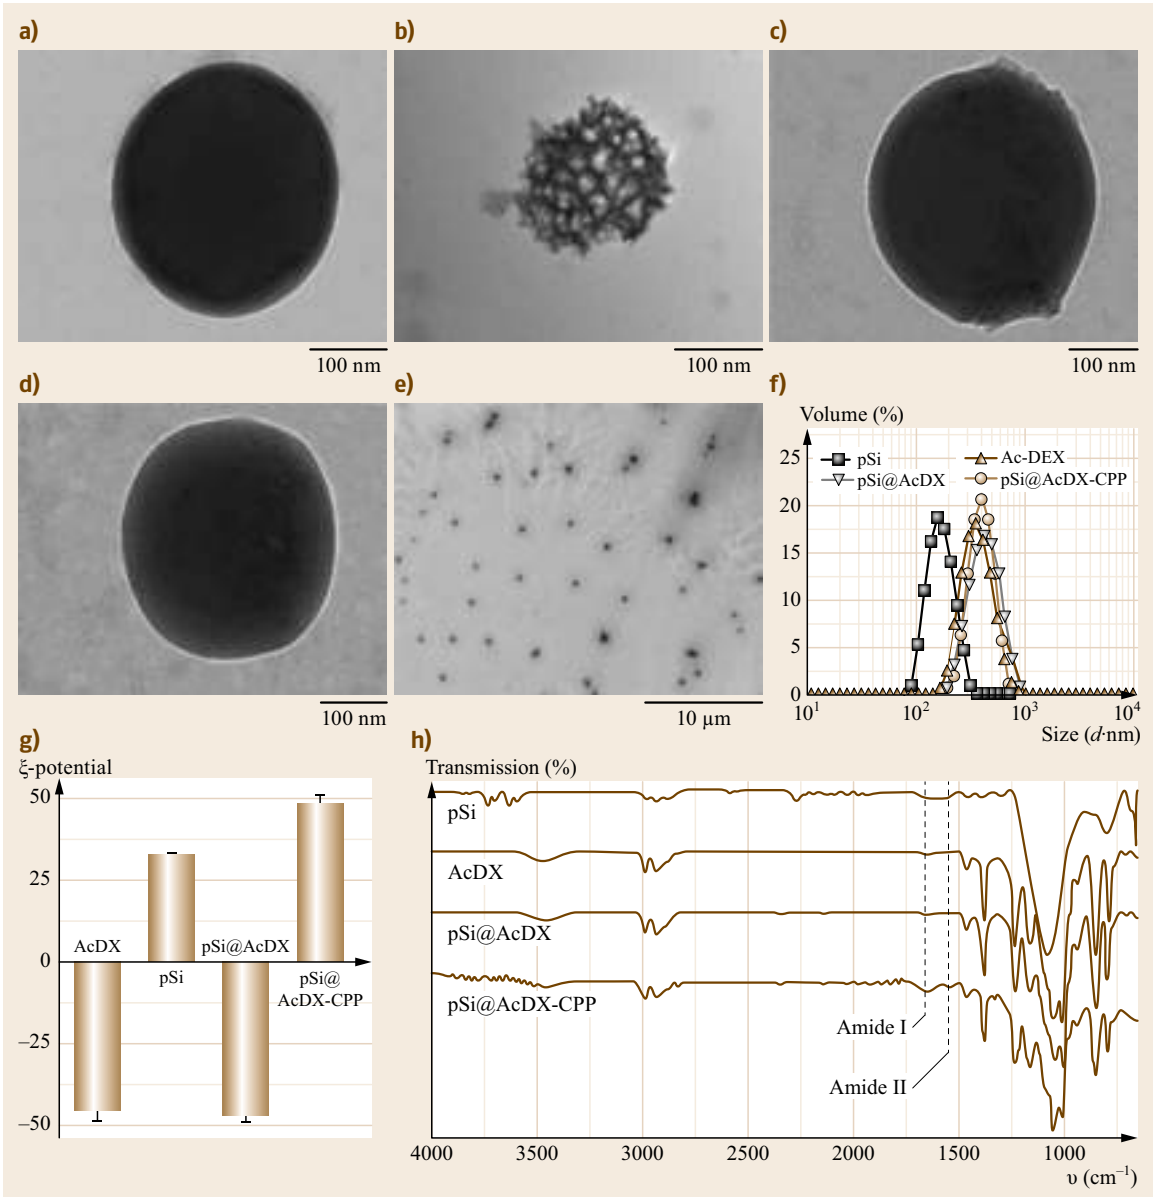

Fig. 21.17a–h TEM images of AcDX **(a)**, pSi **(b)**, pSi@AcDX **(c)** and **(d)** pSi@AcDX-CPP showing the encapsulation of a pSi nanoparticle within the AcDX nanoparticle. **(e)** Low-magnification TEM image and **(f)** volume-based size distribution of the highly homogeneous pSi@AcDX-CPP. **(g)** ζ-potential of the prepared nanosystems. **(h)** FTIR spectra of the nanocarriers confirming the encapsulation of pSi inside the AcDX matrix and the successful surface functionalization with CPP (after [21.81])

drugs into a single nanocarrier system, which can deliver a correct ratio of each drug to the target of interest, generating synergistic therapeutic effects, suppressing the drug resistance and severe adverse effects, as well as allowing controlled drug exposure over time. Therefore, by using a one-step microfluidic method, an advanced nanocomposite consisting of an encapsulated pSi nanoparticle and an acid-degradable polymeric matrix (acetalated dextran; AcDX), pSi@AcDX, was efficiently prepared [21.81] To further enhance the intracellular drug delivery, a nona-arginine cell-penetrating peptide (CPP) was conjugated onto the nanocomposite's surface to form the pSi@AcDX-CPP nanocomposite. The release of the payloads from the nanocomposites was

The total concentration of PTX, SFN, and MTX (circa 1 : 1 : 1, w/w/w) ranged from 0.01 to 100 mg/ml. (after [21.81])

mainly controlled by the degradation rate of the polymeric matrix, which only took place when the pH was lower than 6.0 [21.219, 220]. Figure 21.17 shows an example of the transmission electron microscope (TEM) images, dynamic light scattering (DLS) for size, surface zeta (ζ)-potential for the charge, and Fourier transmission infrared (FTIR) of the prepared nanocomposites.

The above-mentioned nanocomposite was further loaded with different drug molecules for cancer treatment (Fig. 21.18a). Figure 21.18b shows the encapsulation efficiency for the simultaneously loaded PTX, SFN, and methotrexate (MTX) drugs inside the produced nanocomposites. The release studies of the three drugs were conducted at both single pH conditions (pH 7.4 and 5.0), which demonstrated that all the three drugs were trapped inside the pSi@AcDX-CPP (no drug release at pH 7.4), whereas regardless of the solubility of the loaded drugs, they all showed similar release profiles at pH 5.0 (Fig. 21.18c), precisely controlled by the hydrolysis of the AcDX matrix. Finally, the effect of the multidrug-loaded pSi@AcDX-CPP on the proliferation of both MCF-7 and MDA-MB-231 breast cancer cells was evaluated (Fig. 21.18d) [21.81]. Clearly, the combination of free PTX, SFN and MTX remarkably reduced the cell growth in a concentration-dependent manner. After CPP conjugation, the drug-loaded nanocomposite significantly controlled the cell proliferation inhibition, because of the pH-triggered decomposition of the AcDX matrix in the endolysosomal compartments, unlike the bare drug combinations that were indiscriminately more toxic to the cells than the functionalized nanocomposites.

21.5.4 Summary

In this section, a brief overview on the microfluidics techniques used to prepare different nanosystems was presented and discussed. Overall, promising and ad-

vanced multicomposite platforms for controlled drug delivery of multicargoes can be prepared by the microfluidics technique, which is already revolutionizing the drug delivery field. The great advantages of microfluidics are the simplicity and reproducibility of device fabrication, the capability to synthesize nanoparticles with narrower size distributions (< 1% size variation), improved batch-to-batch reproducibility, and higher drug loadings of different cargoes with a theoretical efficiency of 100%.

21.6 Electroless Formation of Metal Nanoparticle Aggregates

Metal nanoparticles are at the backbone of disciplines and techniques like optics, spectrometry and medicine because of their unique optical properties. These properties have been known since ancient times despite the physical/operational principle behind them being obscure. It is sufficient to evoke the art of decoration in Romans (forth century AD), of which a striking example is represented by the Lycurgus cup, as well as by numerous vessels and windows made of decorated glass. Roman glass workers discovered, in fact, that the addition of precious metals (such as gold or silver) during the processing of the molten glass allowed them to obtain a product that changed color depending on the light conditions. In particular, they used salts of gold whose ions, under the effect of the heat of the molten glass, were reduced to metallic nanoparticles. After cooling, the precious nanoparticles remained trapped in the matrix of silicon oxide (glass), creating a decorated glass, now known as *dichroic* glass, characterized by light-dependent colors both in reflection and in transmission. Moreover, in Italy, during 15th and 16th centuries, silver and gold salts were mixed in a paste of clay and vinegar and applied to vessels to obtain, after cooking, the reduction of metal ions to metallic nanoparticles and decorations with wonderful dichroic effects [21.221]. What is the *magic* process that transforms metal salt into particles with such color effects? The described examples are the first registered examples of nanotechnology applications: in particular, examples of a process to generate metal nanoparticles that in modern science is known as *electroless* deposition. This process consists of the chemical reduction of metal ions into metal nanoparticles in aqueous solution: it is the elected method for the metal plating of materials especially in electronic products. The reduction of the metal ions occurs by adding a reducing agent to the solution: metal ions attract the necessary electrons for their reduction from the reaction or oxidation of a reducing agent. The presence of a catalyzer accelerates the process, but sometimes it is the substrate itself that works as the catalyzer on which metal ions and the reducing agent are adsorbed: in this condition the process is an autocatalytic process. Moreover, the reaction does not need electrical current to proceed: it is a spontaneous process. The generic reaction between the metal ions Me^{n+} and the reducing agent Red is

$$m\,Me^{n+} + n\,Red = m\,Me^{0} + n\,Ox\,, \tag{21.1}$$

where n are the electrons necessary to produce the atomic metal Me^0. The driving force of the process is the potential differences of the two redox half-reactions. The Nernst equation gives the relation between the redox potential and the equilibrium constant K_{eq}

$$E_{eq} = E_0 + \frac{RT}{nF}\ln K_{eq}\,, \tag{21.2}$$

where an equilibrium/quasi-equilibrium state of the system is assumed and E_{eq} is the equilibrium electrode potential, E_0 is the standard reduction potential, $R = 8.314\,JK^{-1}\,mol^{-1}$ is the absolute gas constant, T is solution temperature, n is the number of electrons involved in the reaction, and $F = 96\,485\,C\,mol^{-1}$ is the Faraday constant. Moreover, it is known that K_{eq} can be expressed as

$$K_{eq} = \frac{k^+}{k^-} = \frac{\prod_{j=1}^{N}[a(C_j)]^{\nu_j^+}}{\prod_{j=1}^{N}[a(C_j)]^{\nu_j^-}}\,, \tag{21.3}$$

where k^+, k^- are the kinetics constant of the direct and reverse reactions, ν^+, ν^- are the stoichiometric coefficients of the direct and reverse reactions, $a(C_j)$ is the activity of the j-th chemical component in the electrolytic solution, and N is the total number of chemical components. In the specific case of dilute solutions, the equilibrium constant can be rewritten as

$$K_{eq} = \frac{\prod_{j=1}^{N}[Ox]_j^{\nu_j^+}}{\prod_{j=1}^{N}[Red]_j^{\nu_j^-}}\,, \tag{21.4}$$

where $[Ox]_j$ is the molar concentration of the j-oxidized species (the reagents of the redox reaction) and $[Red]_j$ is the molar concentration of the j-reduced species (the products of the redox reaction) [21.222, 223]. The equations above show how the thermodynamic and the kinetics of the electroless process are strongly connected

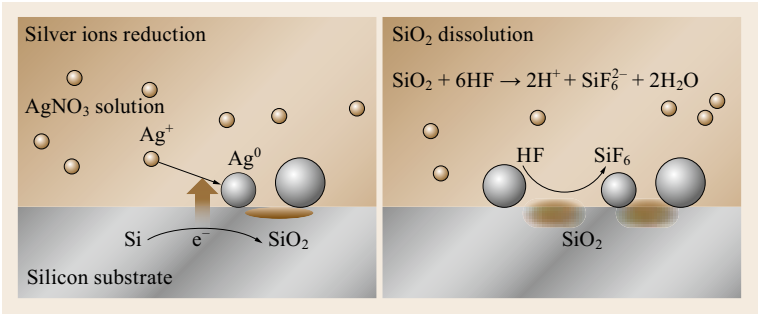

Fig. 21.19 Schematic of electroless deposition of silver on silicon

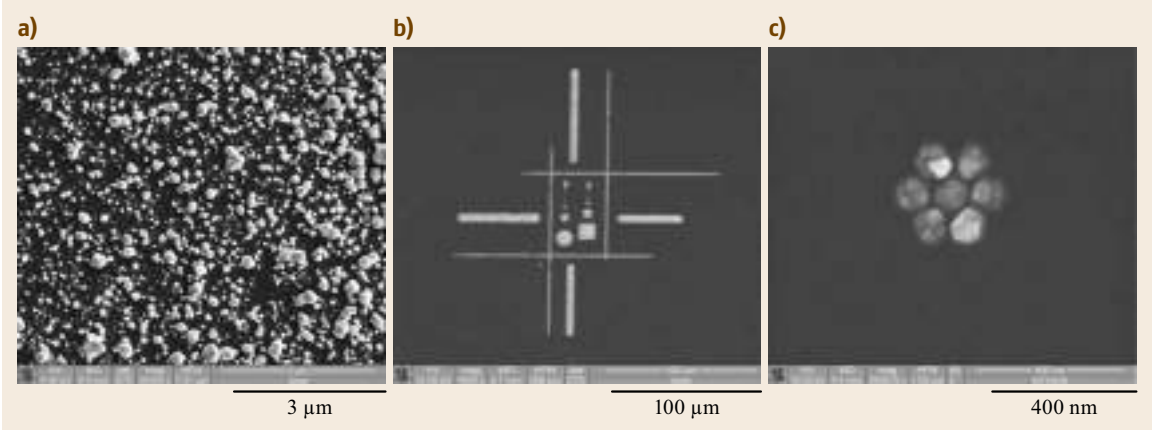

Fig. 21.20a–c Silver nanoparticles are deposited on silicon substrates. The final shape of the structures depends on the pattern obtained through electron beam lithography methods (**b,c**); in the absence of a lithographed pattern, nanoparticles are generated on the substrate with a random distribution (**a**)

and that the total reaction is influenced by concentrations in solution, temperature, time of reaction and type of metals. A particular case is the electroless deposition of metals on a substrate of a semiconductor like silicon. Metal ions exchange electrons with silicon itself which is, at the same time, the reducing agent and catalyzer. The reaction's solution consists of a 0.15 M HF aqueous solution and a metal salt (as auric chloride ($AuCl_3$) or silver nitrate ($AgNO_3$)) dissolved in an opportune concentration. The metal salt concentration and the process conditions (temperature and reaction time) must be adjusted according to the size of silicon samples in solution and the desired metal nanospheres' diameter. The function of hydrofluoric acid is to dissolve silicon oxide resulting from the reaction, making useful new silicon atoms from the substrate, as in Fig. 21.19.

For the particular case of silver nanoparticles, the reactions are:

At the anode (silicon oxidation)

$$\mathrm{Si} + 2\mathrm{H_2O} \rightarrow \mathrm{SiO_2} + 4\mathrm{H^+} + 4\mathrm{e^-}\,. \tag{21.5}$$

At the cathode (silver reduction)

$$\mathrm{Ag^+} + \mathrm{e^-} \rightarrow \mathrm{Ag^0}\,, \tag{21.6}$$

where redox potentials are $E_{01} = -0.86\,\mathrm{V}$, $E_{02} = 0.8\,\mathrm{V}$ [21.224]. Similarly, the reactions for gold nanoparticles are:

At the anode (silicon oxidation)

$$\mathrm{Si} + 2\mathrm{H_2O} \rightarrow \mathrm{SiO_2} + 4\mathrm{H^+} + 4\mathrm{e^-}\,. \tag{21.7}$$

At the cathode (gold reduction)

$$\mathrm{Au^{3+}} + 3\mathrm{e^-} \rightarrow \mathrm{Au^0}\,. \tag{21.8}$$

For this configuration, the standard redox potentials for the two half-reactions are $E_{03} = -0.86\,\mathrm{V}$, $E_{04} = 1.52\,\mathrm{V}$ [21.225, 226]. Both silver and gold react with a similar mechanism, which involves a nucleation phase with the formation of metallic nuclei and then a phase of grain growth. The kinetics of reaction are different for the two metals and in particular it is slower for gold with respect to silver. Moreover, gold forms a greater number of particles with respect to silver, obtaining smaller grains. The mechanism is not very well understood, but it is speculated that the reason behind a similar behavior might reside in the higher potential value of gold with respect to silver, which promotes the nucleation

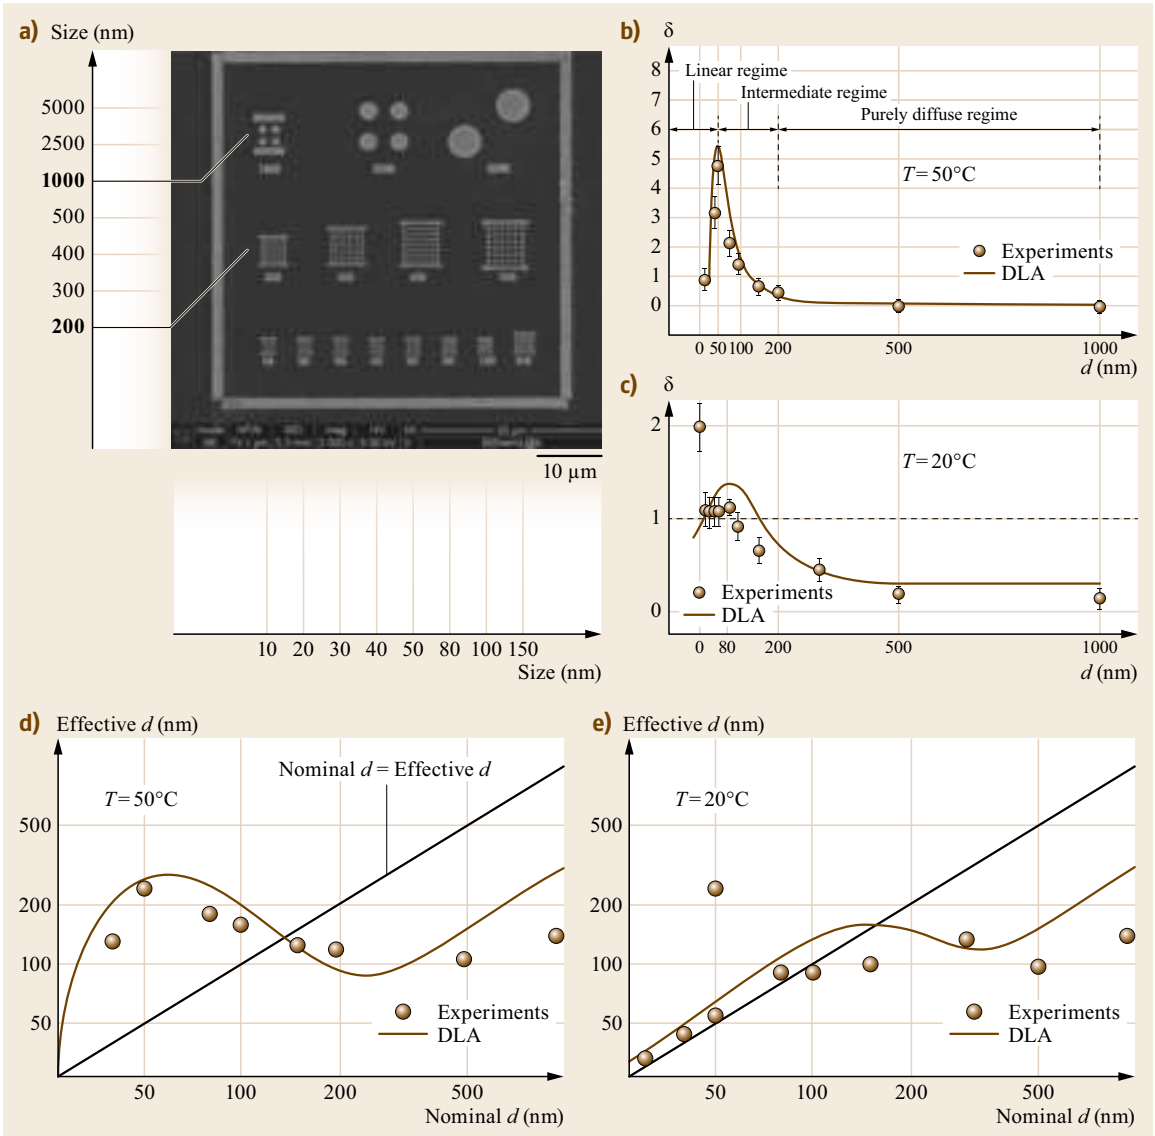

Fig. 21.21a–e In a number of experimental growths in which pattern size was varied over a significant range **(a)**, it was found that silver nanoparticle exhibit the maximum density for a 50 nm pattern size at $T = 50\,^{\circ}\mathrm{C}$ **(b)**, and for a 80 nm pattern size at $T = 20\,^{\circ}\mathrm{C}$ **(c)**. At each temperature, this meant the deviations from nominal and real particle size for different pattern sizes could be found **(d,e)**. A pattern is a template from which particles are obtained after electroless deposition (after [21.107])

of more particles and unbalances the equilibrium of the reactions.

Recent developments of nanofabrication techniques, such as electron beam lithography (EBL) or focused ion beam (FIB), have improved control over the size and shape of nanopatterns. The electroless technique is a simple method to fill those patterns and obtain metal nanoparticles with the desired characteristics. Consider a silicon substrate patterned with a microscale (in the case of optical lithography) or nanoscale (in the case of electron beam lithography) motif. On putting a similar sample in a solution of metal salt, a redox reaction is initialized that is typical of the electroless process: the reaction yields the formation of metal nanograins in the patterned portions of the silicon substrate (holes) exposed to the solution (Fig. 21.20). In Fig. 21.20, silver nanoparticles are deposited on silicon substrates. The final shape of the structures de-

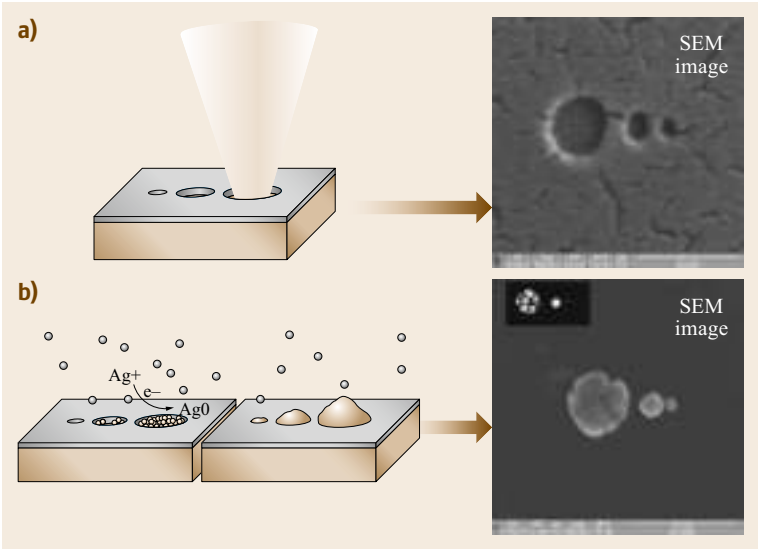

Fig. 21.22a–b Nanolenses are arrays of three silver spheres on a plane in which the size and distance between the spheres progressively reduces. Nanolenses can be obtained by integrating an electron beam lithography technique for the formation of a pattern on a silicon substrate with nanometric resolution **(a)** with a process of electroless deposition **(b)**, which loads the pattern to obtain the final nanoparticles

pends on the pattern obtained through electron beam lithography methods (Fig. 21.20b,c); in the absence of a lithographed pattern, nanoparticles are generated on the substrate with a random distribution (Fig. 21.20a).

Coluccio et al. [21.107] studied the combined effects of the geometry and the growth conditions on size and distribution of the silver nanoparticles. They demonstrated a very high sensitivity of the roughness and compactness of particle clusters to the variables of the process, including pattern size and pattern distance. They found a limiting hole diameter below which metal growth follows a linear regime for which isolated smooth spheres are obtained. Above this limit the structures are discontinuous (Fig. 21.21). This is an important observation because it introduces a criterion of optimal design for the fabrication of nanoparticles in nanophotonics, where tight control over the size and shape of the particles is required.

Thus, by combining electron beam lithography for pattern formation at the nanoscale (that is a top-down approach) with electroless deposition (that is a bottom-up approach), one may obtain nanoparticles with a precise control over the geometry of the particles. The major application of a similar technology is in Raman spectroscopy and surface-enhanced Raman spectroscopy [21.227]. On interacting with an external electromagnetic radiation field, metal nanoparticles sustain localized surface plasmon (LSP) resonance, which is collective oscillation of electrons at the metal–air interface. Similar oscillations are generated in the limit of vanishingly small particle diameters with respect to the EM wavelength, that is when $d \ll \lambda$. Over the particles' surface is thus observed the formation of polarization charges and a consequent dipolar field, which increases the electromagnetic field in close proximity to the particles. In the case of Raman spectroscopy, this phenomenon translates into a giant amplification of the Raman signal of the molecules in close proximity to the metal structures [21.18–20].

Using the described technique, nanostructures were realized to obtain giant SERS effects and probe biological samples with heretofore unattainable resolution. In [21.228], self-similar chains composed of three nanospheres were designed and fabricated, where the diameter of the spheres ranged from 20 to 180 nm and the gap between the smaller spheres was below 10 nm (Fig. 21.22). A similar design guarantees that the EM field in the gap is increased up to one thousand times, and the Raman signal, which goes with the power of four of the EM field, up to the incredible figure of 10^{12} times. A similar increment allows the detection of individual molecules in the gap; notice also that since the gap has a size of few nanometers, it functions like a zoom, or a filter, enhancing the signal of a few molecules against an interfering background. A similar nanolens was arrayed in a rectangular grid to obtain repeated units of the nanolens (Fig. 21.23). In contrast to an individual nanolens, an array of nanolenses may be exploited for the analysis of biological samples in a statistical approach. Notice that in this interpretation, a nanolens in the array is a pixel that carries single measurements. Using this strategy, *Coluccio* et al. [21.228] recognized single-point mutation in a subset of peptides extracted from the BRCA1 protein (a protein responsible for breast cancer) with a sensitivity in the picomolar (10^{-12} M) range. The same strategy was used to detect DNA oligonucleotides with six DNA bases (Fig. 21.24) [21.228]. Interestingly,

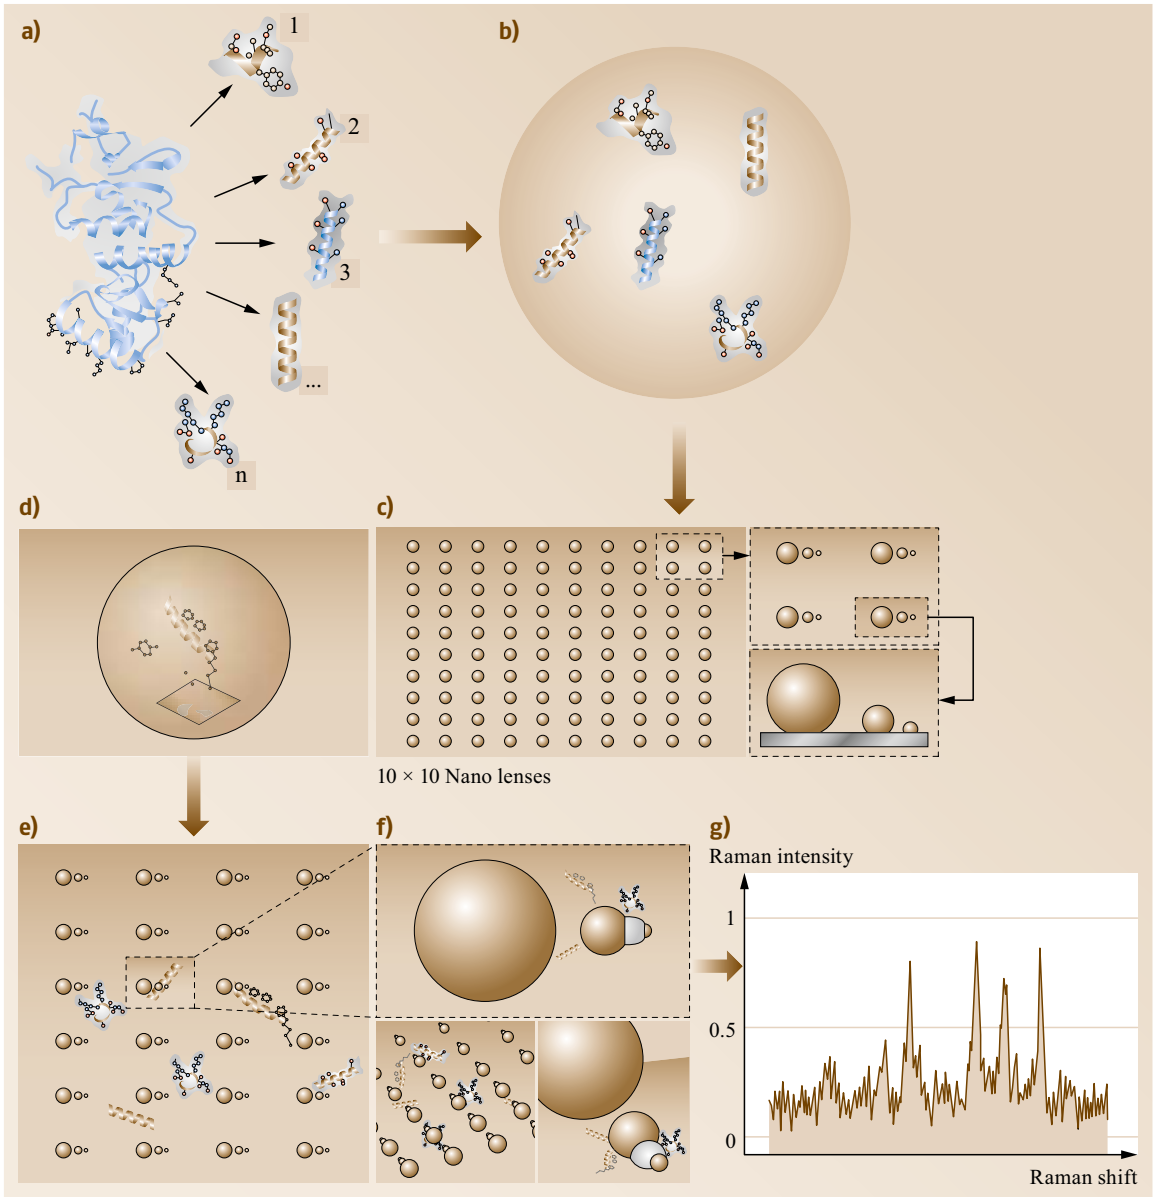

Fig. 21.23a–g Nanolenses were packed into an array to verify single mutations in peptides extracted from the BRCA1 protein **(a)**. The peptides mixture was extracted **(b)** and deposited on a nanolense matrix **(c)**. Due to the small size of each nanolense hot spot, only short fragments could fit into those spots **(e,f)** and be analyzed by SERS **(g)** (after [21.228])

oligonucleotides with nine bases could be detected only using a fitting procedure, in that nine bases did not entirely fit in the hot spots of the device.

21.6.1 DLA Methods Can Predict Electroless Formation of Metal Nanoparticles

In the described method, metal ions stick together to form the intended structures. Under certain experimental conditions, nanoparticles exhibit a dendritic structure (Fig. 21.25) with a recursive motif, which may be described using a fractal formalism.

Fractals are generally observed in nonequilibrium growth processes, where complex structures are obtained using short algorithms. This suggests that the electroless deposition of nanoparticles may be reproduced using mathematical modeling and computer simulations. In a recently proposed approach [21.229],

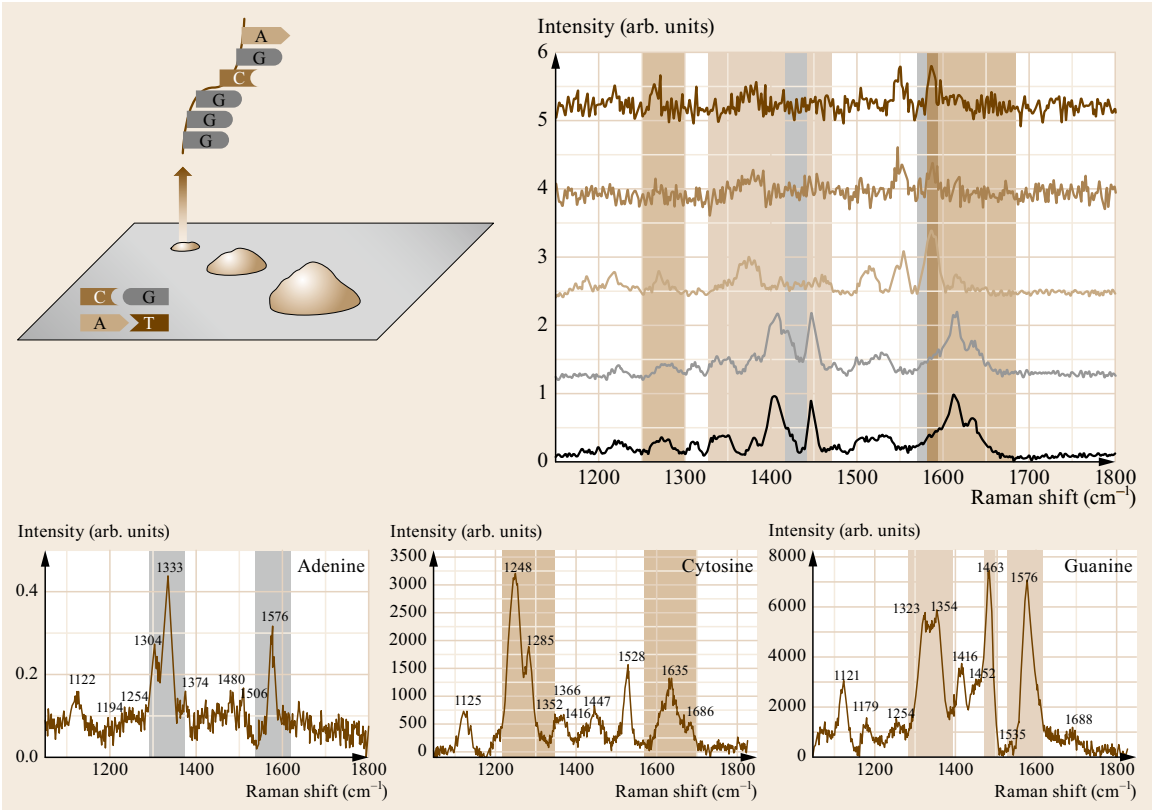

Fig. 21.24 Nanolenses arrays and Raman spectroscopy were used to detect DNA bases in short (six) and long (nine) oligonucleotide sequences

diffusion-limited aggregation (DLA) models were used to decipher the mechanisms of particle growth at the nanoscale. DLA is a simulation method based on simple algorithms in contrast to models that instead make use of analytical solution of equations [21.230]. In many situations it is possible to model a system by entities that diffuse and occasionally react upon encountering each other. These systems are governed by two time scales: the diffusion time, which is the characteristic time required for two particles to meet, and the reaction time, which is the characteristic time for particles to react when held in proximity (within the reaction range) to each other. When the diffusion time dominates over the reaction time, the process is limited by diffusion. Electroless aggregates can be correctly described by DLA models because in electroless deposition diffusion is the main driving force that regulates the dynamics of aggregation [21.229, 231, 232]. The model makes it possible to decipher, at an atomic level, the rules governing the evolution of the growth front, and to explore ways to tailor film morphology to obtain specific characteristics. DLA was formulated for the first time in the pioneering works of *Witten* and *Sander* in the early 1980s [21.233, 234], where the rules of aggregation of small building blocks into supramolecular structures was introduced, as are recapitulated below.

The Model

In what follows, we will describe the DLA model in the particular case of electroless nanoparticle growth on patterned silicon substrates, generated for example through electron beam lithography techniques, as in [21.107, 228]. In doing so, the domain where ions are represented is divided into two regions: the silicon substrate exposed to growth, and the inert resist surface, which defines the boundaries of deposition. In the model, the displacement of a metal ion at any time is arbitrary, and thus the trajectory of the particles can be correctly described by a random walk, resembling a Brownian motion (Fig. 21.26a).

Brownian motion is a continuous-time probabilistic process, and its use is motivated by mathematical convenience and the accuracy of the model to describe an otherwise complex phenomenon. At very short timescales, the motion of a particle undergoing Brownian motion is dominated by its inertia, its dis-

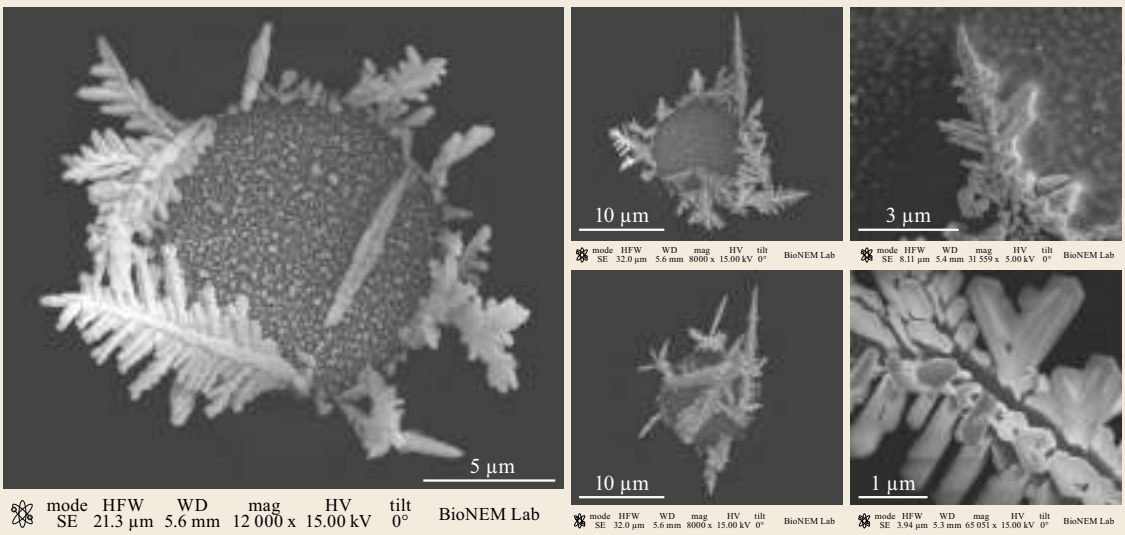

Fig. 21.25 Under certain conditions of electroless deposition, final structures reveal a dendritic fractal structure

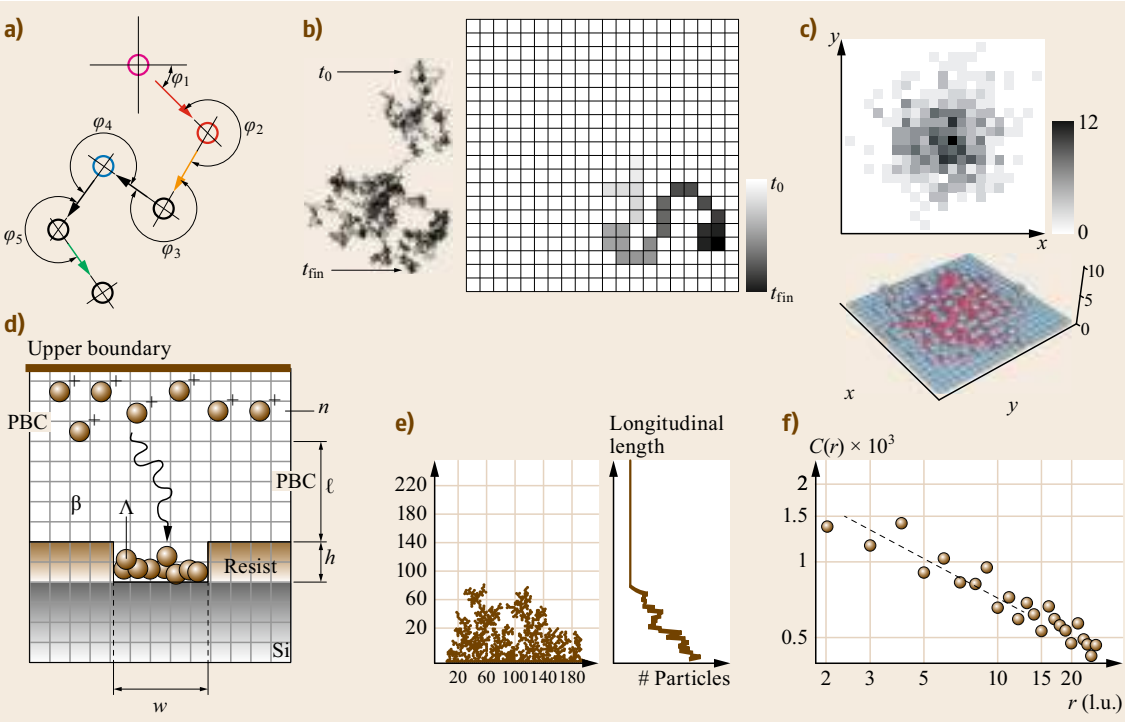

Fig. 21.26a–f Electroless deposition can be simulated using DLA methods. The displacement of individual ions in solution is described by a random Brownian motion **(a)**. The displacement can be reproduced in a grid where displacement takes discrete steps **(b)**. Brownian motion is described by statistics of the second order **(c)**. The entire system can be reproduced in a grid using this concept **(d)**. The simulated aggregate **(e)** has a fractal nature and its fractal dimension can be derived from power spectrum density methods **(f)**. For the present configuration, the parameters of the simulations were adjusted as follows. The simulation was halted after a number of iterations Ni=O(10^{10}). The total number of particles N, and the length of each seed were held fixed, being $N = 2000$, length $(\xi) = 25$ (l.u.)

placement will be linearly dependent on time, $\Delta x = v\tau$, and this can be reproduced or simulated in a regular grid (Fig. 21.26b) where particles are dislodged by the finite distance Δx in the time interval τ, that is the mean time between collisions. The instantaneous velocity of the particles, v, is maintained constant during τ, and it would depend solely upon the energy of the system. The distribution of displacement probability of the Brownian particle itself is best described using a Gaussian density function, centered around the origin of the walk, that means that the most probable position of a particle after a sufficiently large number of steps is its initial position (Fig. 21.26c). The root mean square distance of the walk gives a measure of the extent of spread of the particle ensemble, and this would be proportional to time [21.235]

$$\langle r^2 \rangle = \langle x^2 \rangle + \langle y^2 \rangle = 4Dt \,, \tag{21.9}$$

where x, y, and r are the Cartesian coordinates in the plane, while the celebrated Stokes–Einstein equation may be used to derive the diffusion coefficient D [21.236]

$$D = \frac{k_\mathrm{B}T}{6\pi\mu a} \,, \tag{21.10}$$

where k_B is the Boltzmann constant, T the absolute temperature of the system, μ the viscosity of the medium, and a is the diameter of a particle with mass m. D can be alternatively expressed in terms of Δx and τ as

$$D = \frac{\Delta x^2}{2\tau} = \frac{(v\tau)^2}{2\tau} = \frac{k_\mathrm{B}T}{2m} \,, \tag{21.11}$$

where the kinetic theory of gases has been used to obtain the right-hand term of (21.11) [21.235]. Notice that, on comparing (21.9) and (21.10), given the results of the simulations, the behavior of the real system would be determined.

This concept may be used to simulate the deposition of metal ions in a patterned silicon substrate. Consider, for ease of visualization, the scheme in Fig. 21.26d. The well defines the region of the domain exposed to growth, i. e., the patterned silicon substrate (for applications in which pattern distance cannot be neglected, the wells can be more than one). At a distance l from the well, N particles are released in the system, where N should be chosen with care to reproduce the initial concentration of silver ions. At any cycle the particles move within a regular square pattern of cells by one lattice unit (l.u.), and thus the mean path length is $\Delta x = 1$ l.u. At the sides (that is, the left and the right) of the domain, periodic boundary conditions (PBC) are imposed, and when an individual particle passes through one of those faces, it instantaneously reappears on the opposite face with the same velocity. In topological terms, the plane can be thought of as being mapped onto a torus; by doing so, an infinite perfect tiling of the system is simulated in the longitudinal direction, and this accounts for the fact that the area of the wells is small compared to the area above the wells. At the upper boundary of the system, and at the side walls of the well, a bouncing condition is imposed, whereby the particles that collide with those boundaries would rebound in an opposite direction. At the lower border of the system, the seeds ξ represent the regions of fresh silicon substrate exposed to growth. The length of the seed (that is, the length of the well) can be conveniently adjusted according to the problem at study. Therefore, ξ is a line of nucleation sites. The structure of the aggregate $\beta(t)$ will depend upon the length of the seed and the chemical conditions of growth. When a particle migrates to touch ξ it stops, is incorporated by ξ, and the size of the aggregate is augmented by one unit. At the same time, a new particle is instantaneously created and randomly positioned in the upper region of the domain to keep the total number of particles n constant during the process. After a certain number of repetitions, aggregates are formed as in the example of Fig. 21.25e. The multibranched arrangement of particles recalls the dendritic, fractal nature that electroless grown systems reveal under certain growth conditions.

The structure of clusters of occupied lattice sites exhibits geometric scaling relationships, which are characteristic of fractals and which can be used to estimate an effective fractal dimensionality. In similar aggregates, the fractal dimension D_f exhibits a limiting value of about $5/3$. The fractal dimension is a parameter that can be used to describe intimately the topography of a variety of systems, especially at the nanoscale. The importance of D_f resides in the fact that it is used in the definition of certain parameters or properties that describe the deposit.

For instance, as the thickness T of the aggregate scales with the total number of deposited particles n, as [21.237]

$$T \approx n^{1/(D_\mathrm{f}-1)} \tag{21.12}$$

the fractal dimension is also correlated to the distribution or number I of clusters with size S as a function of cluster size [21.237]

$$I(S) \approx S^{-(1+1/D_\mathrm{f})} \,. \tag{21.13}$$

Most importantly, the mean cluster size can be deduced and correlated to n via a very simple power law, being [21.238]

$$S \approx n^{D_\mathrm{f}/(D_\mathrm{f}-1)} \tag{21.14}$$

and thus, given n, which can be easily calculated, the mean cluster size can be readily derived. The packing or density factor κ can therefore be obtained as the ratio of S to the size of a single pattern, $\kappa = S/d$. Thus κ is a measure of the compactness of the aggregates. It is used to verify the influence of process parameters on the aggregate/particle quality. Larger κ indicates compact nanoparticles similar to their nominal shape.

The fractal dimension of numerical aggregates can be derived from their power spectrum density function $C(r)$; Fig. 21.26f. $C(r)$ delivers the information content of a cluster as a function of the characteristic length scale r. In a log–log diagram, $C(r)$ has a linear behavior. In such a diagram, if the slope of $C(r)$ is high, the information content decays rapidly with r, and conversely the information content ranges over wider length scales if the slope is low. From the slope, one may derive the fractal dimension as $D_f = (8-B)/2$. The mathematical procedure necessary to find $C(r)$ goes beyond the purpose of this section and can be found in [21.239].

Application of DLA Growth in Silver Nanoparticle Growth

In [21.229], a diffusion-limited aggregation approach and Fourier analysis were utilized to describe the nature of electroless deposits. In aggregates in which the size of the patterns was varied over a significant range, it was found the best pattern size for electroless silver particle growth is 50 nm at T=25 °C and 80 nm at T=50 °C. In [21.240], in simulations in which pattern distance was varied, it was found that the distance between patterns influences growth and that, when pattern distance is equal to or greater than three times the pattern size, particle quality is maximized. This suggests that in producing silver nanoparticles with electroless methods, one may use design maps akin to state diagrams in their graphical representation, in which on varying both pattern size and pattern distance in the diagram, for fixed chemical conditions and temperature, one may understand the effects of the process parameters on particle quality (κ), and choose the best combination of pattern size and pattern distance (input) for obtaining nanoparticles with desired characteristics (output).

21.7 2-D and 3-D Optical Nanostructures

In the majority of severe diseases, the detection of traces of biological species from the human body (blood and its components, saliva, biopsies, etc.) is of extreme importance for the possible impacts on human health. The early detection of several illnesses (e.g., cancer, neurodegenerative diseases or others) could anticipate the therapy of the same disease and arrest its development and progression. This would improve the life quality of the involved persons and additionally reduce the health care costs. That is why it is important to develop advanced screening and early diagnostic devices.

However, a great number of issues come into play before body fluids may be used in routine screening procedures and for early detection of severe illnesses [21.241]. In recent years, part of the scientific community has been moving towards the development of innovate bioanalytical tools that allow it to reach unprecedented resolution and to simplify the protocol of analysis, satisfying the aforementioned needs.

The handling and analysis of complex biological samples, and in particular individuating a single component among a cluster of molecules, is challenging and conventionally requires complicated protocols to pretreat complex samples [21.242]. Early diagnosis is often dependent on the detection of a few molecules in diluted solutions, which are invisible to the current sensors due to a limit on the resolution of analysis. Moreover, for certain screening procedures it is important not to affect the phenotype of the biological sample [21.243], especially for certain screening procedures that require analysis over long periods of a specific sample (e.g., a specific cell population). Thus it becomes important to introduce new methodologies that are not invasive with respect to the samples. Finally, the heterogeneity of behavior of the human body and its response to medical treatments requires the development of bioanalytical tools compatible with personalized medicine, and this is translated into the development of devices that are portable, fast, and provide high-throughput and high-content analysis with reduced costs. One way to overcome these issues is the development of microfluidic devices and innovative label-free plasmonic/spectroscopic nanosensors [21.244].

21.7.1 Integration of Optical Nanostructures in Microfluidic Devices

Microfluidics is an interdisciplinary discipline that focuses on the transport, manipulation and analysis of small amount of liquids, cells and particles [21.245]. Microfluidic devices have been developed and exploited by several research groups as bioanalytical tools [21.246]. This is due to several advantages over

conventional bioanalytical technologies. In fact, these devices guarantee high portability, accurate control for handling of samples, simplified sample pretreatment protocols, low consumption of samples and reagents, high resolution of analysis and low costs of production and analysis [21.247].

There are many examples in the literature of microfluidic devices used for analytical purposes. These have been developed for DNA detection [21.248], protein analysis [21.249], and detection of other biomarkers (e.g., discriminating healthy from tumor cells, phenotypes cell screening, etc.) [21.250].

A microfluidic device is capable of handling biological samples with very high accuracy and resolution, simplifying the protocol of analysis [21.251]. A particular and interesting case is the possibility to screen cell populations with single-cell resolution [21.252].

It is well known that individual cells, even those identical in appearance, differ in numerous characteristics. Due to this heterogeneity, traditional biochemical assays, which analyze cells in bulk, do not allow us to get rich information when single cells are studied. Single-cell analysis allows the investigation of cell activities and potentially new biomarkers. A sequential handling and manipulation of cells and cell suspensions then becomes important for scientific research and clinical diagnostic applications. Usually, cells are cultured and analyzed in large-scale environments such as Petri dishes. Therefore, it is difficult to analyze individual cells without the influence of other cells. These issues can be overcome by using microfluidics [21.253].

It is also crucial to analyze the composition of a single cell at a subcellular level or metabolites, and this would be a step forward in the conventional analysis of cells. Another critical issue is thus to individuate a sensing methodology that allows a resolution of analysis at the single-cell level [21.254]. Monitoring of cells over a longer period is most frequently performed by fluorescence microscopy. However, it is quite common that the fluorescent dyes used for specific subcellular staining interfere with the development of cells, changing their phenotype and metabolism. Another limitation is that fluorescent dyes bleach quite fast. Finally, this technique allows the investigation of known molecules only. These aspects make fluorescence staining strategies less desirable with respect to label-free sensing methodologies. This can be done, for instance, by integrating plasmonic nanostructured devices with Raman spectroscopy. Raman spectroscopy has been used to determine cellular status, such as living cells, dead cells, apoptotic cells, proliferating cells, differentiating cells, and tumor or healthy cells. Raman spectroscopy can be integrated into microfluidic devices, providing accurate control over biological samples (on single cells) and allowing samples to be left over long periods in physiological or conditioned environments.

The main advantages of such a technique are:

- The capability to perform analysis in a label-free manner, reducing the pretreatment steps for a biological sample
- The specificity of analysis due to a specific fingerprint for each biological substance
- The possibility to analyze biological substances in water solutions.

The main disadvantage is the small probability that a Raman scattering event can occur, and in some cases this could produce very weak signals, difficult to detect in complex biological microenvironments. Fortunately, plasmonic nanostructures can strongly improve the Raman effect, with enhancing factors up to 10^{12}, and producing the well-known SERS effect (surface enhanced Raman scattering). Then, the integration of plasmonic nanosensors into microfluidic devices will circumvent the issue of small Raman scattering cross-section, and will produce a valid tool for label-free biochemical analysis in microfluidic environments.

Plasmonic nanosensors are metal nanostructures in which surface plasmons are generated by an external exciting laser source, producing a large enhancement of the Raman signal when the plasmonic resonance conditions are matched. The microscopic origin of the SERS effect relies solely on a local enhancement due to surface metal (Au and Ag) nanoparticles. Obviously this effect is firmly determined by the presence of the metallic nanostructures or a roughened metal surface, and only when the probed molecules are close to them can the SERS effect arise. Finally, the high spatial resolution of the nanostructures allows the resolution of very complex mixtures, simplifying the pretreatment protocol of biological samples [21.228].

For example, a microfluidic device integrating microfluidic traps, able to handle single cells, coupled to a Raman spectrometer has high potential for the analysis of living cells. In this case the choice of the appropriate materials for the fabrication processes of each piece composing the microfluidic device becomes crucial for performing proper Raman measurements. In fact, these have to produce a negligible background signal during Raman analysis (e.g., calcium fluoride).

Single-cell analysis allows the study of drug stimulation and can distinguish the diversity of the individual cell activities, and potentially allows the investigation of new biomarkers. A sequential handling and manipulation of cells and cell suspensions then becomes important for scientific research and clinical diagnostic applications. The advent of microfabrication technology in the field of tissue engineering has enabled

new and innovative ways to analyze cellular interactions in bioreactors and cell behavior in a microfluidic environments that mimic in vivo body conditions. The microfluidic bioreactors or microbioreactors are microscale versions of conventional bioreactors with significant advantages in terms of cost-effectiveness, portability, performance, and materials used. Microfluidic devices can ensure accurate single-cell handling by simple microfluidic control with minimal consumption of reagents.

The exploitation of a plasmonic nanodevice coupled to a Raman spectrometer would allow (thanks to the localization of light in small structures and the resulting enhancement of the electromagnetic field) the study of single biomolecules with high spatial resolution, directly on the cellular membrane of a single cell.

The plasmonic nanodevices integrated into microfluidic devices can have different geometries and configurations. Two examples will be given in the next sections.

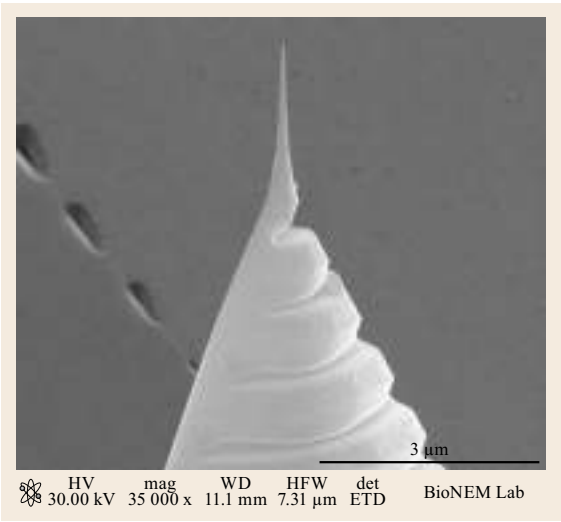

Fig. 21.27 SEM image of a nanoplasmonic device (after [21.249] with permission from Elsevier)

21.7.2 Three-Dimensional Optical Nanostructure

Plasmonic nanodevices can be made of a dielectric *core* with a conical geometry, covered by a metal layer as shown in Fig. 21.27.

These devices were grown using electron beam induced deposition from a gas precursor containing a platinum-carbon polymer ($(CH_3)_3Pt(CpCH3)$) and deposition of gold by sputtering. The devices had a base of about 400 nm, a height of 2.5 µm and a radius of curvature at the tip of about 5 nm

These devices are based on the amplification of the electromagnetic field due to the adiabatic compression of the wavelength of a plasmon polariton on the metal layer of a nanocone. In this way it is possible to obtain a resolution that depends on the radius of the tip of the cone (approximately 10 nm), which is a much lower resolution than the diffraction limit of light.

The outer interface between the gold layer and the surrounding dielectric medium constitutes a surface for the propagation of plasmon polaritons (PPs). The PPs are excited by the Raman laser source that is coupled to a grating realized at the base of the cone. Grating periodicity is adjusted in order to produce an optimal coupling with the 532 nm laser light of Raman microspectroscopy equipment. Once excited, PPs travel along the cone side and undergo adiabatic compression as described in [21.255]. Along with adiabatic compression, a large enhancement of the electromagnetic field is produced at the cone tip, thus producing an enhancement of the Raman signal of biomolecules close to the tip. During Raman measurements the objective focus is at the level of the cone tip in order to fully exploit the signal enhancement. Consequently the illumination of the grating is not optimal, but even in this condition a good coupling with the far-field light is achieved, as demonstrated in [21.255]. The sharpness of the tip cone, with a tip radius in the nm range, ensures high enhancement factors and high spatial resolution for Raman measurements.

These nanodevices can be integrated in a microfluidic system close to microfluidic traps where individual cells can be trapped and analyzed. The traps consist of microfluidic cavities placed within a microfluidic channel of dimensions a bit larger than a cell (about 20–25 µm). At the bottom of the cavity was fabricated a narrow channel (about 3 µm wide), which allowed the sucking in of the cells passing in the proximity of the cavity. When the cell reaches the bottom of the cavity, it plugs the narrow channel avoiding further suction. In this way, it is possible to trap cells in series. By alternating the direction of the motion, it is possible to displace the cell from the cavity and suck it again in the same cavity but with a different orientation, so that it is possible to analyze different parts of the membrane of the same cell (Fig. 21.28).

21.7.3 Two-Dimensional Optical Nanostructure

Alternative plasmonic nanodevices can be made by using a 2-D configuration such as nanodimers integrated in microfluidic traps, as shown in Fig. 21.29.

In this case, the trap is realized by fabricating a constriction in width along the channel. It has been

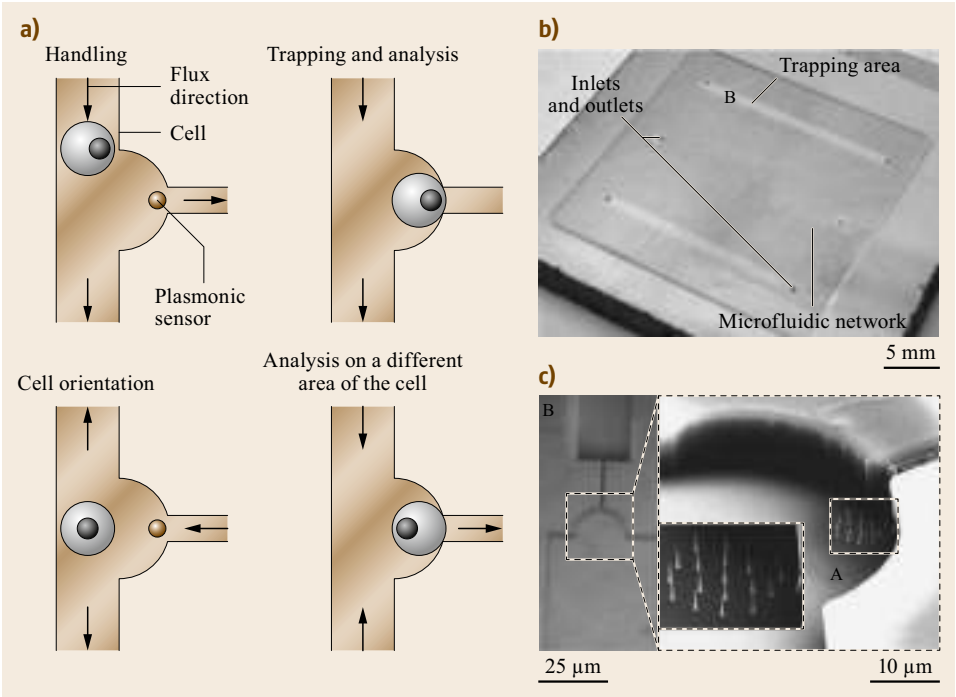

Fig. 21.28 **(a)** Schematic representation of the cell trapping and analysis protocol. The buffer movement allows trapping or releasing the cell. **(b)** Isometric view of the microfluidic device. **(c)** Optical microscope image of the microfluidic trap and SEM image of the microfluidic trap integrating the nanodevices (after [21.249] with permission from Elsevier)

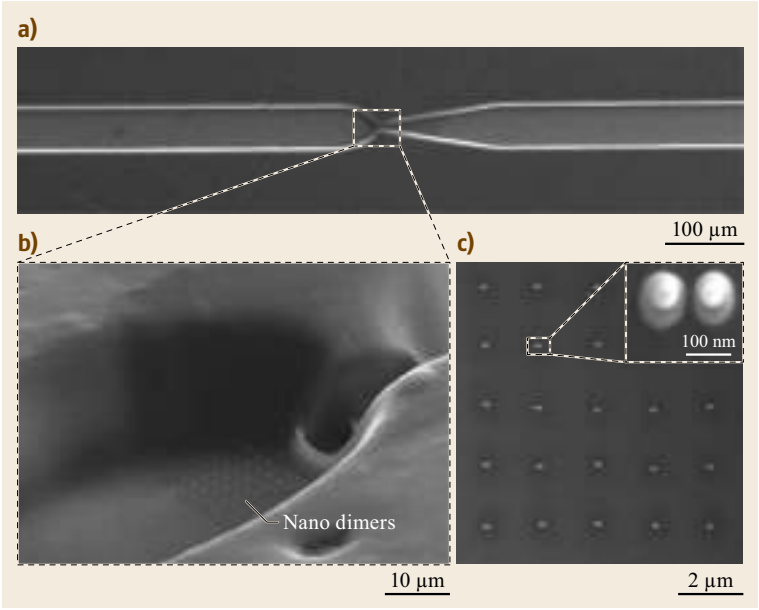

Fig. 21.29a–c Scanning electron image of the microfluidic trap and the integrated array of nanodimers. **(a)** Top view; **(b)** isometric view; **(c)** zoom in the area where the nanodimers are integrated (after [21.244], Optics Express)

designed in such a way that the cell is only temporarily trapped. A dynamic change of the flow conditions is responsible for cell entrapment. When a constant flow rate is applied a cell is moved toward the trap. When the cell is stopped at the constriction, the fluidic resistance increases accordingly and since the flow rate is constant, the pressure drop increases locally. The increase in pressure increases the forces acting on the cell surface and this provokes a cell deformation that allows the same cell to move through the trap, continuing its motion in the channel. After that, another cell approaches the trap. The role of the trap is to stop the cell for a well-defined amount of time necessary to record the Raman spectrum, which can be executed in about

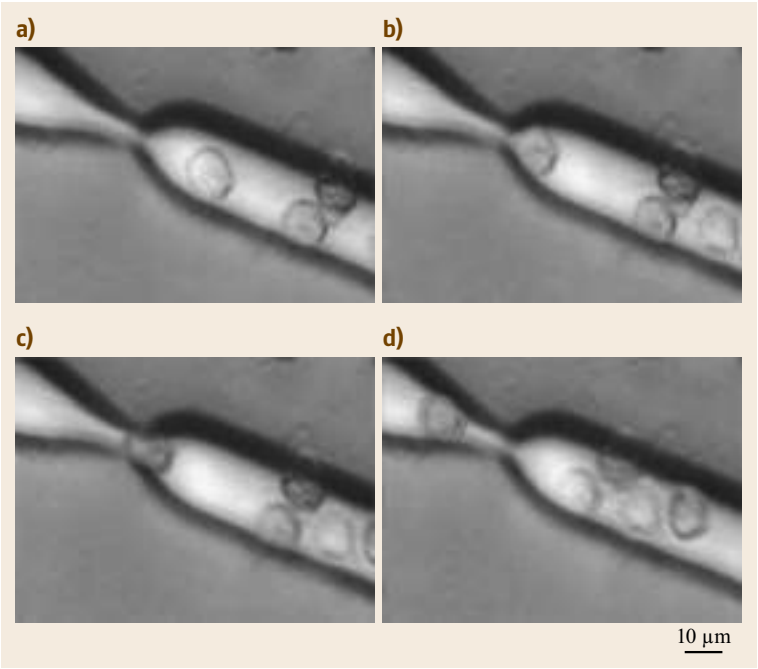

Fig. 21.30a–d Sequence of the cell analysis mechanism: **(a)** the cell approaches the trap followed by other cells ($t = 0$ s); **(b)** the cell is trapped and the flow is stopped ($t = 2$ s) – in this phase Raman measurements can be performed on the cell ($t = 4$ s); **(c)** the increasing pressure due to the clogged channel deforms the cell forcing it through the trap ($t = 6$ s); **(d)** the cell is released and continues to move over the trap while other cells approach the trap, aligning themselves to it ($t = 8$ s) (after [21.244] Optics Express 2016)

3 s. In such a way, it is possible to perform a continuous analysis of cells by Raman spectroscopy in a passive way (Fig. 21.30).

In this case the nanodimers can be fabricated by electron lithography and electroless deposition as already described in the other sections.

An advantage of such a configuration is that it is more compatible with mass-production fabrication protocols. Three-dimensional nanodevices are more complicated and expensive to fabricate but the freedom to work in three dimensions allows the exploitation of better nonlinear optical properties, obtaining more efficient plasmonic nanodevices.

Acknowledgments. Dr. Hélder A. Santos acknowledges the Academy of Finland (project numbers 252215 and 281300), the University of Helsinki and the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013)/ERC Grant agreement number 310892 for financial support. 22. Biological Molecules in Therapeutic Nanodevices

Stephen C. Lee, Bharat Bhushan

In this chapter, we discuss the incorporation of molecules into nanodevices as functional device components. Our primary focus is on biological molecules, although we also discuss the use of organic molecules as functional components of supramolecular nanodevices. Our primary device interest is in devices used in human therapy and diagnosis, though when it is informative, we discuss other nontherapeutic nanodevices containing biomolecular components. We discuss design challenges associated with devices built from prefabricated components (biological macromolecules) but that are not as frequently associated with fully synthetic nanodevices. Some design challenges (abstraction of device object properties, inputs, and outputs) can be addressed using existing systems engineering approaches and tools (including unified modeling language), whereas others (selection of optimal biological macromolecules from the billions available) have not been fully addressed. We discuss various assembly strategies applicable to biological macromolecules and organic molecules (self-assembly, chemoselective conjugation) and their advantages and disadvantages. We provide an example of a functional mesoscale device, a planar field-effect transistor (FET) protein sensor, that depends on nanoscale components for its function. We also use the sensor platform to illustrate how protein and other molecular engineering approaches can address nanoscale technological problems, and argue that protein engineering is a legitimate nanotechnology in this application. In developing the functional FET sensor, both direct adsorption of protein analyte receptors as well as linkage of receptors to the sensing surface through a polymer layer were tested. However, in the realized FET sensor, interfaces consist of a polymer layer linked to the semiconductor surface and to an analyte receptor (a protein). Nanotribology and other surface-science investigations of the interfaces revealed phenomena not previously documented for nanoscale protein interfaces (lubrication by directly adsorbed proteins, increases in friction force associated with polymer-mediated increases in sample compliance). Furthermore, the studies revealed wear of polymer and receptor proteins from semiconductor surfaces by an atomic force microscopy (AFM) tip which was not a concerted process, but rather depth of wear increased with increasing load on the cantilever. These studies also revealed that the polymer–protein interfaces were disturbed by nanonewton forces, suggesting that interfaces of immunoFET protein sensors translated to in vivo use must likely be protected from, or hardened to endure, abrasion from tissue. The results demonstrate that nanoscience (in this case, nanotribology) is needed to design and characterize functional planar immunoFET sensors, even though the sensors themselves are mesoscale devices. The results further suggest that modifications made to the sensor interfaces to address these nanoscale challenges may be best accomplished by protein and interfacial engineering approaches.

22.1 Definitions and Scope

Nanotechnology is a field in rapid flux and development, as this volume shows, and definition of its metes and bounds, as well as identification of subdisciplines embraced by it, can be difficult and controversial. The term *nanotechnology* means many things to many people, and aspects of multiple disciplines, from physics to information technology to biotechnology, legitimately fall into the intersection of the Venn diagram of disciplines that defines nanotechnology. The breadth of the field allows almost any interested party to contribute to it, but the same ambiguity can render the field diffuse and amorphous. If nanotechnology embraces everything, what then is it? Consideration of the scope of the field may be useful.

To frame the discussion, we will define nanotechnology as the discipline that aims to satisfy desired objectives using materials and devices whose valuable properties are based on a specific nanometer-scale element of their structures. As opposed to nanoscience, nanotechnology is application oriented, so nanoscience is important to nanotechnology primarily to the extent that it is relevant to device design, function or application.

The meaning of *therapeutic* is self-explanatory and refers here to intervention in *human* disease processes (although many of the approaches discussed are equally applicable to veterinary medicine). We confine our discussion mostly to therapeutics used in vivo, because such applications clearly benefit from the low invasiveness that ultrasmall, but multipotent, nanotherapeutics potentially offer. It is debatable whether imaging, diagnostic or sensing devices can be considered therapeutic in this context, though as we will see, sensing/diagnostic functionalities are often inextricable elements of therapeutic nanodevices, and it is difficult to consider smart nanotherapeutics without discussion of their sensing capabilities. Therapeutics incorporating diagnostic capabilities (via their capability for sensing or imaging contrast delivery) are now recognized as their own class of drug entities, referred to as *theranostics* (see below).

Our definition of nanotechnology is both broader and narrower than more common definitions. First, our definition embraces macroscale structures whose useful properties derive from their nanoscale aspects. Second, we have a *device-centric* bias: we are interested in devices that perform multistep work processes. Third, consistent with our device-centric bias, the term *specific* (as in, *specific nanometer-scale elements*) is intended to exclude materials whose utility derives solely from properties inherent to being finely divided (high surface-to-volume ratios, for instance), or other material, chemical, and physical properties unless those properties contribute to specific device function. We made this exclusion based on our assessment that therapeutic nanodevices are more intriguing than nanomaterials per se (see below), although we will engage these attributes where they are germane to specific device or therapeutic applications. Fourth, our definition implies that limited nanotechnology has been available since the 1970s in the form of biotechnology. Based on their nanoscale structures, individual biological macromolecules (such as proteins) often exhibit the coordinated, modular multifunctionality that is characteristic of purpose-built devices (Fig. 22.1).

Biological macromolecules rely on the deployment of specific chemical functionalities with specific relative distributions in space with nanometer (and greater) resolution for their function, so the inclusion of molecular engineering aspects of biotechnology under the nanotechnology rubric is legitimate, despite the discomfort this may cause to traditionally trained engineers. As we will see, intervention in human disease often requires inclusion of biomolecules in therapeutic devices, as frequently no functional synthetic analogue of active proteins and nucleic acids is available. As we will discuss, specific nanoscale device problems also can be addressed with biotechnology and protein engineering approaches, so the legitimacy of inclusion of biotechnology in nanotechnology is now beyond debate.

An analogous argument can be made that organic chemistry is an early form of nanotechnology. Compared with organic small molecules, protein functional capabilities and properties are generally more complex and more dependent on their conformation in three-dimensional space at nanometer and subnanometer scales. The nanotechnology sobriquet, therefore, *may* be more appropriate to biotechnology than to organic chemistry. However, supramolecular chemistry

and therapeutic supramolecular devices depend on specific design features of organic molecules and assemblies thereof, so organic chemistry might be viewed as an even earlier version of nanotechnology, based on an argument very similar to that we use for biotechnology.

As described above, this chapter focuses primarily on nanoscale therapeutic devices as opposed to therapeutic nanomaterials. Devices are integrated functional structures and not admixtures of materials, compounds or substances. Devices exhibit desirable emergent properties inherent to their design, properties that emerge as the result of the spatial and/or temporal organization, coordination, and regulation of action of individual components. The organization of components in devices allows them to perform multistep, cogent work processes that cannot be mimicked by simple admixtures of individual components. In fact, if device functions can be mimicked well by simple mixtures of components, the labor involved in configuring and constructing a nanoscale device is not warranted. Our device definition thus excludes nanomaterials used as drug formulation excipients (pharmacologically inert materials included in formulations that improve pharmacophore uptake, biodistribution, pharmacokinetic, handling, storage or other properties), but embraces those same materials as integral components of drug-delivery or other clinical devices.

22.1.1 Design Issues

The biotechnology industry historically has focused on production of individual soluble protein and nucleic acid molecules for pharmaceutical use, with only limited attention paid to functional supramolecular structures [22.2–8]. This bias toward free molecules flies in the face of the obvious importance of integrated supramolecular structures in biology and, to the casual observer, may seem an odd gap in attention and emphasis on the part of biotechnologists. The bias toward single-molecule, protein therapeutics follows from the fact that biotechnology developed as an industrial activity, governed by market considerations. Of the potential therapeutics that might be realized from biotechnology, single-protein therapeutics are among the easiest to realize from both technical and regulatory perspectives, and so warrant extensive industrial attention. This is changing, however, and more complex entities (actual supramolecular therapeutic devices) have and will appear with increasing frequency in the 21st century.

New materials derived from micro-/nanotechnology provide the opportunity to complement the traditional limits of biotechnology by providing scaffolds that can support higher-level organization of multiple biomolecules to perform work activities that could not be performed by mixtures of free, soluble molecules. Such supramolecular structures have been called nanobiotechnological devices [22.9], nanobiological devices [22.2–8], and semisynthetic nanodevices, and they figure prominently in therapeutic nanotechnology. Some such devices have sensing and diagnostic capabilities, and therefore belong to the already discussed class of theranostic agents (see [22.9] for a recent example of a multifunctional theranostic nanoparticle, and [22.10] for a recent review of such multifunctional nanoparticulate magnetic resonance imaging contrast agents in cardiovascular disease).

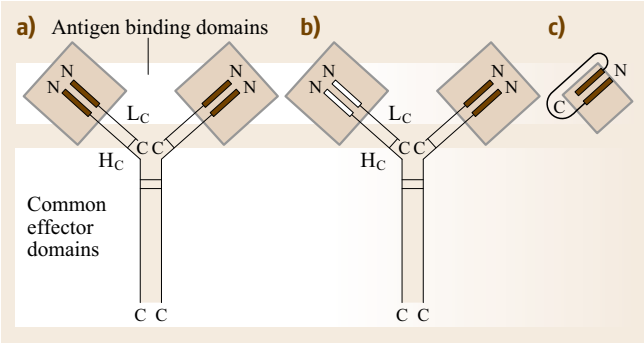

Fig. 22.1a–c Antibodies resemble purpose-built devices with distinct functional domains [22.1]. Native immunoglobulin class G (IgG) antibodies are composed of four polypeptide chains: two heavy chains (Hcs) and two light chains (Lcs), joined by interchain disulfide linkages (*lines* between Hc and Lc moieties). Amino and carboxy termini of individual polypeptide chains are indicated by N and C. Antigen-binding domains are responsible for specific antigen recognition, vary from antibody to antibody, and are indicated by the *thicker lines*. Common effector functions (Fc receptor binding, complement fixation, etc.) are delimited to domains of the antibodies that are constant from molecule to molecule. **(a)** A native IgG antibody is monospecific but bivalent in its antigen binding capacity. **(b)** An engineered, bispecific, bivalent antibody capable of recognizing two distinct antigens. **(c)** An engineered antibody fragment (single-chain fragment variable (Fv) or SCFv) that is monospecific and monovalent can recognize only one antigenic determinant and is engineered to lack common effector functions. This construct is translated as a single, continuous polypeptide chain (hence the name SCFv) because a peptide linker (indicated by the *connecting line* in the figure) is incorporated to connect the carboxy-end of the Hc fragment and the amino-end of the Lc fragment

22.1.2 Identification of Biomolecular Components

Design of nanodevices is similar to design of other engineered structures, providing that the special properties of the materials (relating to their nanoscale

aspects such as quantum, electrical, mechanical, biological properties, etc.), as well as their pharmacological properties, are considered. Therapeutics interact with patients on multiple levels, ranging from organismal to molecular, but it is reasonable to expect that most nanotherapeutics will interface with patients at the nanoscale [22.2–16]. Typically, this means interaction between therapeutics and patient biological macromolecules, supramolecular structures, organelles, cells or tissues, which in turn often dictates the incorporation of biological macromolecules (and other biostructures) into nanodevices [22.2–10]. Incorporating biological structures into (nanobiological) devices presents special challenges that do not occur in other aspects of engineering.

Unlike fully synthetic devices, semibiological nanodevices must incorporate prefabricated biological components (proteins, nucleic acids or derivatives thereof), and therefore intact nanodevices are seldom made entirely de novo. As a corollary, knowledge of properties of nanobiological device components is usually incomplete, as the molecules were not made by human design, so their properties are not known a priori and must be discovered. Therefore the range of activities inherent to any nanobiological device design may be much less obvious and less well defined than for fully synthetic devices. Further complicating the issue, the activities of biological molecules are often multifaceted (many genes and proteins exhibit pleiotropic activities), and the full range of functionality of individual biological molecules in interactions with other biological systems (as in nanotherapeutics) is often not known. This makes the design and prototyping of biological nanodevices an empirically intensive, iterative process [22.2–16].

Paralleling the paucity of information typically available about individual proteins, the number of distinct natural proteins in the biologic world is unknown but exponentially high (certainly in excess of 10^{13} distinct molecules [22.17]). When one considers engineered proteins, particularly those made by high-throughput mutagenesis methods, the number of existing protein sequences rises additional orders of magnitude. Most of these molecules remain to be discovered, so their individual properties (that might be critical to device designers, such as functional pH and temperature ranges, ionic requirements, cofactor requirements, radiation tolerance, resistance to degradation, etc.) are mostly unknown. Among the relative handful of proteins that are known, properties are typically incompletely known, and those properties that are known often are not those of greatest interest in selecting a protein as a nanodevice component. In fact, existing protein databases focus primarily on pharmacological properties or evolutionary relationships between proteins. We have proposed the building of databases useful specifically for nanobiotechnology, though this has yet to occur [22.5, 17, 18]. Existing protein databases, based as they are on phylogenetic, protein sequence, protein structure or protein primary function information, are not satisfactory for nanodevice design, if such design is to be realized as a discipline in and of itself, and if the immense power of biologic nanotechnology is to be realized to any significant extent. As it is, inventors of nanobiotechnological devices often rely on their personal knowledge of biology and biochemistry to select biological components for devices. It is obvious then, that the devices designed by even the most sophisticated biologists are very likely to be suboptimal. As a corollary, this means that nanobiological device designers must have significant biological expertise. This constitutes a huge barrier to entry for nonbiologists who could otherwise contribute importantly to the field. Thus, the lack of an appropriate protein database and accompanying search tools implies an immense opportunity cost for the field of biologic nanotechnology.

Biological macromolecules have properties, particularly those relating to their stability, that can limit their use in device contexts. In general, proteins, nucleic acids, lipids, and other biomolecules are more labile to physical/biochemical insult than are many synthetic materials. With the possible exceptions of topical agents or oral delivery and endosomal uptake of nanotherapeutics (both involving exposure to low pH), device lability in the face of *physical* insult is generally a major consideration only in ex vivo settings (relating to device storage, sterilization, etc.), because physical conditions that would destroy the device would be bad for the patient as well. However, living organisms remodel themselves constantly in response to stress, development, pathology, and external stimuli. For instance, epithelial tissues and blood components are constantly eliminated and regenerated, and bone and vasculature are continuously remodeled. The metabolic facilities responsible (circulating and tissue-bound proteases and other enzymes, various clearance organs, the immune system, etc.) can potentially process biological components of nanobiological therapeutic devices as well as endogenous materials, leading to partial or complete degradation of nanotherapeutic structure, function, or both. Furthermore, immune and wound responses protect the host against pathogenic organism incursions, by mechanisms that involve sequestering and degrading pathogens. Nanobiological therapeutics are subject to the actions of these host defense systems as well as normal remodeling processes. Various strategies to stabilize biomolecules and structures in heterologous in vivo environments are applicable to nanobiological therapeutics. Conversely, instability of

active biocomponents can offer a valuable and simple way to delimit the activity of nanotherapeutics containing biomolecules.

22.1.3 Design Paradigms

Several early attempts to codify the canonical properties of ideal nanobiological devices, and therapeutic nanodevices in particular, have been made [22.1, 5, 11–15, 19, 20]. These attempts to codify design constitute a limited set of design guidelines that are summarized in Table 22.1. Naturally occurring, functional biological components generally exist in the context of higher-order systems that support the organisms of which they are a part. In general, nanobiological devices contain biological components that retain their function in new (device) contexts. In other words, one must incorporate into the device enough of a functional biological unit (nucleic acid, protein, oligomeric protein complex, organelle, cell, etc.) to allow that unit to perform the function for which it was selected. If one wishes, for example, to appropriate the specific antigen-recognition property of an antibody for a device function (say, in targeting, as discussed later), it is not necessary to incorporate the entire 150 000 atomic mass unit (AMU) antibody, the bulk of which is devoted to functions other than antigen recognition (Fig. 22.1) [22.21], but it *is* critical to incorporate the approximately 20 000 AMU of the antibody essential for specific antibody–antigen binding (the variable domain, Fig. 22.1).

Device function is the result of the summed and various activities of biological and synthetic device components. The nanobiological device designer can exert control over the relative organization of biological device components, which allows biomolecular components of devices abstracted from their native context to contribute to overall device functions that are entirely different from those in which they participated in their original, organismal contexts.

All of these features are illustrated in the bacmid, or Bac-to-Bac, system, a commercially available molecular cloning device ([22.22–24] and Fig. 22.2). Bacmid configures prokaryotic and eukaryotic genetic elements from multiple sources into a device for producing recombinant eukaryotic viral genomes in bacteria, a function that is unprecedented in nature. The system is feasible because of the modularity of the genetic elements involved and because of the strict control of the relative arrangement of genetic elements allowed by recombinant deoxyribonucleic acid (DNA) technology. Analogous cloning devices based on comparable arrangements of bacterial and eukaryotic regulatory and structural genes are reviewed in [22.18]. Other nucleic acid devices using genetic control elements from phylogenetically various sources are being developed to preprogram the micro- and nanoscale architectural properties and physiological behavior of living things [22.25, 26].

Bacmid provides an example of a nontherapeutic nanobiological device and illustrates some specific design approaches for building functional devices with biocomponents. Bacmid complies fully with those design recommendations of Table 22.1 that are not therapeutic device specific. However, Table 22.1 provides guidelines only. Systems engineering approaches commonly used in software and computer engineering provide a more rigorous framework to consider nanodevice design [22.17, 18]. Systems tools such as unified modeling language (UML) allow more precise depiction of nanobiological devices than do most text descriptions. A simplified UML use-case of bacmid is presented in Fig. 22.3.

Table 22.1 Some ideal characteristics of nanodevices [22.1, 5, 11–15, 19, 20]

(a) Characteristics of all nanobiological devices
Biological molecules must retain function.
Device function is the result of the summed activities of device components.
The relative organization of device components drives device function.
Device functions can be unprecedented in the biological world.
(b) Desirable characteristics of therapeutic platforms
Therapeutics should be minimally invasive.
Therapeutics should have the capacity to target sites of disease.
Therapeutics should be able to sense disease states in order to: • Report conditions at the disease site to clinicians • Administer metered therapeutic interventions.
Therapeutic functions should be segregated into standardized modules.
Modules should be interchangeable to tune therapeutic function.

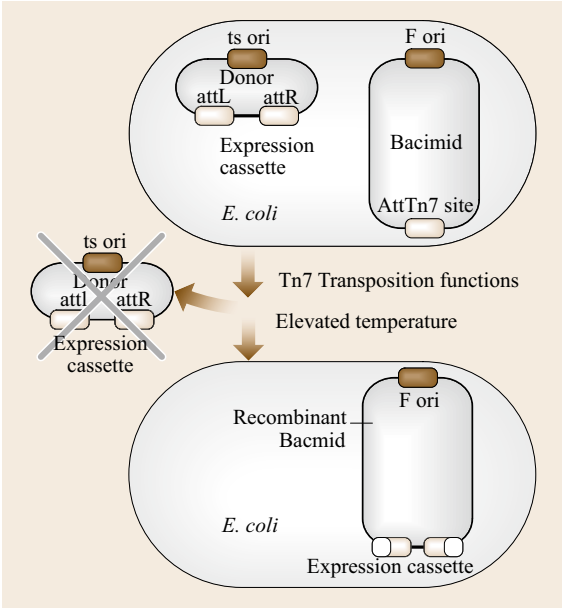

Fig. 22.2 The bacmid molecular cloning system as it is represented in the molecular biology literature. Bacmid is a molecular device designed to allow efficient production of recombinant insect viruses (baculovirus) in *Escherichia coli* [22.22–24]. Baculovirus is replicated in *E. coli* by the F plasmid origin of replication (*F ori*), and as such, is called a bacmid. The bacmid also includes an engineered transposable DNA element 7 (Tn7) attachment site isolated from the chromosome of an enteric bacteria (*Att*Tn7). *Att*Tn7 can receive Tn7 elements transposed from other cellular locations. A donor plasmid (donor) is replicated by a temperature-sensitive plasmid pSC101 origin of replication (*ts ori*). The donor also incorporates an expression cassette containing both the gene of interest for ultimate expression in insect cells and a selectable genetic marker operable in *E. coli*. The expression cassette is flanked by DNA sequences (*att*L and *att*R) that are recognized by the Tn7 transposition machinery. Tn7 transposition machinery resides elsewhere in the same *E. coli* cell. When donor plasmid is introduced into *E. coli* containing bacmid, Tn7 transposition machinery causes the physical relocation of expression cassettes from donor plasmid to bacmid. Unreacted donor plasmid is conveniently removed by elevating the incubation temperature, causing the ts pSC101 replicon to cease to function and, in turn, causing the donor to be lost. If selection for the genetic markers within the expression cassette is applied at this point, the only *E. coli* that survive are those containing recombinant bacmid (i. e., those that have received the gene for insect cell expression by transposition from the donor). Recombinant bacmid are conveniently isolated from *E. coli* and introduced into insect cell culture, where expression of the gene of interest occurs (after [22.25])

Most importantly, UML forces designers to abstract knowledge of component (object) functions and properties and to express them in terms of object inputs and outputs. This makes device designs modular by explicitly identifying object properties and limitations: any object producing the same outputs and accepting the same inputs can be substituted for the original component in the functional nanodevice. By this means, UML notation transforms nanodevice designs from one-off individual designs into general designs for a class of functionally similar devices [22.18]. In general, biologist inventors have intuitively used these systems design approaches to design devices, as we discuss [22.18]. However, UML-enforced explicit callout of component properties that are necessary and sufficient for device function makes design of isofunctional devices easier. An argument might be made that, in some cases, UML expression of a device design, an example of which is shown in Fig. 22.3, may render related devices (that are implied in the UML depiction) obvious. If so, broad use of UML in nanobiotechnology might have significant intellectual property implications.

In nanotherapeutic applications, devices should be noninvasive and target therapeutic payloads to sites of disease to maximize therapeutic benefit while minimizing undesired side-effects. This, of course, implies the existence of therapeutic effector functions in these nanodevices, to give devices the ability to remediate a physiologically undesirable condition. Beyond that, several desirable attributes relate to sensing of biomolecules, cells or physical conditions (sensing disease itself, identification of residual disease, and potentially responding to intrinsic or externally supplied triggers for payload release). Other properties relate to communication between device subunits (for instance, between sensor and effector domains of the device) or between the device and an external operator. With appropriate design, device functions can be modular, as illustrated by the early, hypothetical dendrimer-based therapeutic shown in Fig. 22.4a [22.11, 16, 27–29].

22.1.4 Utility and Scope of Therapeutic Nanodevices

Therapeutic nanotechnology will be useful when the underlying biology of the disease states involved is amenable to intervention at the nanoscale. While several disease states and physiological conditions (cancer, vaccination, cardiovascular disease, etc.) are particularly accessible to nanoscale interventions, some nanotechnological approaches may be applicable more broadly, in indications we currently cannot predict. Much as was the case with the introduction of recombi-

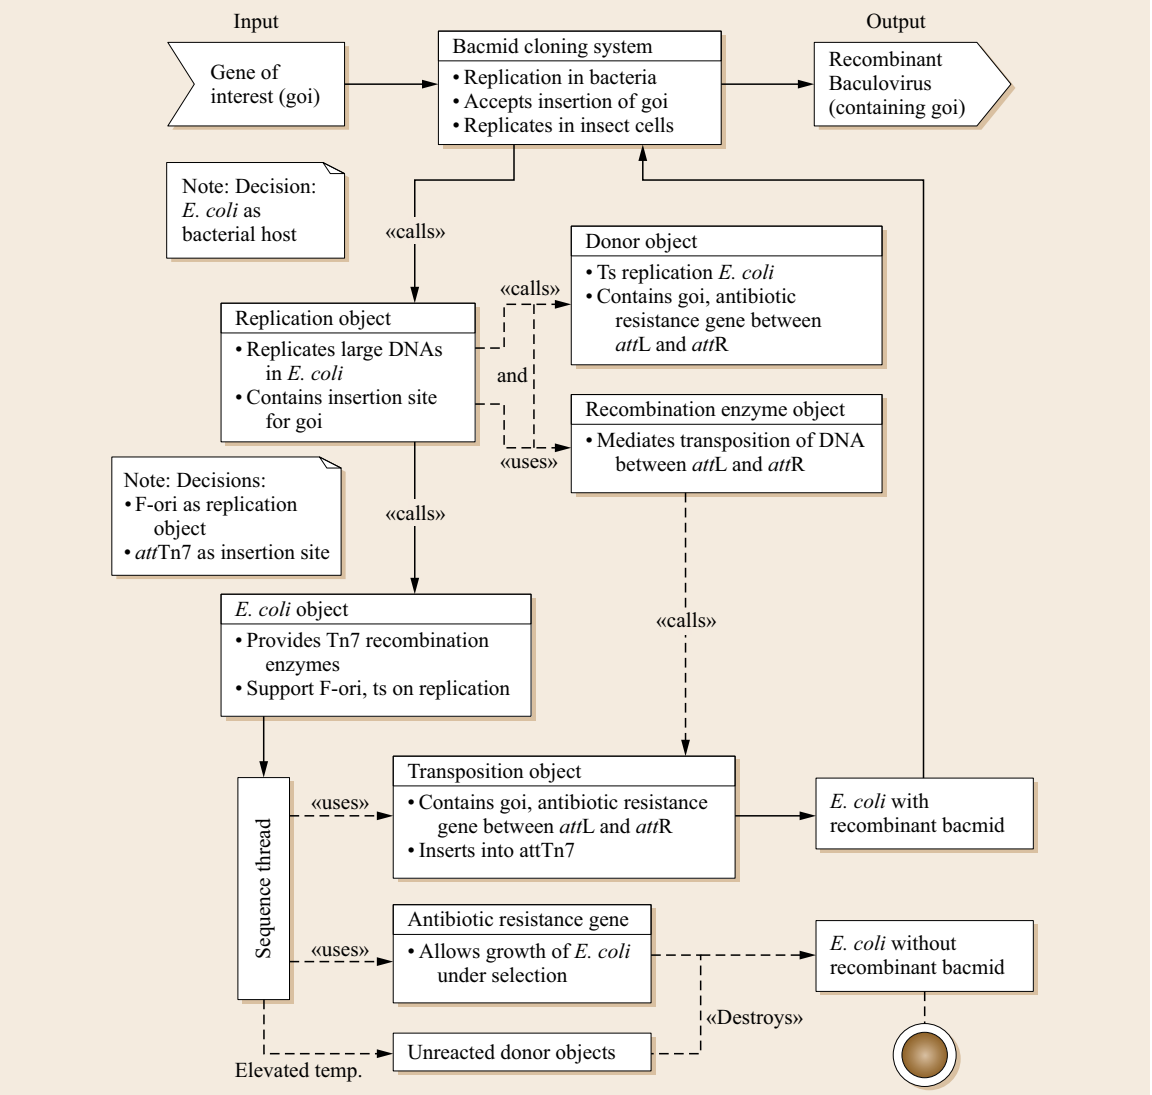

Fig. 22.3 The bacmid system represented as a use-case with unified modeling language (UML). Objects are represented by *boxes*, split horizontally into compartments. The *topmost compartment* contains the object name, the *middle compartment* contains the object attributes, and the *bottom compartment* contains the object operations (if different from the object attributes). Notes contain expository information such as design decisions. Sequence threads indicate serial events in process flow. Process flow is indicated by *solid arrows*. *Dashed arrows* indicate communication between objects and, for the purposes of illustrating bacmid, are labeled as *uses* (the object utilizes a second object), *calls* (the object elicits an action from a second object), and *destroys* (a step that causes the loss or destruction of one or more objects). End of process is indicated. The abstraction of the function of individual objects driven by UML may make other analogous devices (similar to bacmid, but substituting one or more isofunctional objects) obvious [22.17, 18]. In protein-containing devices, systematic identification of isofunctional objects could be facilitated using protein databases modified as suggested in [22.17] (after [22.18])

nant protein therapeutics, nanotherapeutics may present regulatory and pharmacoeconomic challenges related to their novelty and their cost of goods (COGs). However, there is little doubt that nanobiological devices providing clear patient benefit, and whose production, regulatory approval, and distribution are amenable to feasible business models, will enter clinical practice.

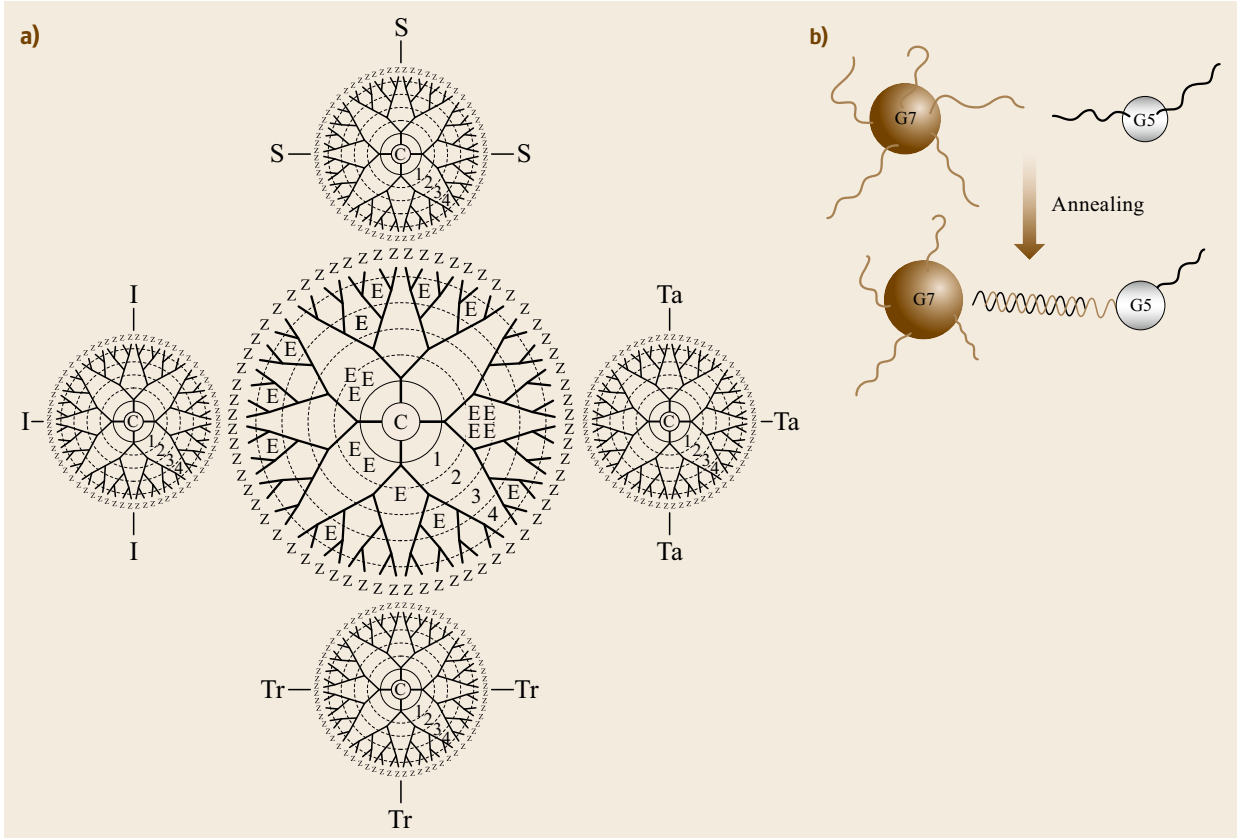

Fig. 22.4 (a) A hypothetical, modular nanotherapeutic agent patterned after the dendrimer-based cluster agent for oncology of *Baker* [22.27–29]. Self-assembling, multidendrimer structures as shown are sometimes referred to as tecto(dendrimers). Each polyamidoamine (PAMAM) dendrimer subunit is grown from an initiator core (C), and the tunable surface groups of the dendrimers are represented by Z. In this device, each dendrimer subunit has a specific, dedicated function in the device: the central dendrimer encapsulates small-molecule therapeutics (E), whereas other functional components are segregated to other dendrimer components. These include biochemical targeting/tethering functions (Ta), therapeutic triggering functions to allow activation of prodrug portions of the device by an external operator (Tr), metal or other constituents for imaging (I), and sensing functions (S) to mediate intrinsically controlled activation or release of therapeutic. This design constitutes a therapeutic platform [22.14, 16] because of its modular design. The depicted device is only one possible configuration of an almost infinite number of analogous therapeutics that can be tuned to fit particular therapeutic needs by interchanging functional modules (after [22.16]). (b) A more sophisticated assembly strategy for dendrimer therapeutics that utilizes self-assembly of biomolecules [22.30–32]. Individual dendritic polymers (spheres representing generation 5 and generation 7 PAMAM dendrimers) are conjugated with single-stranded (ss) oligonucleotides (*light and dark gray lines*). When oligonucleotides of two dendritic polymers are complementary, individual oligos hybridize, forming double-stranded (ds) DNA complexes, linking the two dendritic polymers. An interesting feature of this assembly system is the rigidity of short dsDNA (< 50 base pair) segments. This allows assembly of objects at precise, tunable nanoscale distances (after [22.30])

22.2 Assembly Approaches

Assembly of components into devices is amenable to multiple approaches. In the case of devices comprising a single molecule or processed from a single crystal (some microfabricated structures, single polymers, or grafted polymeric structures) assembly may not be an issue. Integration of multiple, separately microfabricated components may sometimes be necessary and may sometimes drive the need for assembly, even for silicon devices. Furthermore, many therapeutic nanodevices contain multiple, chemically diverse components

that must be assembled precisely to support their harmonious contribution to device function.

22.2.1 Low-Throughput Construction Methods

Low-throughput device construction methods are more applicable to construction of prototypes for research purposes than to production of commercial therapeutics. For example, direct-write technologies can obtain high (nanometer-scale) resolution; electron-beam (e-beam) lithography is a technique requiring no mask and can yield resolutions on the order of tens of nanometers, depending on the resist materials used [22.33]. Resolution in e-beam lithography is ultimately limited by electron scattering in the resist and electron optics, and like most direct-write approaches, e-beam lithography is limited in its throughput. Parallel approaches involving simultaneous writing with up to 1000 shaped e-beams are under development [22.33] and may mitigate limitations in manufacturing rate.

Atomic force microscopy (AFM) approaches utilize an ultrafine cantilever tip (typically with tip diameters of 50 nm or less) in contact with, or tapping, a surface or stage. The technique can be used to image molecules, analyze molecular biochemical properties (such as ligand–receptor affinity [22.34]), or manipulate materials at the nanoscale. In the latter mode, force microscopy has been used to manipulate atoms to build individual nanostructures since the mid-1980s, though the manufacturing throughput of *manual* placement of atoms and nanoscale components by force microscopy is limited, even with highly multiplexed arrays of cantilevers.

Dip-pen nanolithography (DPN) is a force microscopy methodology that can achieve high-resolution features (features of 100 nm or less) in a single step. In DPN, the AFM tip is coated with molecules to be deployed on a surface, and the molecules are transferred from the AFM tip to the surface as the coated tip contacts it. DPN also can be used to functionalize surfaces with two or more constituents and is well suited for deployment of functional biomolecules on synthetic surfaces with nanoscale precision [22.35, 36]. DPN suffers the limitations of synthetic throughput typical of AFM construction strategies.

Much as multibeam strategies might improve throughput in e-beam lithography [22.34], multiple tandem probes may significantly increase assembly throughput for construction methods that depend on force microscopy, but probably not sufficiently to allow manufacture of bulk quantities of nanostructures, as will likely be needed for consumer nanotherapeutic devices. As standard of care evolves increasingly toward tailored courses of therapy [22.37], individual therapeutics will become increasingly multicapable and powerful. Potentially, fewer copies of a nanotherapeutic may be required per patient, and each patient's nanotherapeutic may be tailored to him/her. It is not inconceivable that this might make relatively low-throughput synthesis/assembly methods practical, though this remains to be seen. If tailored therapeutics become the standard, the pharmaceutical industry will be irrevocably changed, with the concept of the *blockbuster* that can produce multiple billions of dollars in revenue per year through sales of a single agent to a broad population made no longer relevant. Business models in the pharmaceutical industry may be changed beyond recognition, and in the fullness of time, pharmacies could begin to resemble the formularies of old, with the capacity to make a specific preparation for an individual patient on site, but now using sophisticated bio- and nanotechnologies.

Individualized therapies for one patient are likely to differ from those for other patients by their incorporation of engineered molecules that are immunologically, toxicologically or physiologically tolerable by each individual host. Device functional properties will be tuned to integrate with individual host physiologies. One facile way to achieve patient-specific theranostics might be to design a modular device whose properties are tuned by substitution of biochemically isofunctional components, but whose other properties (immunological, toxicological, etc.) are suited to individual patients. This sounds like the modular nanodevice construction strategy we advocate [22.17, 18]. Should this come to pass, pharmaceutical companies will have to find a way to claim as intellectual property immense collections of similar function, but individually tailored, nanotherapeutic devices. Patenting each device individually is economically and logistically impossible, and a patent on a single specific nanotherapeutic might be easily *invented around* by competitors. One possible solution may be to structure patent claims broadly, around UML representations of nanotherapeutics that explicitly call out the critical characteristics of objects to identify alternate, isofunctional objects that might be substituted for the objects of the device in its original design [22.18]. This may capture a group of analogous, related theranostics, rather than an individual nanotherapeutic, or it may make some or all of the analogous devices obvious in the eyes of the patent examiner. This would likely preclude the proliferation of devices, each captured by its own patent, but template off a single central invention, as occurred with analogues of bacmid [22.18].

For the moment, though, ideal manufacturing approaches for nanotherapeutic devices resemble either

industrial polymer chemistry, occurring in bulk, in convenient buffer systems, or in massively parallel industrial microfabrication approaches. In any case, therapy for a single patient may involve multiple billions of individual nanotherapeutic units, so each individual nanotherapeutic structure must require only minimal input from a human technician. Self-assembly, when feasible, allows device construction without ongoing human intervention.

22.2.2 Supramolecular Chemistry and Self-Assembly

Exploitation of the self-assembly properties of dendrimers and its exploitation to build a modular therapeutic has already been alluded to in Fig. 22.4a. Self-assembly has long been recognized as a potentially critical labor-saving approach to the construction of nanostructures [22.38], and many organic and inorganic materials have self-assembly properties that can be exploited to build structures with controlled configurations. Self-assembly processes are usually driven by thermodynamic forces and generally result in structures that are not covalently linked. Intra-/intermolecular forces driving assembly can be electrostatic or hydrophobic interactions, hydrogen bonds, and van der Waals interactions between and within subunits of the self-assembling structures or the assembly environment. Thus, final configurations are limited by the ability to *tune* the properties of the subunits and control the assembly environment to generate particular structures.

Highly hydrophobic carbon nanotubes spontaneously assemble into higher-order [22.39] structures (nanoropes and multiwall carbon nanotubes) as the result of hydrophobic interactions between individual tubes [22.39]. C_{60} fullerenes and single-wall carbon nanotubes (SWCNT) also spontaneously assemble (Fig. 22.5) into higher-order nanostructures called *peapods* [22.40], in which fullerene molecules are encapsulated in nanotubes. The fullerenes of peapods modulate the local electronic properties of the SWCNT in which they are encapsulated and may allow tuning of carbon nanotube electrical properties, perhaps as in one-dimensional (1-D) carbon nanotube field-effect transistors (FETs) [22.41]. Several self-assembled carbon structures and carbon-structure-containing devices are depicted in Fig. 22.5.

In drug delivery, the most familiar self-assembled nanostructures are micelles [22.42–44]. These structures are formed from the association of block copolymer subunits (Fig. 22.6), each individual subunit containing hydrophobic and hydrophilic domains. Micelles spontaneously form when the concentration of their subunits exceeds the critical micelle concentration (CMC) in a solvent in which one of the polymeric domains is insoluble (Fig. 22.6). The CMC is determined by the insoluble polymeric domain, and can be adjusted by control of the chemistry and length of the immiscible domain, as well as by control of solvent conditions. Micelles formed at low concentrations from low-CMC polymers are stable at high dilution. Micelles formed from polymer monomers with high CMCs can dissociate upon dilution, a phenomenon that might be exploited to control release of therapeutic cargos. If desired, micelles can be stabilized by covalent cross-linking to generate shell-stabilized structures [22.42–44]. Size dispersity and other properties of micelles can be manipulated by control of solvent conditions, incorporation of excipients (to modulate polymer packing properties), temperature, and agitation. From the standpoint of size, reasonably monodisperse preparations (polydispersities of 1−5%) of nanoscale micellar structures can be prepared.

The immense versatility of industrial polymer chemistry allows micellar structures to be tuned chemically to suit the task at hand. They can be modified for targeting (by appending ligands that recognize particular targeting sites to their surfaces) or to support higher-order assembly of micelles. They can be made to imbibe therapeutic or other molecules for delivery and caused to dissociate or disgorge themselves of payloads at desired times or bodily sites under the influence of local physical or chemical conditions. The tunability of these and other properties at the level of monomeric polymer subunits (as well as the level of assembled higher-order structures) makes micelles potentially powerful nanoscale vehicles for the delivery of drugs or imaging contrast agents.

In its most sophisticated manifestation, synthetic polymer self-assembly strategies can allow the generation of three-dimensional structures of highly defined nanoscale morphology. The production of controlled self-assembled structures can be affected by synthesis and assemble specific organic chemical compounds of controlled structure and chirality. Nanoscale molecular assemblies of this nature are said to be the result of supramolecular chemistries. Supramolecular chemistries exploit designer knowledge of molecular geometries, intramolecular interactions (hydrophobic, metal chelation, hydrogen bonding, and dipole interactions), and intramolecular packing properties to drive formation of nanoscale structures of controlled shape [22.45, 46]. As the referenced reviews [22.45, 46] show, supramolecular chemistry can produce space-filling nanostructures of stunning regularity, beauty, and elegance. However, what is most exciting in the context of therapeutic nanodevices (in our opinion) is the

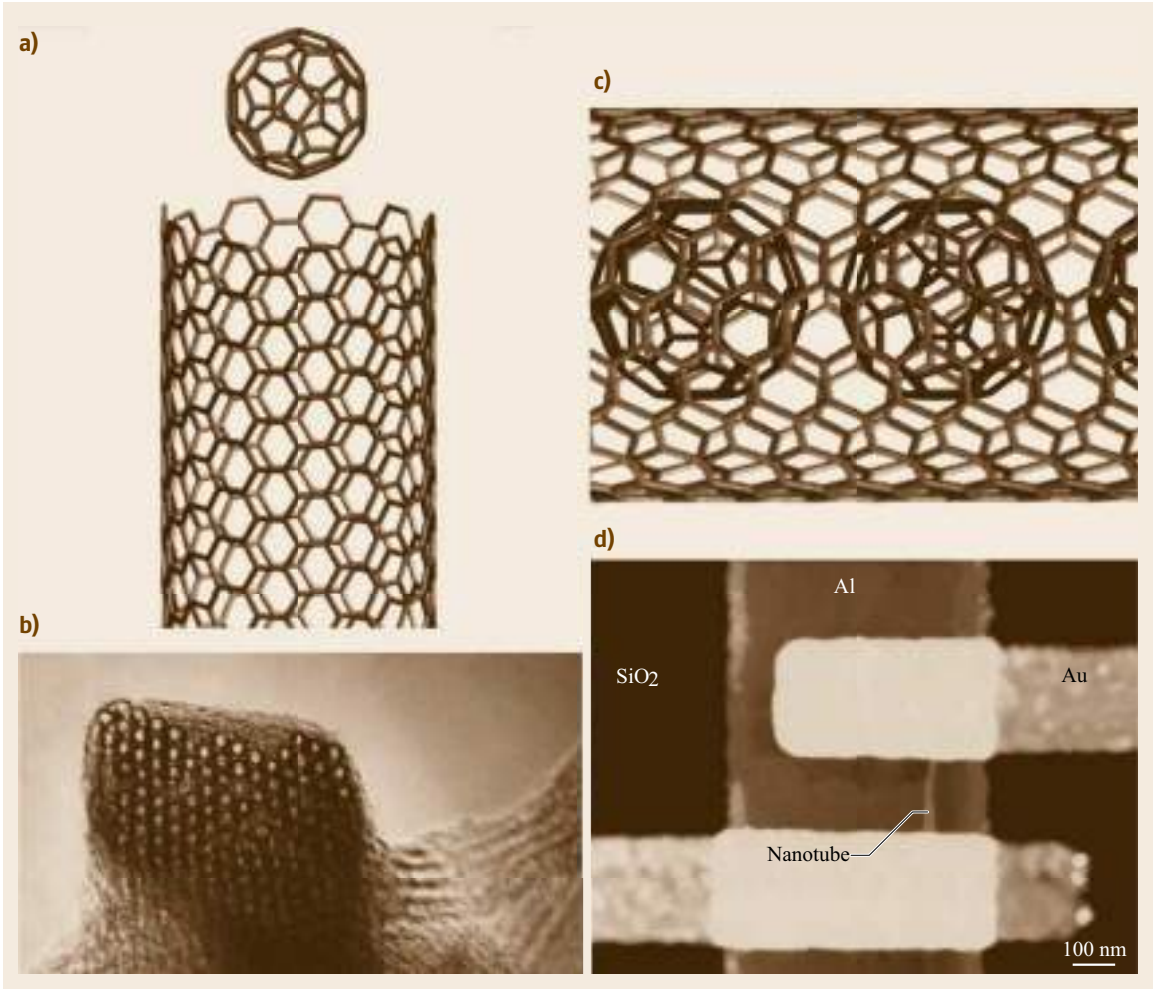

Fig. 22.5 **(a)** Shown to scale are two highly defined carbon nanostructures: a C_{60} fullerene and (10,10) single-wall carbon nanotube (SWCNT). **(b)** A self-assembled nanorope composed of carbon nanotubes that assemble by virtue of hydrophobic interactions [22.39–41]. **(c)** Schematic depiction of another self-assembled carbon nanostructure (a peapod) consisting of the fullerenes and SWCNT of **(a)**, with the fullerenes encapsulated in the SWCNT [22.40]. Fullerene encapsulation in the peapod modulates the local electronic properties of the SWCNT. **(d)** A nanotube field-effect transistor (FET) consisting of gold source and drain electrodes on an aluminum stage with a carbon nanotube serving as the FET channel [22.41] (after [22.39–41])

tunable biological activity of some supramolecular assemblies.

Incorporation of pharmacophores into supramolecular structures can render the structures biologically active. *Tysseling-Mattiace* and colleagues recently reported a supramolecular assembly (IKVAV peptide amphiphile, or IKVAV PA) with biologic activity in vitro and in vivo [22.47, 48]. IKVAV PA is based on amphiphilic polymer monomers, as are micelles; but unlike micelles, IKVAV PA is assembled from polymeric monomers whose chemistries are tuned to allow them to preferentially assemble into linear nanoscale filaments rather than spheres (Fig. 22.7). IKVAV PA nanofibers further coalesce into a gel under physiological salt and pH conditions. Thus, aqueous solutions of IKVAV PA spontaneously form a gel when injected in vivo.

The designers incorporated the peptide isoleucine–lysine–valine–alanine–valine (IKVAV) into the polar head group of each amphiphilic polymer monomer. IKVAV is a neuroactive peptide derived from the protein laminin, and is presented at immensely high valency on the surface of assembled IKVAV PA nanofilaments. In the central nervous system, IKVAV peptide is known to inhibit differentiation to glial cells and promote neu-

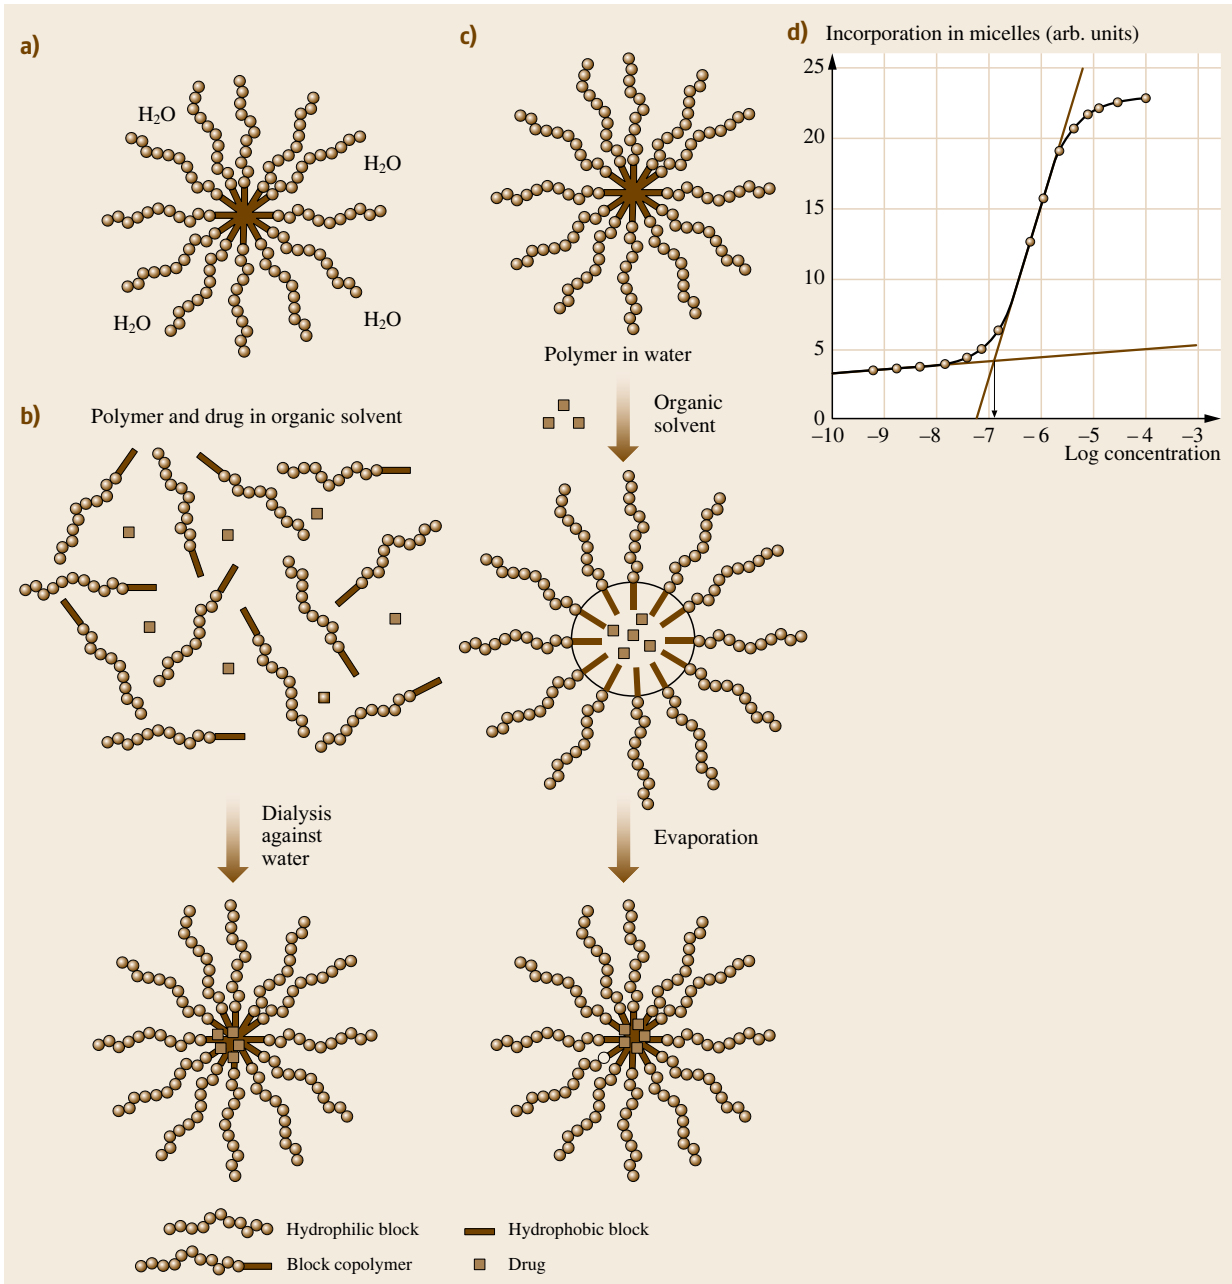

Fig. 22.6a–d Micellar drug-delivery vehicles and their self-assembly from block copolymers [22.42–44]. **(a)** Morphology of a micelle in aqueous buffer. Hydrophobic and hydrophilic polymer blocks, copolymers containing the hydrophilic polymer blocks, copolymers containing the blocks, micelles generated from the block copolymers, and (hydrophobic) drugs for encapsulation in the micelles are indicated. **(b)** Micelle self-assembly and charging with drug occurring simultaneously when the drug–polymer formulation is transitioned from organic to aqueous solvent by dialysis. **(c)** Preformed micelles can be passively imbibed with drugs in organic solvent. Organic solvent is then removed by evaporation, resulting in compression of the (now) drug-bearing hydrophobic core of the micelle. **(d)** An illustration of concentration-driven micelle formation. At and above the critical micelle concentration (CMC), block copolymer monomers assemble into micelles rather than exist as free block copolymer molecules. The *arrow* indicates the CMC for this system (after [22.42–44])

ronal outgrowth. Glial cells have a primary role in laying down scar tissue after spinal cord injury, and scar tissue is a key inhibitor of neurite outgrowth to repair the break.

In a murine model of induced spinal cord injury, IKVAV PA was injected into the site of spinal breaks. Relative to controls, injected animals exhibited reduced neurite apoptosis, reduced glial cell differentiation and scar tissue formation, and increased transit of the site of injury by descending (motor) neurons and by ascending (sensory) neurons (Fig. 22.7). These histological improvements in treated animals were accompanied by behavioral improvements (significant recovery of injury-induced motor and sensory deficits) that persisted longitudinally after the IKVAV PA was known to have been cleared from the site of injury. These improvements in motor and sensory function were unprecedented in the spinal injury model, and will be highly significant if translated to human therapy.

Furthermore, equimolar amounts of IKVAV peptide injected into the sites of injury produced no significant neurological improvements relative to control animals. That is, the structure provided by the amphiphilic polymer assembly is necessary to IKVAV PA therapeutic function. Consequently, IKVAV PA fits our definition of a nanodevice, and consists of an assembly module (the amphiphilic polymer monomers) and a bioactive module (IKVAV).

Design of self-assembling polymeric units that form specific nanoscale structures requires organic chemical synthetic capabilities and modeling skills that are not widely distributed in the physical and biological nanotechnology communities, but they do constitute genuine nanotechnologies, in as much as supramolecular chemistry facilitates multicomponent functional structures whose functions depend on structurally defined nanoscale components. The potential of supramolecular structures in therapy is immense.

Supramolecular chemistry of synthetic peptides has provided pharmacologically active antimicrobial structures (Fig. 22.8) [22.49, 50]. In the anti-infective architecture, individual peptide components are flat, circular molecules. The planar character of the toroidal subunits is a consequence of the alternating chirality of alternating DL amino acids (AAs) in the primary sequence of the peptide rings, currently only possible for synthetic peptides. Ribosomes recognize and incorporate into nascent polypeptides only L amino acids, and so, as a result of AA chirality and bond strain, peptides made by ribosomes cannot be flat, closed toroids like those of the peptidyl anti-infective agents. Alternation of D and L AAs is not possible in proteins made by ribosomal synthesis, though as we discuss below, this may

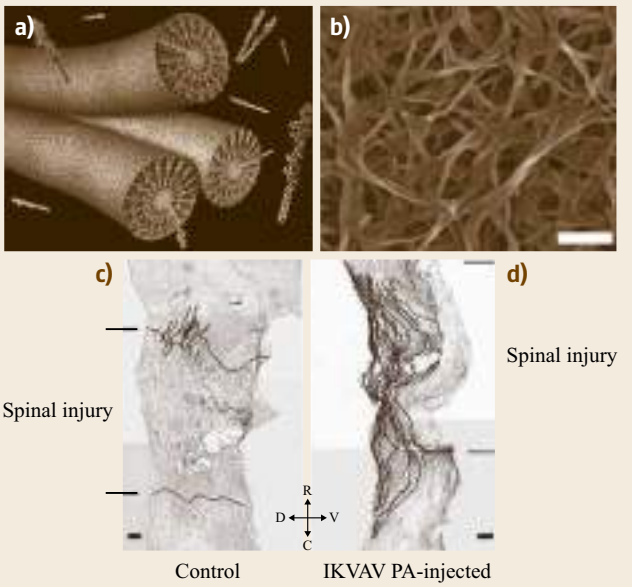

Fig. 22.7a–d The self-assembling neuroactive agent IKVAV PA (IKVAV peptide amphiphile) promotes regeneration of axons across sites of mechanically induced spinal injury in mice. **(a)** Schematic representation showing individual PA molecules assembled into a bundle of nanofibers interwoven to produce IKVAV PA. **(b)** Scanning electron micrograph image showing the network of nanofibers in vitro; *scale bar* in **(b)** indicates 200 nm. **(c,d)** Representative tracings of descending motor axon fibers within a distance of 500 μm rostral of the lesion in vehicle-injected **(c)** and IKVAV PA-injected **(d)** mice. The *dotted lines* demarcate the borders of the area of spinal cord injury. *Colored lines* indicate descending motor neurons impinging on the lesion. *Scale bars* in **(c,d)** indicate 100 μm. R – rostral; C – caudal; D – dorsal; V – ventral. IKVAV PA also promotes lesser, but still significant, regeneration of sensory neurons (not shown [22.48]). IKVAV PA-induced improvements in regeneration of axons are associated with significant behavioral improvements in mice. The self-assembly properties of IKVAV PA is essential to its function: IKVAV peptide alone does not promote regeneration [22.47, 48] (after [22.48])

change. Much as in α-helical domains of ribosomally synthesized proteins, however, the AA R-groups (which are of varying hydrophobic or hydrophilic chemical specificities) are arranged in the plane of the closed D, L rings, extending out from the center of the rings. Hydrogen bonds between individual rings govern self-assembly of the toroids into rod-like stacks, while the R-groups dominate interactions between multiple stacks of toroids and other macromolecules and structures. The planar toroidal subunits can be administered as monomers and self-assemble into multitoroid rods (Fig. 22.8) at the desired site of action (in biological membranes). The peptide toroid R-groups are

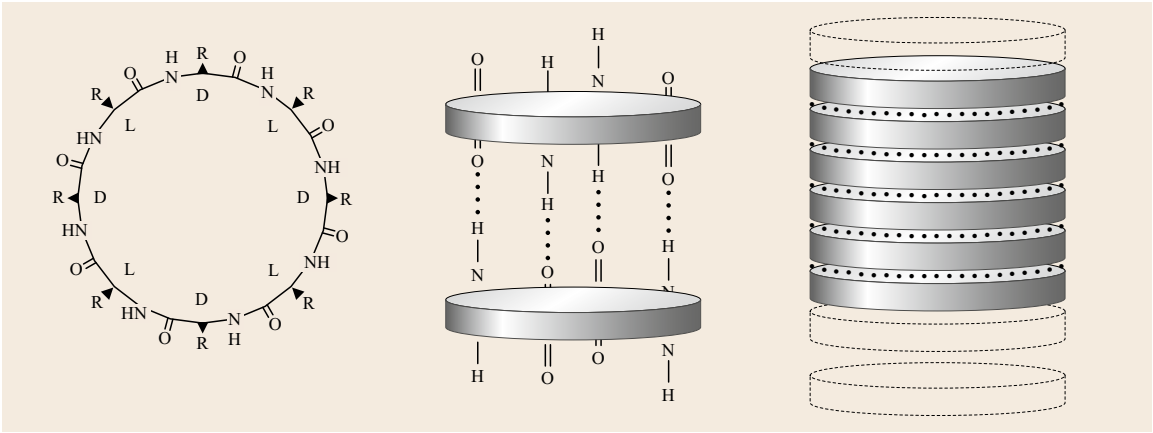

Fig. 22.8 A self-assembling peptide antibiotic nanostructure [22.49, 50]. Peptide linkages and the α-carbons and their pendant R-groups are indicated. The synthetic peptide rings are planar as a result of the alternating chirality (D or L) of their amino acid (AA) constituents. R-groups of AAs radiate out from the center of the toroid structure. Individual toroids self-assemble (stack) as a result of hydrogen-bonding interaction between amine and carboxy groups of the peptide backbones of adjacent toroids. The surface chemistry of multitoroid stacks is tuned at the level of the AA sequence and, therefore, R-group content of the synthetic peptide rings. The chemical properties of the stacked toroid surfaces allow them to intercalate into the membranes of pathogenic organisms, with lethal consequences. The specific membrane preferences for intercalation of the compound are tuned by control of the R-group content of the toroids (after [22.49, 50])

chemically tuned so that the rod structures into which they spontaneously assemble intercalate preferentially in specific lipid bilayers (i. e., in pathogen versus host membranes). Moreover, the assembled rods may undergo an additional level of self-assembly into multirod structures, spanning pathogen membranes [22.49, 50]. Intercalation of the self-assembled rods into pathogen membranes reduces the integrity of pathogen membranes selectively, potentially rendering agents toxic to pathogens but not to hosts.

Other self-assembling, nanoscale antibiotics with morphologies more like that of micellar structures [22.42–44] have been described (N8N antimicrobial nanoemulsion [22.51]). They, as well as the self-assembling D, L peptide toroids [22.49, 50], represent critically needed, novel antibacterial agents. Resistance to traditional, microbially derived antibiotics often is tied to detoxifying functions associated with secondary metabolite synthesis; these detoxifying functions are essential for the viability of many antibiotic-producing organisms [22.52]. The genes encoding such detoxifying functions are rapidly disseminated to other microorganisms, accounting for the rapid evolution of drug-resistant organisms that has bedeviled antimicrobial chemotherapy for the last half-century. Synthetic nanoscale antibiotics, such as peptide toroids [22.49, 50] and N8N antimicrobial nanoemulsion [22.51], act by mechanisms entirely distinct from those of traditional secondary metabolite antibiotics, and presumably no native detoxifying genes exist for these supramolecular antibiotics *because* they are structures not produced by evolution. Therefore, novel nanoscale antimicrobials may not be subject to the unfortunately rapid rise in resistant organisms associated with most secondary metabolite antibiotics, though this remains to be seen. As bacterial infection continues to reemerge as a major cause of morbidity and mortality in the developed world, as a consequence of increasing antibiotic-resistant pathogens, novel, nanoscale antibiotics will become increasingly important.

Biological macromolecules undergo self-assembly at multiple levels, and like all instances of such assembly, biological self-assembly processes are driven by thermodynamic forces. Some biomolecules undergo intramolecular self-assembly (as in protein folding from linear peptide sequences, Fig. 22.9). Higher-order structures are, in turn, built by self-assembly of smaller self-assembled subunits (for instance, structures assembled by hybridization of multiple oligonucleotides, enzyme complexes, fluid mosaic membranes, ribosomes, organelles, cells, tissues, etc.). Assemblies of higher-order structures, such as oligomeric proteins, are driven by the same forces that drive intramolecular protein folding.

Naturally occurring proteins are nonrandom copolymers of 20 chemically distinct amino acid (AA) subunits. The precise order of AAs (i. e., via interactions between AA side-chains) drives the linear polypeptide

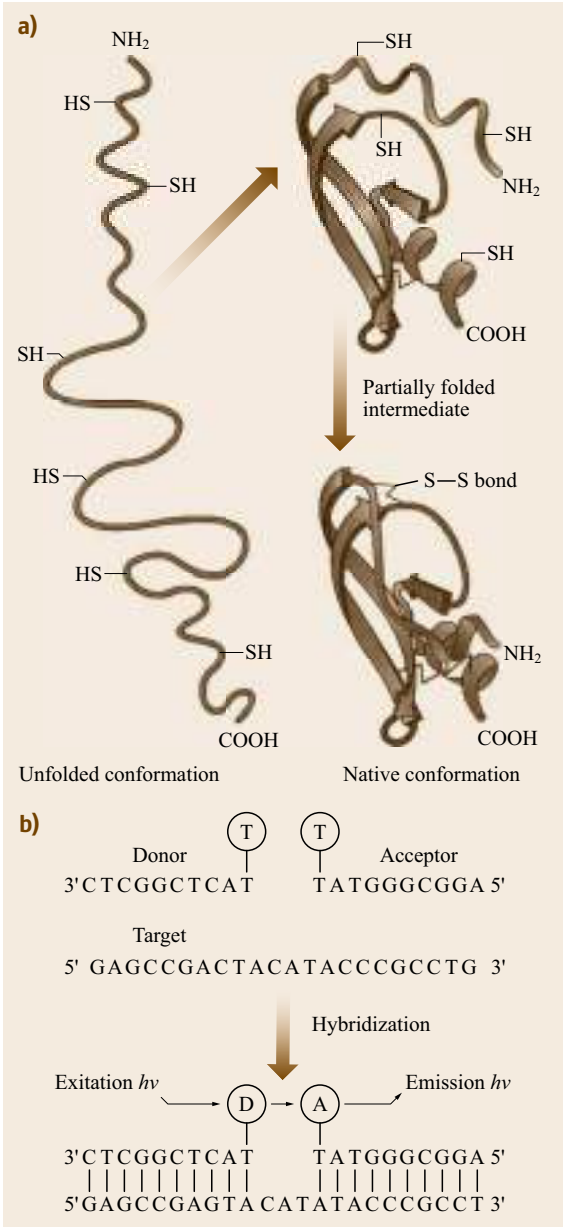

Fig. 22.9a,b Self-assembly of biological macromolecules. **(a)** Linear peptide chains (with amino- and carboxy-ends, as well as sulfhydryl groups of cysteine residues indicated) undergo a multistep folding process that involves the formation of secondary structures (α-helices, indicated by heavy helical regions, and β-sheet regions, indicated by the heavy arrows) that themselves associate into a tertiary structure. Final conformation is stabilized by the formation of intrachain disulfide linkages involving cysteine thiol groups. **(b)** A fluorescence transfer device that depends on self-assembly of biomolecules. The device is composed of donor (D) and acceptor (A) molecules brought into close proximity (within a few angstroms) by the base-pair hybridization of complementary oligonucleotides. When the structure is assembled, acceptor and donor are energetically coupled, and fluorescence transfer can occur [22.53, 54] (after [22.54]) ◄

chains to form specific secondary structures (the α-helices and β-sheet structures seen in Fig. 22.9). The secondary structures have their own preferences for association, which in turn leads to the formation of the tertiary and quaternary structures that constitute the folded protein structures. In its entirety, this process produces consistent structures that derive their biological functions from strict control of the deployment of chemical specificities (the AA side-chains) in three-dimensional space.

Biomolecules can be used to drive assembly of nanostructures, either as free molecules or when conjugated to heterologous nanomaterials (Fig. 22.9). For instance, three-dimensional nanostructures can be made by DNA hybridization [22.53–56]. Such DNA nanostructures can exhibit tightly controlled topographies but have limited integrity in terms of geometry [22.56], due to the flexibility of double-stranded (ds)DNA of 200 or more base pairs in length.

Often the domains of biomolecules responsible for assembly and recognition are small, continuous, and discrete enough that they can be abstracted from their native context as assembly modules and appended to other nanomaterials for direct formation of controlled nanoscale architectures. Antibodies and other specific biological affinity reagents can be used to assemble hybrid nanostructures (Fig. 22.9). Oligonucleotides are particularly intriguing in this application.

Unlike longer DNA segments, shorter dsDNA segments (of 50 base pairs or less) are rigid. The rigidity of short ds oligonucleotides has been cleverly exploited to build multidendrimer complexes (Fig. 22.4b) [22.30–32]. Dendrimers in these complexes are held at very precise distances from one another, defined by the length of the dsDNA segments. Nanometer-scale interdendrimer distances measured by AFM and other methods are within 10% of distances predicted from the dsDNA length [22.30, 31]. The length of the ds oligonucleotide is defined by the DNA sequence, and is easily tuned. This assembly strategy is currently being used to build multidendrimer anticancer devices, analogous to those envisioned in Fig. 22.4a, albeit with greater synthetic control and stability. The implications of the strategy goes well beyond dendrimer complexes, and might be used to impose precise distance relationships

on nanoscale components or between nanoscale components and surfaces in devices.

22.2.3 Chemoselective Conjugation

Several chemoselective bioconjugate approaches have arisen from the field of protein semisynthesis [22.20, 57, 58]. These protein synthetic chemistries allow site-specific conjugation of polypeptides to heterologous materials in bulk, as the result of conjugation between exclusive, mutually reactive electrophile–nucleophile pairs, one on the polypeptide, the other on its conjugation partner. Chemoselective conjugation strategies have been applied to the synthesis of multiple nanobiological devices [22.1, 1–8, 15, 57–60].

Proteins are profoundly dependent on their three-dimensional shapes for their activities: chemical derivatization at critical AA sites can profoundly and negatively impact protein bioactivity. Because conjugation can be directed to preselected sites via chemoselective approaches, and since the sites of conjugation in the protein can be chosen because the proteins tolerate adducts at those positions, proteins coupled to nanomaterials by such chemoselective methodologies often retain their biological activity. In contrast, protein bioactivity in conjugates often is lost or profoundly impaired when proteins are coupled to nanomaterials using promiscuous chemistries. For instance, promiscuous chemistries (1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) conjugation [22.61]) used to conjugate cytokines to nanoparticles tend to inactivate human interleukin (hIL)-3 and other cytokines. The same protein–particle bioconjugates retain bioactivity if judiciously chosen chemoselective conjugation strategies are used [22.1, 59, 60].

The potential utility of chemoselective conjugation for incorporation of active biological structures into semisynthetic nanodevices cannot be overestimated. In fact, some protein engineering methods that can change protein topography, and therefore the spatial relationships between proteins and the device nanocomponents to which they are conjugated, can be used to control protein–device spatial arrangements only in circumstances where the association between the protein and device is nonrandom and oriented, as can occur via chemoselective conjugation.

Protein sequences are said to be circularly permuted (CP) when their parental amino- and carboxy-ends are ligated together, and new amino- and carboxy-ends are introduced elsewhere in the protein sequence. There are as many potential CP variants of a given protein as there are AAs in the protein sequence. In each distinct variant, the CP sequence initiates (and ends) at a different AA of the parental sequence.

The fact that many proteins tolerate circular permutation of their primary AA sequences came as a surprise to molecular biologists. Nonetheless, multiple examples of biofunctional CP proteins have been documented [22.62–71]. We recently developed a method that displays all possible CP variants of a protein on the surfaces of phage particles. Phage-presented CP proteins can be conveniently screened for function by their affinity for a target (for a known ligand of the parent protein, for instance). We call this process scanning circular permutation [22.72, 73], and it allows functional screening of every possible CP variant of a protein of interest.

One of the remarkable findings of the scanning CP work was the finding that a large fraction (as many as $\frac{1}{3}$, and possibly more) of the distinct CP variants of a test protein were bioactive [22.72]. Many of the new amino- and carboxy-ends of functional CP variants fell within known secondary structural domains of the parent protein, and yet CP variants interrupting those secondary structural domains exhibited full bioactivity. This all suggests that the linear order of protein AA and secondary structural domains as they occur in natural proteins may not be requisite for protein structure and function, and further that multiple biofunctional CP variants of many proteins may be possible [22.62–72]. Scanning CP [22.72] provides a high-throughput way to identify biofunctional CP variants and to build collections of CP versions of a single parent sequence.

When proteins are conjugated to a polymer interface by a single, specific amino acid (as by chemoselective conjugation [22.20, 57, 58]), their orientations are more or less regular (limited by the conformational freedoms of the protein and interfacial polymers themselves). Typically, chemoselective conjugation is limited solely to protein N-termini, producing consistent orientation relative to the surface. Circular permutation alters protein topology to modulate distances between protein functional domains (such as antigen-combining sites of SCFvs or single chain fragment variables) and N-termini (where conjugation uniquely occurs, and so proximal to the surface). Together, chemoselective conjugation and circular permutation modulate protein orientation on surfaces to allow tuning of distance to surfaces and protein functional domains (like antigen combining sites) [22.72, 73]. This effect is illustrated for a hypothetical antibody fragment (so-called single-chain Fv or SCFv) in Fig. 22.10. The potential utility of changing these distances is discussed in the context of a nanobiotechnological sensor system below. In this sensor, certain key nanoscale distances are the primary determinants of overall sensor function, and we will show how circular permutagenesis and other molecu-

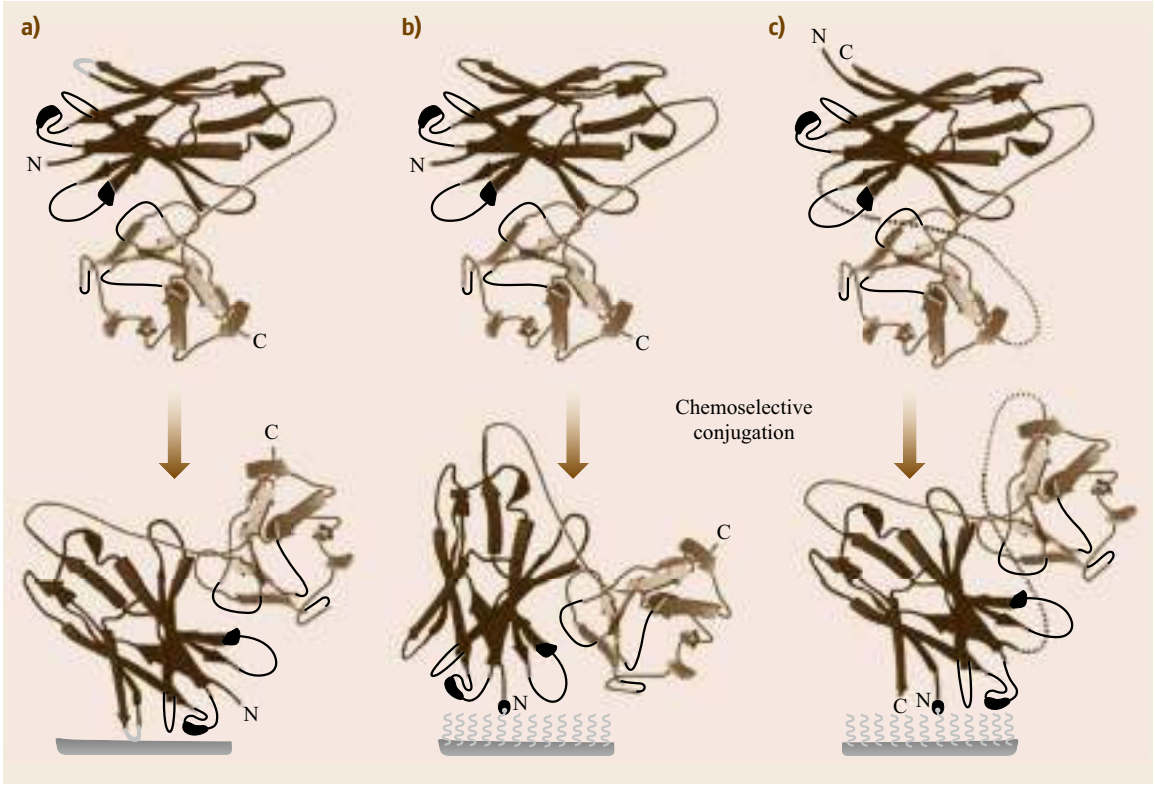

Fig. 22.10a–c Examples of protein engineering manipulations that could potentially alter the orientations of proteins (SCFvs) deployed on micromachined surfaces. Ribbon diagrams of SCFvs (VH–VL configuration) to be deposited on a SiO_2 surface. VH is shown in *dark brown*, VL in *light brown*. Complementarity-determining regions (CDRs) of VH and VL are shown in *black*. CDRs direct specific antigen recognition. Micromachined metal oxide surface is represented by a *brown bar*. A polymeric layer on the surface is represented by *wavy lines*. N- and C-ends of SCFvs are indicated. Chemoselective ligation between N-ends of SCFvs and polymer is indicated. **(a)** Affinity peptide-SCFv: surface-specific affinity peptide selected from a display library (for instance, SiO_2- [22.74, 75] or Al_2O_3-binding [22.76] peptide) is inserted into the SCFv antibody fragment (*gray line*). The affinity peptide binds to the surface, effectively orienting the SCFv and determining the proximity of the CDRs to the SiO_2 surface. **(b)** Parent SCFv: chemoselective conjugation of a modified SCFv (with an N-terminal aldehyde; [22.1, 59, 60, 72, 73] to the polymer layer. Note the position of the VH CDRs. **(c)** A circularly permuted variant of a SCFv: chemoselective conjugation of a circularly permuted [22.72, 73], but otherwise comparable, SCFv. In **(b)** and **(c)** , note that chemoselective conjugation produces a consistent orientation of SCFvs and that, relative to the parent SCFv, CP alters the proximity of the CDRs to the surface (after [22.73])

lar biology approaches can be used to address problems occurring at the nanoscale.

22.2.4 Unnatural Amino Acids to Support Chemoselective Conjugation of Biologically Produced Proteins

Early protein chemoselective conjugation methods depended on either protein or peptide chemical synthesis to introduce a nucleophile or electrophile into the protein sequence for chemoselective conjugation, or on some postsynthesis processing of a native AA to a chemically reactive group [22.20, 57, 58]. Typically, the reactive group has been at an end of a polypeptide (most typically, at the N-end). Recently, more elegant and versatile methods to introduce reactive groups to polypeptides via ribosomal synthesis have developed. These methods utilize biologically produced proteins made in expression host systems engineered to introduce unnatural AAs (UAAs) at specific sites in proteins. UAAs can have a variety of functional side-chains, including chromophores, fluors, photoreactive groups or chemically reactive groups. To the extent that reactive functionalities of UAAs can participate in chemoselective conjugations with other chemical groups, this approach can be used to prepare proteins for chemo-

selective conjugation to other surfaces or nanoscale moieties. Importantly, since the UAAs are introduced by ribosomal protein synthesis, the position of the UAA, and therefore the site of chemoselective conjugation, is not limited to the end of the protein sequence. Chemoselective conjugation can potentially be made to occur at any AA of the polypeptide sequence. Such UAA-incorporating systems have been developed in prokaryotic, lower eukaryotic [22.77, 78], and mammalian expression systems [22.79], potentially allowing proteins with UAAs to be synthesized in host systems of varying expression properties or with host-specific posttranslational modifications.

These systems for ribosomal introduction of UAAs at specific sites in biologically produced proteins have several general features in common [22.77–79]. They exploit suppression of nonsense codons (of which there are three in *E. coli*, and which, in wild-type strains, stop protein translation) by a mutant transfer ribonucleic acid (RNA) (a so-called suppressing tRNA) whose anticodon loop is homologous to the nonsense codon that will drive UAA insertion into nascent protein. Not only must this mutant tRNA recognize the nonsense codon, but it must also have the capacity to be charged with the desired UAA by a corresponding aminoacyl-tRNA synthase. Generating aminoacyl-tRNA synthases that can recognize both the suppressing tRNA and the desired UAA requires extensive genetic engineering effort. To ensure specificity of UAA incorporation, the aminoacyl-tRNA synthase cannot recognize any native AA, and cannot direct charging of any of the host's other tRNAs.

As current (2008) metabolic engineering capabilities go, UAA-incorporating systems must rank as the most sophisticated described to date. Nonetheless, their output is engineered protein with reactive groups at predetermined AA positions within them. These reactive groups can be conjugated chemoselectively to other nanoscale components, to effect changes in the spatial relationship of particular protein functional domains and the components to which proteins are conjugated. A collection of proteins differing from one another only by the position of the UAA that participates in chemoselective conjugation could have a utility to nanotechnologists that closely parallels that of a collection of circularly permuted proteins. As Fig. 22.10 shows, circular permuted proteins chemoselectively conjugated to surfaces can be used to tune distance between underlying surfaces and protein functional domains. Incorporation of UAAs and chemoselective conjugation therefore might also be used for analogous purposes in nanobiological devices.

22.3 Sensing Devices

The need for *smart* therapy is a key theme of therapeutic nanotechnology, and of pharmacology as a whole. We discussed above the emerging class of theranostic agents that include sensing or diagnostic functions.

Drugs with narrow therapeutic windows should ideally be delivered only to their desired site of action and be pharmacologically active only when their activity is needed. These strategies can limit undesired secondary effects of therapy, some of which can be debilitating or life threatening. One possible approach to this issue is the incorporation of sensing capability (specifically, the capacity to recognize appropriate contexts for therapeutic activity) into nanotherapeutic devices. Sensing capability may allow self-regulation of a therapeutic device, reporting to an external clinician/device operator (as in imaging applications, see below), or both.

Biosensors are typically considered to be multifunctional, multicomponent devices [22.80]. Usually a biosensor system is composed of a signal transducer, a sensor interface, a biological detection (bioaffinity) agent, and an associated assay methodology, with each system component governed by its inherent operational considerations. Signal transducers are moieties that are sensitive to a physicochemical change in their environment and that undergo some detectable change in chemistry, structure or state as the result of analyte (the thing to be sensed) recognition. Analytes for nanotherapeutic application could be biomolecules, such as proteins, small molecules (organic or inorganic), and ions (salts or hydrogen ions), or physical conditions (such as redox state or temperature). Interfaces are the sensor components that interact directly with the analyte. For sensor use in nanotherapeutic devices, immobilized or otherwise captured biological molecules (proteins, nucleic acids) often constitute the active parts of biosensor interfaces. Whatever the chemical nature of the interface, it determines the selectivity, sensitivity, and stability of the sensing system and also is a dominant determinant of sensor operational limits. Assay methodology determines the need (or lack thereof) for analyte tracers, the number of analytical reagents, and the complexity and rapidity of the sensing process.

22.3.1 Planar FET Protein Sensors

To illustrate the potential of biotechnology to solve nanoscale problems, we will focus on protein-sensing immunoFETs (a field-effect transistor sensor which

binds analyte via an antibody molecule or fragment thereof on its sensing surface). Field-effect transistors (FETs) consist of a current source and current drain separated from each other by a semiconductor channel through which current flows. A *gate* to which electrical bias is applied is positioned above the channel to modulate channel conductance. Depending on gate bias, current flow through the FET channel is increased or decreased (Fig. 22.11) [22.81–85]. Electrical properties of FET sensing channels can be modulated by any proximal electric field/charge acting as a gate, allowing configuration of sensors [22.81–91], including, in principal, protein sensors. Receptor molecules (antibody fragments, peptides, aptamers, etc.) that recognize protein analyte molecules are deployed on the sensing channel, and analytes bind to the interface via the receptors. Charges of protein analytes induce a dipole between the surface and the underlying depletion region of the semiconductor, eliciting a gating effect which affects current through the FET. Differently charged analytes interact differentially with charge carriers in the FET, producing analyte-charge-specific responses. FET sensors can be constructed from nanowires (so-called 1-D FETs). One-dimensional structures *may* have much enhanced sensitivity due to their high surface-area-to-volume ratios [22.82–85]. An example of a 1-D FET was shown in Fig. 22.5, and 1-D FETs much like those pictured are widely accepted as nanotechnological devices, though meso- to macroscale planar FET sensors often are not. The reason for considering 1-D FETs as *real* nanotechnology is that 1-D devices contain a nanoscale component (the semiconducting nanowire). They also additionally contain nanoscale receptor molecules. Thus, although physical nanotechnologists often chafe (very unreasonably) at this argument, planar FETs are nanodevices for the same reason as 1-D nanowire FETs are. Planar FETs, though they themselves may be meso- to macroscale, depend on obligately nanoscale components (biomolecular receptors for analytes) for their function. Here we focus on *planar* FETs as a platform to demonstrate how biotechnology can solve a problem occurring at the nanoscale.

The potential utility of FET protein sensing in physiological environments is obvious, but has only recently been realized [22.90, 91]. FET sensor sensitivity to analyte charge is limited by multiple factors [22.81–91], though the key problem cited is typically regarded to be shielding by buffer ions in the high-salt (150 mM Na^+) physiological environment (Fig. 22.12) [22.81–84, 86]. This led to an assessment that planar immunoFETs, owing to the size of antibodies (10–12 nm) and the maximal distance over which analyte charges were thought to be detectable by the FET (sometimes called the Debye length, < 2 nm), were fundamentally infeasible. The

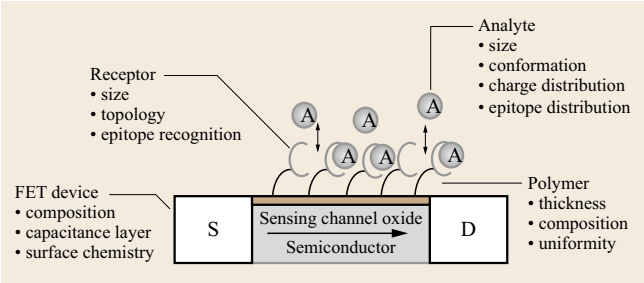

Fig. 22.11 A protein-sensing FET and some of the parameters influencing its function. Current source and drain (S, D) are shown, as is the semiconductor (*gray box*). Capacitance layer/sensing channel oxide is shown in *brown*. Current flowing from the source to the drain in the semiconductor (I_{SD}) is indicated by the *black arrow*, and increases or decreases in response to charges brought to the sensing channel surface as a result of analyte binding. Receptors (SCFvs, streptavidin, etc.) are shown as *gray C-shaped lines* and bind analyte (*gray balls, labeled A*) specifically but reversibly and are conjugated to the sensing channel by an interfacial polymer. Parameters that might be chosen judiciously to optimize the sensor are shown. Note that interfacial optimization occurs primarily on the nanoscale, with specific changes to molecular sizes and orientations

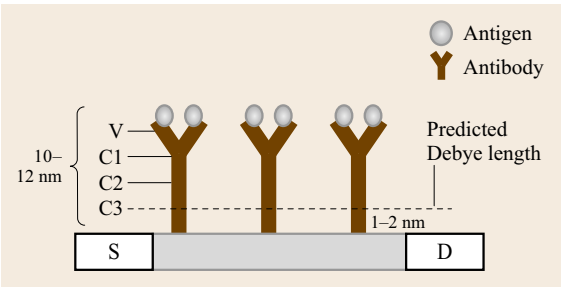

Fig. 22.12 The biochemical basis of the classical analysis interpreted as indicating the infeasibility of planar immunoFETs operating in physiological buffer. Artist's conception of antibodies on FET sensing channel. Antibody domains (constant 1, 2, 3 as C1, C2, C3 and variable as V) are indicated, as is the predicted Debye length in physiological buffer (150 mM salt, about 1–2 nm). FET source and drain (S and D) are shown. Shown is the classical (but wrong, see text) depiction of antibodies adsorbed onto a FET sensing channel solely by their C3 domains. This flawed representation is central to the classical objection to the feasibility of immunoFETs (after [22.81])

classical analysis of immunoFETs reasonably considers ion shielding, but is so fatally flawed in its consideration of receptor protein structures on FET surfaces that it is irrelevant. To biochemists, the fallacies of the classical model are obvious, and biochemists encountering the classical model immediately dismiss it as meaningless,

though much of the sensing community has clung tenaciously to the moribund model. We have discussed the fatal flaws of the classical analysis elsewhere [22.90, 91] and will repeat the discussion only briefly:

1. Use of intact antibody as receptors as in Fig. 22.12 is unnecessary: *much* smaller (10×), antigen-binding antibody fragments are available.
2. Antibodies do not adsorb exclusively at C3 domain (as shown in Fig. 22.12): antibodies bind surfaces in a distribution of orientations.
3. Antibodies contain a flexible region at the crotch of the *Y* called the *hinge* that allows antigen-combining sites vast freedom in their relative positions. The implicit assumption illustrated in Fig. 22.12 is that antibodies are rigid bodies, which is wrong.
4. The effect of antigen (analyte) three-dimensional (3-D) shape and charge distribution on charge proximity to the sensing channel is not considered in classical analysis.
5. The diversity available in native and phage-presented antibody repertoires was not exploited. The impact on sensor properties of analyte receptors (antibodies or fragments thereof) of differing valency, conformations, antigen (analyte) affinity or analyte epitope recognition properties were not considered.
6. Improvement of antibody receptor properties by protein engineering is not considered in the classical analysis.
7. Data directly shows that planar FET protein sensors can detect a biologically important analyte at concentrations which occur in real biological systems under physiological salt conditions [22.90, 91].

Suffice it to say that, if planar immunoFETs are not feasible, the reasoning of the classical assessment has little to do with why they might be infeasible. However, we know from our work that planar FET protein sensors operating at physiological salt concentrations are feasible [22.90, 91], though we show that the distance between the analyte charge and the sensing channels is a key parameter for sensor sensitivity. We will focus on biotechnology approaches to engineer the nanometer distance between bound analyte charges and FET sensing surfaces as an existence proof of the utility of biotechnology to nanotechnology.

22.3.2 Biotechnology Approaches to the *Fundamental Limitations* of Planar ImmunoFETs

First, in the classical model [22.81–84, 86], chemoselective conjugation of receptors (antibodies) to sensing interfaces is not considered. Chemoselective conjugation would have the desirable effect of orienting the antibody layer consistently, from one antibody molecule to the next. Even though the classical representation (as mimicked in Fig. 22.12) shows antibodies adsorbed onto sensing surfaces in an oriented fashion, it is well known to immunologists that antibodies adsorb to surfaces in a stochastic distribution of orientations, binding to the surfaces via a random distribution of antibody surface regions. That is to say that the antibody layer as contemplated in the classical assessment is misrepresented, and the lack of orientation of the antibodies at real interfaces would interfere with many of the available biotechnology strategies to control the distance between the analyte charge and the sensing surface. However, the entire classical assessment of immunoFETs [22.81–84, 86] is based on the incorrect representation of the extent of order in the protein orientation shown in Fig. 22.12. This critical flaw alone invalidates the classical assessment, but there is much more wrong with the assessment than just this point.

Secondly, use of intact antibodies (IgG) as immunoFET receptors is unnecessary: specific epitope recognition function can be isolated on fragments several-fold smaller than intact antibodies [22.21, 92–99]. Single-chain Fv antibody fragments (single-chain fragment variables, SCFvs) are less than half the size of intact antibodies. Single-domain (camelid) antibody fragments, called variable heavy–heavy (VHH), are smaller still: about 10% of the mass of intact antibodies [22.97–99]. There are multiple methods to convert existing antibody genes (isolated from mammalian B-cells) to genes that will direct biologic production of either SCFvs or VHHs recognizing the same antigen (analyte), as well as methods to isolate de novo SCFvs or VHHs that are directed to antigens of interest that are well known to those skilled in the art [22.97–99]. The simple expedient of using an antibody fragment as an immunoFET receptor reduces the distance between the sensing surface and the bound analyte charge to nearly the calculated distance over which buffer counterion shielding is expected to occur (Fig. 22.12 [22.81–84, 86]). Again, failure to consider this fact is in itself sufficient to invalidate the classical assessment. Antibody fragments are convenient substrates for chemoselective conjugation, and we exploit the protein orientation chemoselective approaches in our SCFv layers to engineer analyte–semiconductor distances.

Thirdly, no consideration is given in the classical model to engineering the antibody molecules or fragments thereof to optimize their function as immunoFET receptors. This was a major oversight, even at the time when the classical model was promulgated in the early 1990s. The tools available for antibody engineering are

vast and sophisticated. We have discussed a few of them above (receptor circular permutagenesis [22.72, 73] and introduction of UAAs [22.77–79], both useful in the context of chemoselective conjugation of the antibody or fragments thereof to the sensing interface). As Fig. 22.10 illustrates, the effect of circular permutagenesis of a SCFv is to change the orientation of its antigen-combining sites to the site of chemoselective conjugation. Effectively, the orientation (relative to the immunoFET sensing channel) and therefore the distance charges of analytes bound to antibody fragments is different when analytes are bound to different CP antibody variants. Since charges of protein analytes are not very mobile, the critical distance between analyte charges and sensing surfaces is different with different circularly permuted variants of a single antibody fragment. In the context of the immunoFET, it should be possible to identify those circularly permuted antibody fragments that produce the greatest sensor sensitivity, presumably because they minimize the distance between bound analyte charges and FET sensing surfaces. Similarly, the optimal AA position for a UAA in an antibody fragment could be determined for an antibody fragment used as a FET receptor from the standpoint of immunoFET sensitivity. The approach could tune the distance between underlying surfaces and analyte charges, much as circular permutagenesis can.

There are still many other biotechnology approaches that might be used to optimize receptors for immunoFETs that have been ignored to date. We and multiple others have identified peptides that can specifically bind microfabricated surfaces [22.74–76]. Such peptides might be inserted into SCFv or VHH sequences and used to adhere the SCFv or VHH to the micromachined surface, as we suggest [22.73, 74]. Presumably, variable positions of peptide insertion could lead to differential orientations of antibody fragments on the immunoFET surface, with the potential benefits in terms of FET sensitivity already described for circular permutagenesis or UAA insertion described above. This has the potentially great advantage of adhering immunoFET receptors directly to the sensing surface, but our experience with direct adsorption of receptor proteins on micromachined surfaces have proven direct adsorption to be unsatisfactory in our hands (see below).

The foregoing is a very incomplete list of potential biotechnology approaches to addressing a limitation correctly identified (buffer counterion shielding of analyte charges) but incorrectly analyzed [22.81–84, 86]. Many more approaches are possible, although we will not attempt to enumerate them here. The point is that planar immunoFETs have a nanoscale limitation that can be addressed by biotechnology. Hence, in this application, biotechnology is a bona fide nanotechnology.

22.3.3 Nanotribology of Protein-Sensing Interfaces on Micromachined Surfaces

In FET protein sensors, the critical importance of the sensing interface is clear, implying the need to characterize the interface, and nanotribology and surface characterization have led to the discovery of additional interfacial design parameters and properties that must be considered in immunoFET design. Parameters of interest were thickness of interfaces (related to, but distinct from, the critical distance between bound analyte charges and semiconductor surfaces), surface roughness (smoothness), and interfacial robustness (resistance to wear). Resistance to wear is a critical issue if sensors are to be subjected to abrasion, as by tissue in an in vivo environment.

These studies were performed on silicon surfaces with a thermally grown oxide layer (silica surfaces [22.100–103]) and on a sputter-coated aluminum layer with a native oxide (aluminum surfaces [22.103]). Silicon surfaces simulate the sensing surfaces of a metal–oxide–semiconductor field-effect transistor (MOSFET), whereas aluminum simulates the sensing surface of an AlGaN (aluminum–gallium nitride) heterojunction FET. Native Al_2O_3 oxide which develops on sputter-coated aluminum surfaces is also the most prevalent oxide on the surfaces of AlGaN/GaN heterojunction FETs. All studies were performed with the model receptor protein streptavidin, and not with an antibody fragment.

Lee et al. and *Bhushan* et al. studied the step-by-step morphological changes resulting on silicon surfaces during deposition of a model protein (streptavidin) [22.100, 101]. These studies revealed, among other things, that streptavidin adsorbed to silicon interacted with the surface very weakly. Most of the adsorbed streptavidin could be removed from the surface by rinsing with an aqueous buffer [22.101]. Streptavidin adherence by adsorption to micropatterned asperities on the silicon surface and to the edges of silicon fragments was modestly stronger than to the flat silicon surface, although adhesion was still weak [22.100, 101]. Adhering streptavidin to the silicon surface via a biotinylated silane polymer (3-aminopropyltriethoxysilane (APTES), Fig. 22.13) significantly enhanced resistance to wear [22.101–103].

Ellipsometry of APTES-coated silicon surfaces showed the thickness of the polymer layer to be several-fold the expected monolayer thickness [22.103]. The unexpected thickness of the film likely represents multilayering by APTES, a phenomenon that had been previously reported [22.104–106]. Despite the fact that the sensor with a multilayered APTES layer was suf-

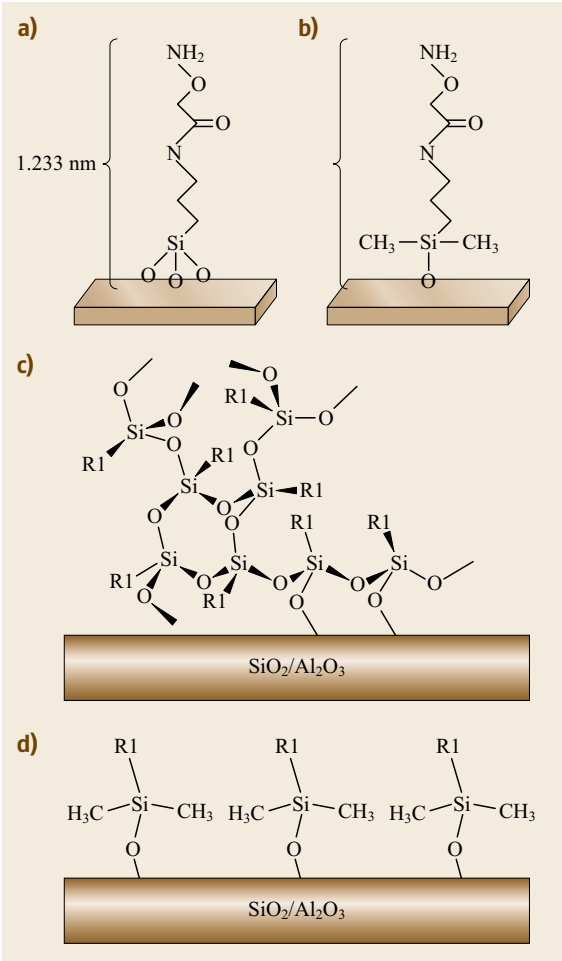

Fig. 22.13a–d Tri- and monoalkoxy silane constituents of the sensor interface on micromachined substrates. In **(a)** and **(b)**, oxyamine-terminated polymers for chemoselective conjugation are shown. **(a)** shows the trialkoxy interfacial polymer and **(b)** its monoalkoxy analogue. As determined by summing bond lengths, the length of polymer in nm is shown. Both ellipsometry (Fig. 22.14) and AFM analysis show that interfaces made with the monoalkoxy version of polymers are thinner and less rough, presumably due to reduced intramolecular silane polymerization [22.103–106]. **(c)** shows a hypothetical film made from trialkoxy polymer of **(a)**, and **(d)** shows a hypothetical film film made with the monoalkoxy polymer of **(b)**. R1 is ($CH_2CH_2NHCOCH_2ONH_2$) (after [22.103])

ficiently sensitive to detect analyte [22.90, 91], thinner interfaces would theoretically increase sensor sensitivity to analyte. Multilayering is related to the trivalency of APTES siloxane residues and is influenced by the deposition method [22.104–106]. Consequently, APTES polymer films were also constructed using a more optimized deposition protocol [22.104]. The more optimal method produced thinner APTES films, as expected (Fig. 22.14). However, peak-to-valley values for APTES films deposited by either protocol were substantially greater than the summed bond lengths of APTES [22.100–103]. The monosiloxane reagent, aminopropyldimethylethoxysilane (APDMES, Fig. 22.13), which has a much diminished capacity to produce multilayers, was also used to build polymer films on silicon. Strikingly, APDMES produced the thinnest films, with thicknesses comparable to the summed bond lengths of the APDMES polymer (Fig. 22.14).

The thicker silane films (based on APTES) were also substantially rougher than the APDMES film. APTES films applied by our original procedure were roughest, followed by APTES films deposited by the more optimal procedure, and APDMES films were the smoothest and most regular. This roughness ranking was conserved after subsequent steps in interface construction (biotinylation of and streptavidin binding to the biotinylated silane polymer, Fig. 22.14 [22.102, 103]). The results observed on silicon surfaces were replicated on aluminum surfaces, with APDMES providing a smoother, thinner interfacial polymer layer than did APTES [22.103]. Furthermore, the rank order of roughness following biotinylation was also conserved for APTES films deposited by our two protocols and APDMES films on aluminum [22.103].

Bhushan et al. [22.103] studied friction and wear of streptavidin deposited by physical adsorption and via a biotinylated APTES polymer layer on the silicon surface. The coefficient of friction for streptavidin-adsorbed silicon surfaces is less than for uncoated silicon [22.103], because the streptavidin acts as a lubricant film. Consistent with this interpretation, coefficients of friction were dependent on the concentration of streptavidin (that is, on the surface density of adsorbed streptavidin molecules, which increases when higher concentrations of streptavidin were used in coating the surfaces), and decreased at higher streptavidin concentrations. At higher densities of adsorbed streptavidin, the surface is more uniform and smoother, and the silicon substrate is more fully covered with protein than at lower concentration. This implies that the streptavidin forms a nearly continuous lubricant film at higher concentration. When streptavidin is linked to the surface through a biotinylated silane polymer, the coefficient of friction increases. This follows from the increased compliance of the underlying silane polymer. When normal load is applied to the surface, the surface is compressed, owing to the increased mechanical compliance afforded by interfacial biotinylated polymer length, flexibility or layering, all resulting in a larger contact area between the AFM tip and in-

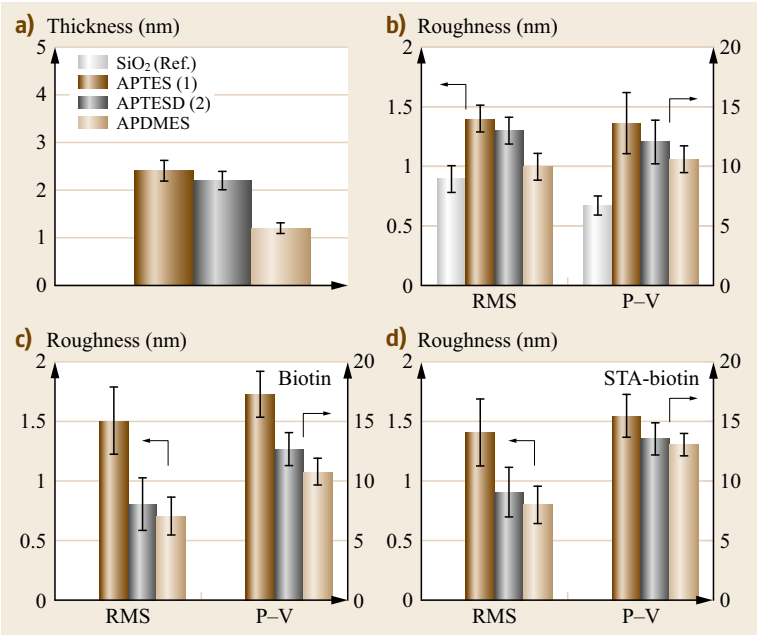

Fig. 22.14a–d Representation of nanotribological properties of films on silicon/SiO_2 surfaces. APTES (1) films were deposited by the method used in our published HFET (heterojunction field effect transistor) protein sensors [22.91, 92], and APTES (2) and APDMES films were deposited by the improved method described in [22.104]. **(a)** Silane film thickness (ellipsometry), **(b)** surface roughness (root mean square (RMS) and peak-to-valley (P–V) values) of silane films, **(c)** surface roughness (RMS and P–V values) of the same three silane films following biotinylation, and **(d)** surface roughness (RMS and P–V values) of the same three silane films following streptavidin binding to the biotin (after [22.103])

terfacial molecules. Since the size of streptavidin is much larger than that of the biotinylated silane polymer, the tightly packed streptavidin molecules cause very little lateral deflection of the tip. In streptavidin surfaces deposited by linkage to a polymer bound to the silicon surface, high contact area and low lateral deflection cause the friction force to increase relative to the same applied normal load on streptavidin surfaces deposited by adsorption [22.102, 103]. Together, these effects produce a *cushioning effect* that runs counter to the lubricating effect observed when protein (streptavidin) is directly adsorbed to the surfaces, increasing the coefficients of friction for streptavidin deposited by a polymer interface. The observations of streptavidin's lubricating properties and polymer–protein interfacial cushioning properties have been replicated on aluminum surfaces [22.103]. We think these are likely general properties of many protein interfaces on micromachined surfaces. We expect that many proteins (such as SCFvs adsorbed onto various metal oxide surfaces) will produce analogous lubricating properties, and that cushioning-mediated friction increases will occur for many polymer–protein interfaces, regardless of the composition of the underlying smooth, micromachined surfaces.

Interestingly, streptavidin bound to silicon surfaces via biotinylated silane polymers had differential resistance to wear, with APTES interfaces (which exhibit the most multilayering) being less robust than interfaces based on APDMES (with limited/no multilayering). The most highly multilayered polymer interfaces had, by definition, larger extents of intermonomer cross-linking, and were less resistant to wear by cantilevers [22.103]. This was interpreted by analogy to graphene layers in graphite, in that bonds between monomers of the polymer layer were more numerous than bonds between the polymer layer and the silicon substrate. Hence, when the polymer layer tore under stress from the cantilever, a larger section of the cross-linked polymer sheet tore free. It was expected that, if the polymer layer were a true, un-cross-linked, self-assembled monolayer, individual polymer monomers would have no way to transfer force applied on them to their neighboring monomers, and so would be individually plucked off the interface by the tip.

These studies also [22.102, 103] occasioned further insights into the mechanism of wear of polymer–protein interfaces on micromachined surfaces. The polymer–protein interfaces (biotinylated silane polymer–streptavidin) on silicon were sufficiently delicate that their wear could not be investigated by contact-mode AFM at any load tested. Contact mode always immediately stripped the surface, even at the lowest loads achievable. Consequently, wear experiments were performed at varying loads in tapping mode, wherein the free amplitude (and hence the load) of the cantilever was systematically varied (Fig. 22.15). As one might expect, as load increased, wear increased. The finding implies that wear of APDMES–streptavidin interfaces on silicon is not a concerted process, but proceeds sequentially more deeply as the applied force increases. That said, all tested interfaces were very delicate, and

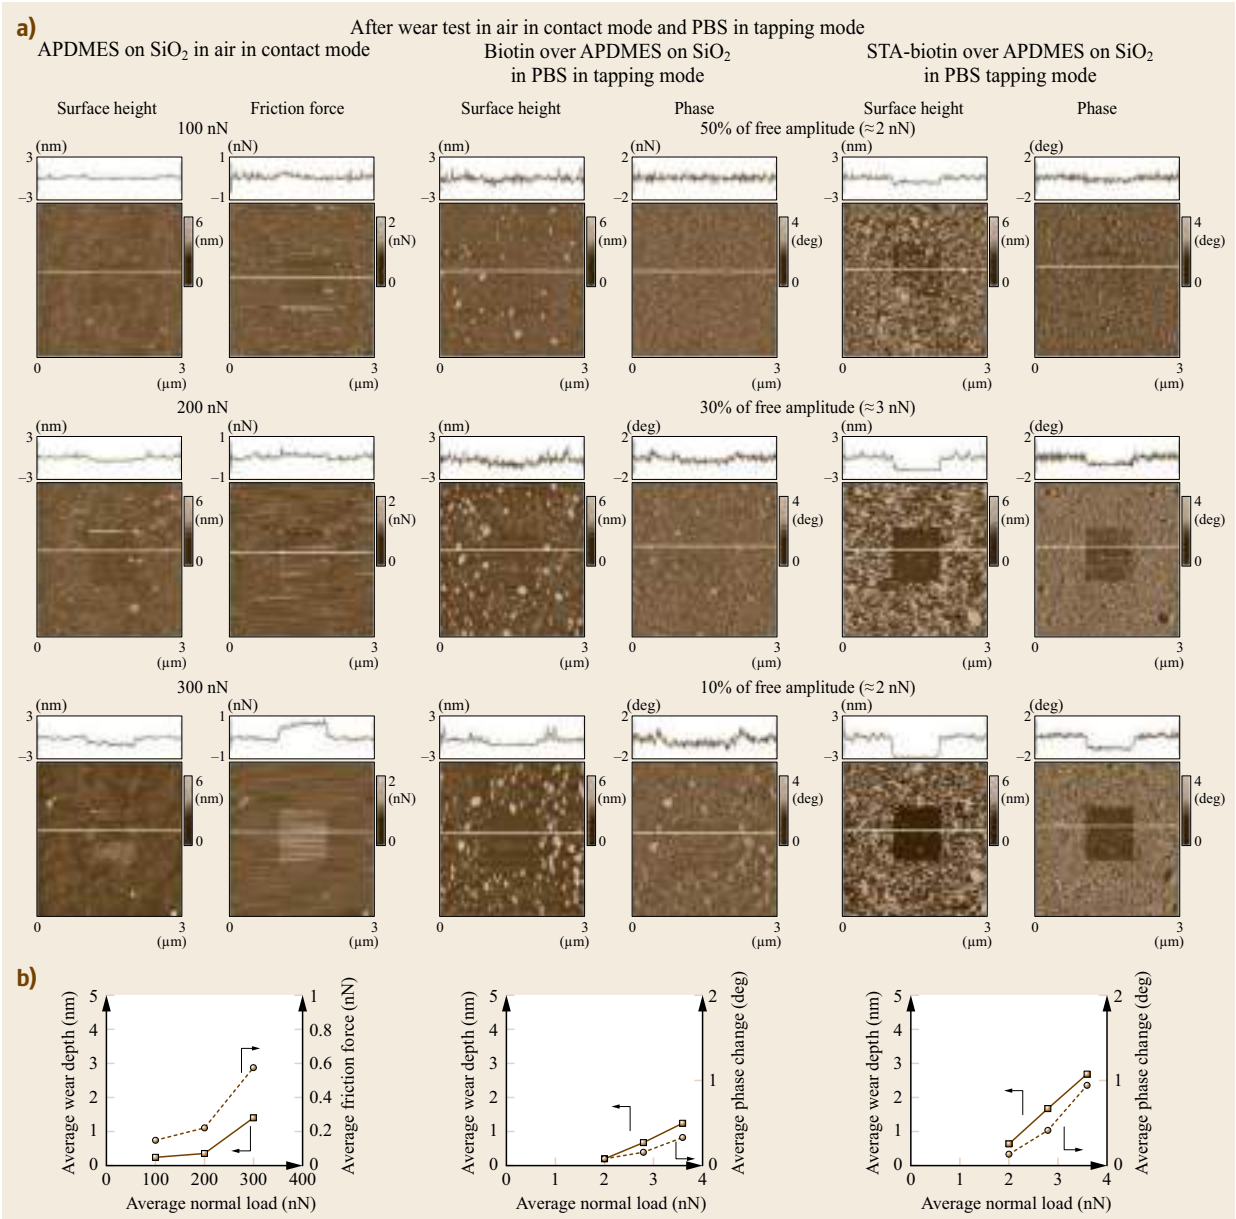

Fig. 22.15a,b Differential wear of interfacial polymer–protein films by AFM operated in tapping mode. **(a)** AFM surface height and friction force/phase angle images and cross-sectional profiles obtained after wear testing in air in contact mode/phosphate buffered saline (PBS) in tapping mode at a range of normal loads and free amplitudes, and **(b)** plot of average wear depth and average friction force/phase angle as a function of average normal load, for APDMES on silicon/SiO_2, biotin over APDMES on silicon/SiO_2, and on STA–biotin on APDMES and silicon/SiO_2 (after [22.103])

required only nanonewton forces to remove them from the surfaces.

It can reasonably be expected that unprotected immunoFET sensors in vivo will experience at least nanonewton abrasive forces. Such forces are likely to be sufficient to strip receptor layers from the immunoFET, and thereby cause sensor failure. This implies that the sensor polymer–receptor interfaces must either be hardened somehow to resist encountered abrasive insult, or that the sensor interfaces must be sheltered from direct, abrasive insult by tissue. This problem is not satisfactorily solved, but is currently under inves-

tigation. However, the point remains that the primacy of the importance of the immunoFET interface drove surface-science and nanotribological study of the interface. As a consequence, we documented properties new to nanoscale tribology of protein interfaces (lubricating and cushioning effects). Nanotribological characterization of models of immunoFET surfaces also revealed another nanoscale parameter that must be addressed before the immunoFETs can be deployed in in vivo clinical or research applications: the robustness to mechanical insult (or lack thereof) of FET receptor layers.

22.4 Concluding Remarks: Barriers to Practice

The effort to produce nanotherapeutic devices is highly interdisciplinary, with a sweep of knowledge that is difficult for any one investigator to master fully. The effort required constitutes a major barrier to entry to the field. Previous versions of this chapter ended with a discussion of the complexity of biology (being much greater than encountered in traditional engineering disciplines), the fashion in which biologists prioritize information, and cultural differences between engineers and biological scientists [22.107]. The chapter discussed some of the ways in which biologists and engineers hold and disseminate information (approaches so vastly different as to interfere with design of nanobiological devices). It also discussed the (then largely unmet) need for significant biological education for biomedical engineers, at least those who will be involved in producing devices that interact with living systems in vivo, or contain components derived from living systems. The consensus regarding the need for biologic training for biomedical engineers appears to be shifting in favor of more biology, in no small part as a result of the increasing prevalence of biologic components in biomedical nano- and microdevices and attempts to transfer those technologies to the clinic. However, there are still conundrums related to how biomedical and other engineers see themselves and see biology that result in lost opportunities.

22.4.1 You Do Not Know What You Do Not Know: The Consequences of Certainty

As discussed above, planar immunoFETs and similar bioFETs operating at physiological salt concentrations were regarded as infeasible from 1991 up until recently [22.81–84, 86]. However, there are now examples of such planar FET protein sensors that can detect protein analytes in physiological buffers at analyte concentrations known to occur in vivo [22.90, 91]. While this might seem to be a breakthrough in sensing technology, this development was delayed for years longer than it needed to be by the intransigent adherence of biosensor specialists to a flawed assessment of feasibility [22.81–84, 86].

The irony was that, with the right FET platform, planar FET sensing of proteins in physiological buffers has always been possible. The sensing community could have discovered this fact 20 years ago, and potentially could have moved to making functional immunoFET sensors for clinical use at that time, but for stubborn adherence to a flawed model of planar immunoFET interface structure. Until as little as a year ago, funding agencies and journals responded to applications or papers discussing planar FETs for protein sensing at physiological salt concentrations as if the documents reflected the proposer's or author's naivete. The direct response was often that the issue of planar FET sensors had been dealt with since 1991, and did not warrant further consideration. This response might have made sense had the classical assessment been theoretically sound, or if it were unsound in some way that required research to discover. However, the assessment was unsound from its first enunciation, largely because it did not take into account knowledge about protein and antibody structure that was available long before 1991. In the original proposal of the assessment, this may have been a result of the (then) poorly appreciated interdisciplinary nature of biosensor technology, or naivete regarding antibody structures and properties.

The classical assessment was promulgated by electrical engineers who had little knowledge of antibody structure, so they made mistakes in aspects of the assessment dependent on understanding antibodies. In its general form, this problem is a pitfall to which all interdisciplinary scientists are vulnerable. By definition, one cannot know what one does not know, and to some extent ignorance must be forgiven, as it is the default human condition. However, it should not have taken a working planar bioFET to overturn the classical assessment. The classical assessment was *dead on arrival*. Immunologists knew on cursory inspection that the classical assessment was nearly without relevance to real protein sensing. Unfortunately, engineers did not. In many cases, they failed to reexamine the assumptions of the classical assessment, in favor of reiterating its conclusion. If anything was done improperly, it was in failing to consider reasoned discussion of the flaws

in the assessment (as above). Doing so may have cost the sensor field 20 years.

This is mentioned without the intent to embarrass persons who proposed or adhered to the classical assessment, but rather to point out that dogmatic certainty has consequences. Error is an ongoing hazard in any interdisciplinary field. As biomedical nanotechnologists, we mention this story with trepidation for our own pronouncements.

22.4.2 Are Proteins and Molecules Legitimately Part of Nanotechnology?

There is a school of thought that holds that nanotechnology deals solely with quantum and other phenomena that manifest only when matter is subdivided into nanoscale particles or structures. This reasoning would exclude supramolecular chemistry depending on organic molecules and devices built from protein or nucleic acid functional components from nanotechnology. If this reasoning is accepted as valid, nanotechnology so defined may have little intersection with human health.

As the reader might assume, such reasoning does not appeal to us. We hope we have presented a compelling case that molecules are essential components of nanotherapeutics. Organic or biologic macromolecules (proteins, nucleic acids, etc.) are necessary for many interactions between living things and therapeutic devices. In part, this is because these molecules are dimensionally and chemically appropriate to interact with the biocomponent of the patient (i. e., the argument of *speaking* to the patient's body in a language it understands). Also, synthetic nanostructures with the precise chemical and topological complexity of biological macromolecules cannot yet be produced or tuned with the same efficacy as biotechnology produces and tunes the properties of proteins (i. e., the argument that biomolecules are the only show in town). Moreover, with the examples of the FET protein sensor and the IKVAV PA amphiphile, we have shown that biotechnology and organic chemistry (respectively) can be used to address problems occurring at the nanoscale. In this sense, they fall reasonably under the rubric of nanotechnology.

The molecular nanocomponents of the immunoFET and IKVAV PA are tuned to suit (at least partially) using systematic knowledge of nanocomponent properties. It is our opinion that engineering is any activity that uses knowledge of component properties to control the behavior of materials and devices containing those components to achieve a desired end. In the case of the biological molecules with which we work, knowledge of properties is frequently fragmentary, limiting our ability to design individual protein molecules de novo, and driving us to use molecular genetic screening techniques to identify variant proteins with desired properties. Nonetheless, we see ourselves as engineers because we use knowledge of our materials (proteins) to its limits to optimize functional devices (immunoFETs, magnetic resonance imaging (MRI) contrast agents). In the future, protein structure is likely to become more amenable to quantitative modeling and design, and the inclusion of protein engineering as a genuine engineering discipline will become less controversial.

At any rate, fortunately for us, and for biomedical nanotechnologists, the restrictive view of the definition of nanotechnology and engineering is less widely held than in the past. These fields will likely become increasingly welcoming to biologists as time passes.

Acknowledgments. The authors acknowledge the contribution to the chapter by Philip D. Barnes. This work was supported in part by grants from the Program for Homeland Security of the Ohio State University (program no. 14 525) and award GRT00011123 (project no. 60 015 533) to S.C.L. from the National Science Foundation.

23. Scanning Probe Microscopy – Principle of Operation, Instrumentation and Probes

Bharat Bhushan, Othmar Marti

Since the introduction of the Scanning Tunneling Microscope (STM) in 1981 and Atomic Force Microscope (AFM) in 1985, many variations of probe-based microscopies, referred to as Scanning Probe Microscopes (SPM), have been developed. While the pure imaging capabilities of SPM techniques are dominated by the application of these methods at their early development stages, the physics of probe-sample interactions and the quantitative analyses of tribological, electronic, magnetic, biological, and chemical surfaces have now become of increasing interest. In this chapter, we introduce various STM and AFM designs, various operating modes, various probes (tips), and AFM instrumentation and analyses.

The scanning tunneling microscope (STM) developed by Dr. Gerd Binnig and his colleagues in 1981 at the IBM Zurich Research Laboratory, Rueschlikon, Switzerland, was the first instrument capable of directly obtaining three-dimensional (3-D) images of solid surfaces with atomic resolution [23.1]. G. Binnig and H. Rohrer received a Nobel Prize in Physics in 1986 for their discovery. STMs can only be used to study surfaces that are electrically conductive to some degree. On the basis of their STM design, in 1985 *Binnig* et al. developed an atomic force microscope (AFM) to measure ultrasmall forces (less than 1 μN) present between the AFM tip surface and the sample surface [23.2] (also see [23.3]). AFMs can be used for measurement of all engineering surfaces that may be either electrically conductive or insulating. AFM has become a popular surface profiler for topographic and normal force measurements on the micro- to nanoscale.

AFMs have been modified in order to measure both normal and lateral forces, and are called lateral force microscopes (LFMs) or friction force microscopes (FFMs) [23.4–11]. FFMs have been further modified to measure lateral forces in two orthogonal directions [23.12–16]. A number of researchers have continued to improve the AFM/FFM designs and used them to measure adhesion and friction of solid and liquid surfaces on micro- and nanoscales [23.9–11, 17–33]. AFMs have been used for scratching, wear, and measurements of elastic/plastic mechanical properties (such as indentation hardness and modulus of elasticity) [23.9–11, 21, 23, 26–32, 34–45].

AFMs have been used for manipulation of individual atoms of Xenon [23.46], molecules [23.47], silicon surfaces [23.48], and polymer surfaces [23.49]. STMs have been used for formation of nanofeatures by local-

ized heating or by inducing chemical reactions under the STM tip [23.50–52] and nanomachining [23.53]. AFMs have been used for nanofabrication [23.10, 36, 54–56] and nanomachining [23.57].

STMs and AFMs are used at extreme magnifications ranging from 10^3 to $10^9\times$ in x-, y-, and z-directions for imaging macro to atomic dimensions with high resolution information and for spectroscopy. These instruments can be used in any environment including ambient air [23.2, 58], various gases [23.17], liquid [23.59–61], vacuum [23.1, 62], low temperatures (lower than about 100 K) [23.63–67], and high temperatures [23.68, 69]. Imaging in liquid allows the study of live biological samples and also eliminates water capillary forces present in ambient air located at the tip-sample interface. Low-temperature (liquid helium temperatures) imaging is useful for the study of biological and organic materials and the study of low-temperature phenomena such as superconductivity or charge-density waves. Low-temperature operation is also advantageous for high-sensitivity force mapping due to the reduction in thermal vibration. STMs and AFMs have also been used to image liquids such as liquid crystals and lubricant molecules on graphite surfaces [23.70–73].

The pure imaging capabilities of variations of probe-based microscope techniques, referred to as scanning probe microscopy (SPM), have dominated the application of these methods at their early development stages. However, the physics and chemistry of probe-sample interactions and the quantitative analyses of tribological, electronic, magnetic, biological, and chemical surfaces have now become of increasing interest. Nanoscale science and technology are strongly driven by SPMs, which allow investigation and manipulation of surfaces down to the atomic scale. With growing understanding of the underlying interaction mechanisms, SPMs have found application in many fields outside basic research fields. In addition, various derivatives of all these methods have been developed for special applications, some of them targeting far beyond microscopy.

A family of instruments based on STMs and AFMs, SPMs have been developed for various applications of scientific and industrial interest. These include STM, AFM, FFM (or LFM), scanning electrostatic force microscopy (SEFM) [23.74, 75], scanning force acoustic microscopy (SFAM) (or atomic force acoustic microscopy (AFAM)) [23.21, 22, 42, 45, 76–78], scanning magnetic microscopy (SMM) (or magnetic force microscopy (MFM)) [23.79–83], scanning near-field optical microscopy (SNOM) [23.84–87], scanning thermal microscopy (SThM) [23.88–90], scanning electrochemical microscopy (SEcM) [23.91], scanning Kelvin Probe microscopy (SKPM) [23.92–96], scanning chemical potential microscopy (SCPM) [23.89], scanning ion conductance microscopy (SICM) [23.97, 98], and scanning capacitance microscopy (SCM) [23.92, 99–101]. The subfamily of instruments that measure forces (e.g., AFM, FFM, SEFM, SFAM, and SMM) are also referred to as scanning force microscopes (SFM). Although these instruments offer atomic resolution and are ideal for basic research, they are most often used for cutting-edge industrial applications that do not require atomic resolution.

Commercial production of SPMs started with STM in 1987 and AFM in 1989 by Digital Instruments, Inc. (now Bruker Instruments, Inc.). For comparisons of SPMs with other microscopies including Transmission Electron Microscopy (TEM) and Scanning Electron Microscopy (SEM), see Table. 23.1 (Bruker Instruments, Inc.). Numbers of these instruments are equally divided into US, Japan, and Europe with industry/university and government lab splits of about 50/50, 70/30, and 30/70, respectively. It is clear that research and industrial applications of SPMs are rapidly expanding. For various examples, see [23.11, 102–110].

This chapter presents an overview of STM and AFM with various operating modes and various probes (tips) used in these instruments. Thereafter, details on AFM instrumentation and analyses are given.

Table 23.1 Comparison of various conventional microscopes with SPMs in 2015

23.1 Scanning Tunneling Microscope

The principle of electron tunneling was proposed by *Giaever* [23.111]. He proposed that if an electrical potential difference is applied to two metals separated by a thin insulating film, a current will flow across the barrier because of the ability of electrons to penetrate it. To be able to measure this tunneling current, the two metals must be spaced no more than 10 nm apart. *Binnig* et al. [23.1] introduced vacuum tunneling combined with lateral scanning. The vacuum provides the ideal barrier for tunneling. The lateral scanning allows surface imaging with exquisite resolution – laterally less than 1 nm and vertically less than 0.1 nm – sufficient to define the position of single atoms. The very high vertical resolution is obtained because the tunneling current varies exponentially with the distance between the metal tip and the scanned surface acting as two electrodes. Typically, tunneling current decreases by a factor of 2 as the separation is increased by 0.2 nm. Very high lateral resolution depends upon sharp tips. *Binnig* et al. [23.1] overcame two key obstacles in regard to damping external vibrations and moving the tunneling probe into close proximity to the sample. Their instrument is called the scanning tunneling microscope (STM). Today's STMs can be used in the ambient environment for atomic-scale imaging of surfaces. Excellent reviews on this subject are presented by *Hansma* and *Tersoff* [23.112], *Sarid* and *Elings* [23.113], *Durig* et al. [23.114], *Frommer* [23.115], *Güntherodt* and *Wiesendanger* [23.116], *Wiesendanger* and *Güntherodt* [23.117], *Bonnell* [23.118], *Marti* and *Amrein* [23.119], *Stroscio* and *Kaiser* [23.120], and *Güntherodt* et al. [23.121].

The principle of the STM is straightforward. A sharp metal tip (one electrode of the tunnel junction) is brought close enough (0.3−1 nm) to the surface to be investigated (second electrode) so that, at a convenient operating voltage (10 mV–1 V), the tunneling current varies from 0.2 to 10 nA, which is measurable. The tip is scanned over a surface at a distance of 0.3−1 nm, while the tunneling current between it and the surface is sensed. The STM can be operated in either the constant current mode or the constant height mode, Fig. 23.1. The left-hand column of Fig. 23.1 shows the basic constant current mode of operation. A feedback network changes the height of the tip z to keep the current constant. The displacement of the tip given by the voltage applied to the piezoelectric drives then yields a topographic map of the surface. Alternatively, in the constant height mode, a metal tip can be scanned across a surface at nearly constant height and constant voltage while the current is monitored, as shown in the right-hand column of Fig. 23.1. In this case, the feedback network responds only rapidly enough to keep the average current constant. The constant current mode is used generally for atomic-scale images. This mode is not practical for rough surfaces. A three-dimensional picture $z(x, y)$ of a surface consists of multiple scans $z(x)$ displayed laterally from each other in the y-direction. It should be noted that if different atomic species are present in a sample, the different atomic species may produce different tunneling currents for a given bias voltage. Thus, the height data may not be a direct representation of the topography of the surface of the sample.

23.1.1 The STM Design of Binnig et al.

Figure 23.2 shows a schematic of one of *Binnig* and *Rohrer*'s designs for operation in ultrahigh vacuum [23.1, 122]. The metal tip was fixed to rectangular piezodrives P_x, P_y, and P_z made out of commercial piezoceramic material for scanning. The sample is mounted on either a superconducting magnetic levitation or a two-stage spring system to achieve a stability of the gap width of about 0.02 nm. The tunnel current J_T is a sensitive function of the gap width d that is

$$J_T \propto V_T \exp(-A\phi^{1/2}d) ,$$

where V_T is the bias voltage, ϕ is the average barrier height (work function), and the constant $A = 1.025\,\mathrm{eV}^{-\frac{1}{2}}\,\mathrm{Å}^{-1}$. With a work function of a few eV, J_T

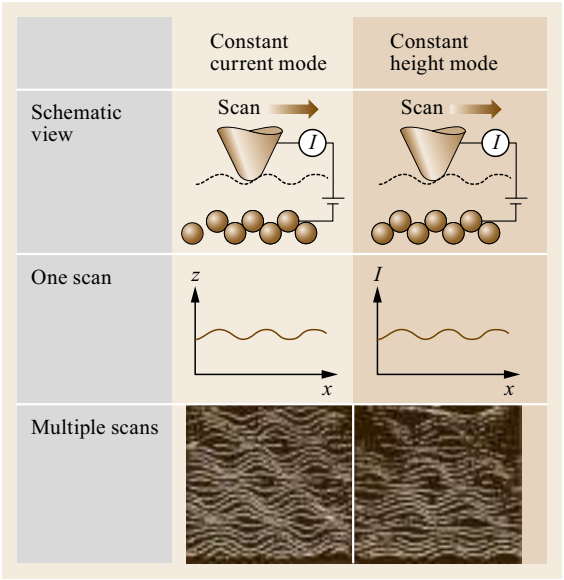

Fig. 23.1 STM can be operated in either the constant current or constant height mode. The *images* are of graphite in air [23.112]

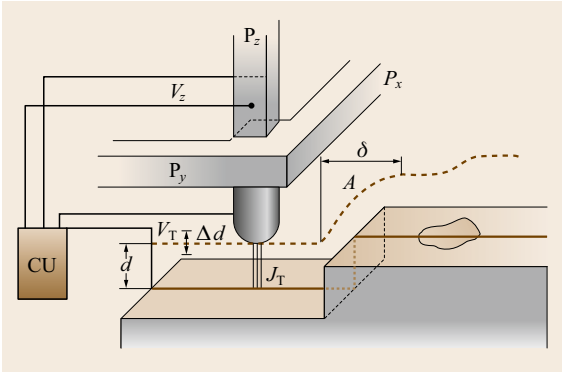

Fig. 23.2 Principle of operation of the STM made by *Binnig* and *Rohrer* [23.122]

changes by an order of magnitude for every angstrom change of d. If the current is kept constant to within, for example, 2%, then the gap d remains constant to within 1 pm. For operation in the constant current mode, the control unit (CU) applies a voltage V_z to the piezo P_z such that J_T remains constant when scanning the tip with P_y and P_x over the surface. At a constant work function ϕ, $V_z(V_x, V_y)$ yields the roughness of the surface $z(x, y)$ directly, as illustrated at a surface step at A. Smearing the step, δ (lateral resolution) is on the order of $(R)^{1/2}$, where R is the radius of curvature of the tip. Thus, a lateral resolution of about 2 nm requires tip radii of the order of 10 nm. A 1 mm diameter solid rod ground at one end at roughly 90° yields overall tip radii of only a few hundred nm, but with closest protrusion of rather sharp microtips on the relatively dull end yields a lateral resolution of about 2 nm. In situ sharpening of the tips by gently touching the surface brings the resolution down to the 1 nm range by applying high fields (on the order of 10^8 V/cm). For example, resolutions considerably below 1 nm were achieved by applying a high field for half an hour. Most experiments were carried out with tungsten wires, either ground or etched to a radius typically in the range of 0.1–10 µm. In some cases, in situ processing of the tips was carried out for further reduction of tip radii.

23.1.2 Commercial STMs

There are a number of commercial STMs available on the market. In 1987, Digital Instruments, Inc. (now Bruker Instruments) located in Santa Barbara, CA, introduced the first commercial STM, the Nanoscope I. In a later model, the Nanoscope IV STM for operation in ambient air, the sample is held in position while a piezoelectric crystal in the form of a cylindrical tube (referred to as a PZT (lead zirconate titanate) tube scanner) scans the sharp metallic probe over the surface in a raster pattern while sensing and outputting the tunneling current to the control station, Fig. 23.3. The digital signal processor (DSP) calculates the desired separation of the tip from the sample by sensing the tunneling current flowing between the sample and the tip. The bias voltage applied between the sample and the tip encourages the tunneling current to flow. The DSP completes the digital feedback loop by outputting the desired voltage to the piezoelectric tube. The STM operates in both the *constant height* and *constant current* modes depending on a parameter selection in the control panel. In the constant current mode, the feedback gains are set high, the tunneling tip closely tracks the sample surface, and the variation in the tip height required to maintain constant tunneling current is measured by the change in the voltage applied to the piezo tube. In the constant height mode, the feedback gains are set low, the tip remains at a nearly constant height as it sweeps over the sample surface, and the tunneling current is imaged.

Physically, the Nanoscope STM consists of three main parts: the head, which houses the piezoelectric tube scanner for three-dimensional motion of the tip and the preamplifier circuit (FET input amplifier) mounted on top of the head for the tunneling current; the base on which the sample is mounted; and the base support, which supports the base and head [23.10]. The base accommodates samples up to 10 mm by 20 mm and 10 mm in thickness. Scan sizes available for the STM are 0.7 µm (for atomic resolution), 12 µm, 75 µm and 125 µm square.

The scanning head controls the three-dimensional motion of the tip. The removable head consists of a piezo tube scanner, about 12.7 mm in diameter, mounted into an Invar shell used to minimize vertical thermal drifts because of good thermal match between the piezo tube and the Invar. The piezo tube has separate electrodes for x, y, and z which are driven by separate

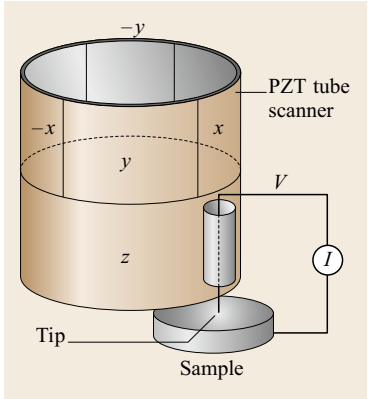

Fig. 23.3 Principle of operation of a commercial STM, a sharp tip attached to a piezoelectric tube scanner is scanned on a sample

drive circuits. The electrode configuration (Fig. 23.3) provides x and y motions which are perpendicular to each other, minimizes horizontal and vertical coupling, and provides good sensitivity. The vertical motion of the tube is controlled by the z electrode which is driven by the feedback loop. The x and y scanning motions are each controlled by two electrodes, which are driven by voltages of the same magnitudes, but opposite signs. These electrodes are called $-y$, $-x$, $+y$, and $+x$. Applying complimentary voltages allows a short, stiff tube to provide a good scan range without large voltages. The motion of the tip due to external vibrations is proportional to the square of the ratio of vibration frequency to the resonant frequency of the tube. Therefore, to minimize the tip vibrations, the resonant frequencies of the tube are high, about 60 kHz in the vertical direction and about 40 kHz in the horizontal direction. The tip holder is a stainless steel tube with a 300 μm inner diameter for 250 μm diameter tips, mounted in ceramic in order to keep the mass on the end of the tube low. The tip is mounted either on the front edge of the tube (to keep mounting mass low and resonant frequency high) (Fig. 23.3) or the center of the tube for large-range scanners, namely 75 and 125 μm (to preserve the symmetry of the scanning). This commercial STM accepts any tip with a 250 μm diameter shaft. The piezo tube requires x–y calibration which is carried out by imaging an appropriate calibration standard. Cleaved graphite is used for the small-scan length head while two-dimensional grids (a gold-plated rule) can be used for longer range heads.

The Invar base holds the sample in position, supports the head, and provides coarse x–y motion for the sample. A spring-steel sample clip with two thumb screws holds the sample in place. An x–y translation stage built into the base allows the sample to be repositioned under the tip. Three precision screws arranged in a triangular pattern support the head and provide coarse and fine adjustment of the tip height. The base support consists of the base support ring and the motor housing. The stepper motor enclosed in the motor housing allows the tip to be engaged and withdrawn from the surface automatically.

Samples to be imaged with STM must be conductive enough to allow a few nanoamperes of current to flow from the bias voltage source to the area to be scanned. In many cases, nonconductive samples can be coated with a thin layer of a conductive material to facilitate imaging. The bias voltage and the tunneling current depend on the sample. Usually they are set at a standard value for engagement and fine-tuned to enhance the quality of the image. The scan size depends on the sample and the features of interest. A maximum scan rate of 122 Hz can be used. The maximum scan rate is usually related to the scan size. A scan rate above 10 Hz is used for small scans (typically 60 Hz for atomic-scale imaging with a 0.7 μm scanner). The scan rate should be lowered for large scans, especially if the sample surfaces are rough or contain large steps. Moving the tip quickly along the sample surface at high scan rates with large scan sizes will usually lead to a tip crash. Essentially, the scan rate should be inversely proportional to the scan size (typically 2–4 Hz for 1 μm, 0.5–1 Hz for 12 μm, and 0.2 Hz for 125 μm scan sizes). Scan rate in length/time, is equal to scan length divided by the scan rate in Hz. For example, for 10 μm × 10 μm scan size scanned at 0.5 Hz, the scan rate is 10 μm/s. Typically, 256 × 256 data formats are most commonly used. The lateral resolution at larger scans is approximately equal to scan length divided by 256.

Figure 23.4 shows an example of STM images of an evaporated C_{60} film on gold-coated freshly cleaved mica taken at room temperature and ambient pres-

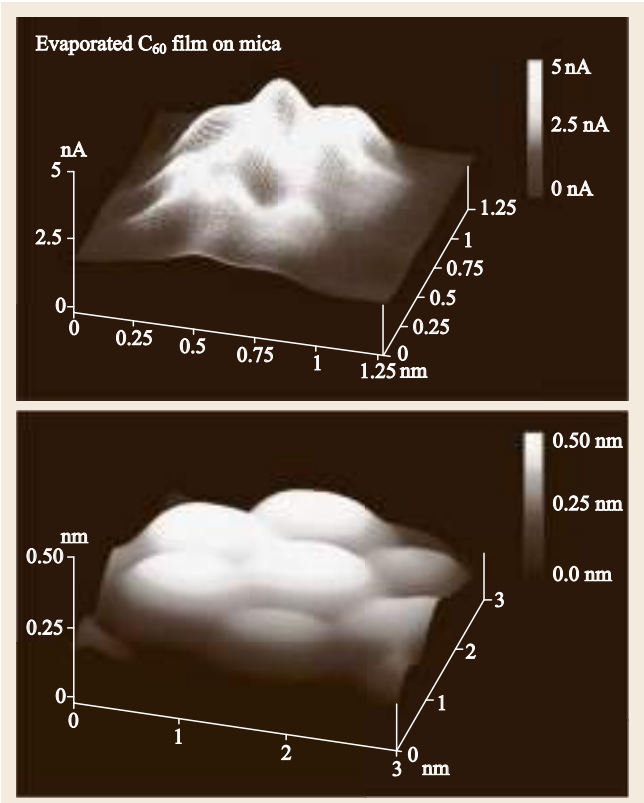

Fig. 23.4 STM images of evaporated C_{60} film on a gold-coated freshly cleaved mica using a mechanically sheared Pt-Ir (80/20) tip in constant height mode (after [23.123])

sure [23.123]. Images with atomic resolution at two scan sizes are obtained. Next, we describe STM designs that are available for special applications.

Electrochemical STM

Electrochemical STM is used to perform and monitor the electrochemical reactions inside the STM. It includes a microscope base with an integral potentiostat, a short head with a 0.7 μm scan range and a differential preamp and the software required to operate the potentiostat and display the result of the electrochemical reaction.

Standalone STM

Standalone STMs, which rest directly on the sample, are able to scan large samples. They are similar to the standard STM, except the sample base has been eliminated.

23.1.3 STM Probe Construction

The STM probe should have a cantilever integrated with a sharp metal tip with a low aspect ratio (tip length/tip shank) to minimize flexural vibrations. Ideally, the tip should be atomically sharp, but in practice, most tip preparation methods produce a tip with a rather ragged profile and that consists of several asperities with the one closest to the surface responsible for tunneling. STM cantilevers with sharp tips are typically fabricated from metal wires of tungsten (W), platinum-iridium (Pt-Ir), or gold (Au) and sharpened by grinding, cutting with a wire cutter or razor blade, field emission/evaporator, ion milling, fracture, or electrochemical polishing/etching [23.124, 125]. The two most commonly used tips are made from either a Pt-Ir (80/20) alloy or tungsten wire. Iridium is used to provide stiffness. The Pt-Ir tips are generally mechanically formed and are readily available. The tungsten tips are etched from tungsten wire with an electrochemical process, for example by using 1 molar KOH solution with a platinum electrode in an electrochemical cell at about 30 V. In general, Pt-Ir tips provide better atomic resolution than tungsten tips, probably due to the lower reactivity of Pt. But tungsten tips are more uniformly shaped and may perform better on samples with steeply sloped features. The tungsten wire diameter used for the cantilever is typically 250 μm with the radius of curvature ranging from 20 to 100 nm and a cone angle ranging from 10 to 60°, Fig. 23.5. The wire can be bent in an L shape, if required for use in the instrument. For calculations of normal spring constant and natural frequency of round cantilevers, see [23.113].

For imaging of deep trenches, high-aspect-ratio controlled geometry (CG) Pt-Ir probes are used, Fig. 23.6. These probes are electrochemically etched from Pt-Ir (80/20) wire and polished to a specific shape which is consistent from tip to tip. Probes have a full cone angle of approximately 15° and a tip radius of less than 50 nm. For imaging of very deep trenches (> 0.25 μm) and nanofeatures, focused ion beam (FIB)-milled CG probes with an extremely sharp tip (radius < 5 nm) are used. For electrochemistry, Pt-Ir probes are coated with a nonconducting film (not shown in the figure).

Pt alloy and W tips are very sharp and have high resolution, but are fragile and sometimes break when contacting a surface. Diamond tips have been used by *Kaneko* and *Oguchi* [23.126]. The diamond tip made conductive by boron ion implantation is found to be chip resistant.

23.2 Atomic Force Microscope

Like the STM, AFM relies on a scanning technique to produce very high resolution, 3-D images of sample surfaces. AFM measures ultrasmall forces (less than 1 nN) present between the AFM tip surface and a sample surface. These small forces are measured by measuring the motion of a very flexible cantilever beam having an ultrasmall mass. While STM requires that the surface to be measured be electrically conductive, AFM is capable of investigating surfaces of both conductors and insulators on an atomic scale if suitable techniques for measurement of cantilever motion are used. In the operation of high-resolution AFM, the sample is generally scanned, rather than the tip as in STM, because AFM measures the relative displacement between the cantilever surface and reference surface, and any cantilever movement would add vibrations. For measurements of large samples, AFMs are available where the tip is scanned and the sample is stationary. As long as the AFM is operated in the so-called contact mode, little if any vibration is introduced.

The AFM combines the principles of the STM and the stylus profiler, Fig. 23.7. In an AFM, the force between the sample and tip is detected rather than the tunneling current to sense the proximity of the tip to the sample. The AFM can be used either in static or dynamic mode. In the static mode, also referred to as repulsive mode or contact mode [23.2], a sharp tip at the end of a cantilever is brought in contact with a sample surface. During initial contact, the atoms at the end of the tip experience a very weak repulsive force due to electronic orbital overlap with the atoms in the sample surface. The force acting on the tip causes a cantilever deflection which is measured by tunneling, capacitive, or optical detectors. The deflection can be measured to within 0.02 nm, so for a typical cantilever spring constant of 10 N/m a force as low as 0.2 nN (corresponding normal pressure $\approx$ 200 MPa for a Si_3N_4 tip with radius of about 50 nm against single-crystal silicon) can be detected. (To put these numbers in perspective, individual atoms and human hair are typically a fraction of a nanometer and about 75 μm in diameter, respectively, and an eyelash and a drop of water have a mass of about 100 nN and 10 μN, respectively.)

In the dynamic mode of operation for the AFM, also referred to as attractive force imaging or noncontact imaging mode (noncontact-AFM or nc-AFM operation), the tip is brought in close proximity (within a few nm) to, and not in contact with the sample [23.127, 128]. The cantilever is deliberately vibrated either in amplitude modulation (AM) mode [23.74] or frequency modulation (FM) mode [23.74, 113, 129, 130]. Very weak van der Waals attractive forces are present at the tip-sample interface. In this technique, the normal pressure exerted at the interface is close to zero (desirable to avoid any surface deformation). In the two modes, surface topography is measured by laterally scanning the sample under the tip while simultaneously measuring the separation-dependent force or force gradient (derivative) between the tip and the surface, Fig. 23.7.

In the contact (static) mode, the interaction force between tip and sample is measured by measuring the cantilever deflection. In the noncontact (or dynamic) mode, the force gradient is obtained by vibrating the cantilever and measuring the shift of resonant frequency of the cantilever. To obtain topographic information, the interaction force is either recorded directly, or used as a control parameter for a feedback circuit that maintains the force or force derivative at a constant value. With an AFM operated in the contact mode, topographic images with a vertical resolution of less than 0.1 nm (as low as 0.01 nm) and a lateral resolution of about 0.2 nm have been obtained [23.3, 59, 131–135]. With a 0.01 nm displacement sensitivity, 10 nN to 1 pN forces are measurable. These forces are comparable to the forces associated with chemical bonding, e.g., 0.1 μN for an ionic bond and 10 pN for a hydrogen bond [23.2]. For further reading, see [23.113–115, 119, 121, 136–140].

Lateral forces being applied at the tip during scanning in the contact mode affect roughness measurements [23.141]. To minimize the effects of friction and other lateral forces in the topography measurements in contact-mode AFMs and to measure topography of soft surfaces, AFMs can be operated in the so-called tapping mode or amplitude modulation mode [23.35, 142].

STM is ideal for atomic-scale imaging. To obtain atomic resolution with AFM, the spring constant of the cantilever should be weaker than the equivalent spring

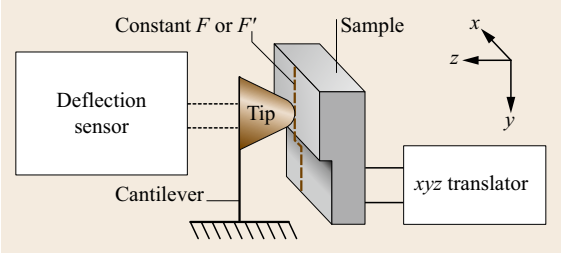

Fig. 23.7 Principle of operation of the AFM. Sample mounted on a piezoelectric scanner is scanned against a short tip and the cantilever deflection is measured, mostly, using a laser deflection technique. Force (contact mode) or force gradient (noncontact mode) is measured during scanning

between atoms. For example, the vibration frequencies ω of atoms bound in a molecule or in a crystalline solid are typically 10^{13} Hz or higher. Combining this with the mass of the atoms m, on the order of 10^{-25} kg, gives interatomic spring constants k, given by $\omega^2 m$, on the order of 10 N/m [23.136]. (For comparison, the spring constant of a piece of household aluminum foil that is 4 mm long and 1 mm wide is about 1 N/m.) Therefore, a cantilever beam with a spring constant of about 1 N/m or lower is desirable. Tips have to be as sharp as possible. Tips with a radius ranging from 20 to 50 nm are commonly available.

Atomic resolution cannot be achieved with these tips at the normal load in the nN range. Atomic structures at these loads have been obtained from lattice imaging or by imaging of the crystal periodicity. Reported data show either perfectly ordered periodic atomic structures or defects on a larger lateral scale, but no well-defined, laterally resolved, atomic-scale defects like those seen in images routinely obtained with STM. Interatomic forces with one or several atoms in contact are 20–40 or 50–100 pN, respectively. Thus, atomic resolution with AFM is only possible with a sharp tip on a flexible cantilever at a net repulsive force of 100 pN or lower [23.143]. Upon increasing the force from 10 pN, *Ohnesorge* and *Binnig* [23.143] observed that monoatomic steplines were slowly wiped away and a perfectly ordered structure was left. This observation explains why mostly defect-free atomic resolution has been observed with AFM. Note that for atomic-resolution measurements, the cantilever should not be too soft to avoid jumps, and also that measurements in the noncontact imaging mode may be desirable for imaging with atomic resolution.

The key component in AFM is the sensor for measuring the force on the tip due to its interaction with the sample. A cantilever (with a sharp tip) with extremely low spring constants is required for high vertical and lateral resolutions at small forces (0.1 nN or lower), but at the same time, a high resonant frequency (about 10–100 kHz) is necessary in order to minimize the sensitivity to vibration noise from the building in which the AFM is located close to 100 Hz. This requires a spring with extremely low vertical spring constant (typically 0.05–1 N/m) as well as low mass (on the order of 1 ng). Today, the most advanced AFM cantilevers are microfabricated from silicon or silicon nitride using photolithographic techniques. (For further details on cantilevers, see a later section). Typical lateral dimensions are on the order of 100 µm, with thicknesses on the order of 1 µm. The force on the tip due to its interaction with the sample is sensed by detecting the deflection of the compliant lever with a known spring constant. This cantilever deflection (displacement smaller than 0.1 nm) has been measured by detecting tunneling current similar to that used in STM in the pioneering work of *Binnig* et al. [23.2] and later used by *Giessibl* et al. [23.65], by capacitance detection [23.144, 145], piezoresistive detection [23.146, 147], and by four optical techniques namely:

1. By optical interferometry [23.4, 5, 148, 149] and with the use of optical fibers [23.66, 150]
2. By optical polarization detection [23.81, 151]
3. By laser diode feedback [23.152]
4. By optical (laser) beam deflection [23.6, 7, 62, 132, 133].

Schematics of the four more commonly used detection systems are shown in Fig. 23.8. The tunneling method originally used by *Binnig* et al. [23.2] in the first version of the AFM uses a second tip to monitor the deflection of the cantilever with its force-sensing tip. Tunneling is rather sensitive to contaminants, and the interaction between the tunneling tip and the rear side of the cantilever can become comparable to the interaction between the tip and sample. Tunneling is rarely used and was mentioned earlier for historical purposes. *Giessibl* et al. [23.65] used it for a low-temperature AFM/STM design. In contrast to tunneling, other deflection sensors are far away from the cantilever at distances of microns to tens of mm. The optical detection methods are believed to be more sensitive, reliable, and easily implemented than other techniques [23.113, 139]. The optical beam deflection method has the largest working distance, is insensitive to distance changes, and is capable of measuring angular changes (friction forces). Therefore, it is the most commonly used method in commercial SPMs.

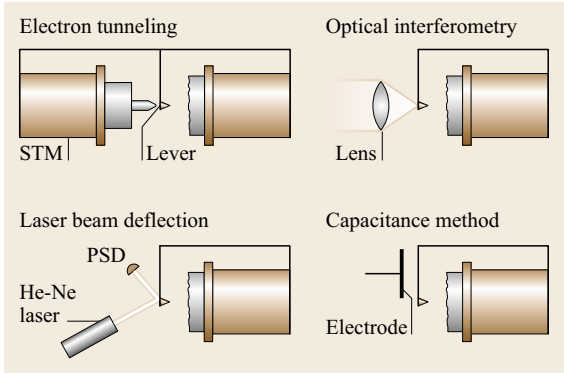

Fig. 23.8 Schematics of the four detection systems for measurement of cantilever deflection. In each set up, the sample mounted on the piezoelectric body is shown *on the right*, the cantilever *in the middle*, and the corresponding deflection sensor *on the left* (after [23.139])

Almost all SPMs use piezo translators to scan the sample or, alternatively, to scan the tip. An electric field applied across a piezoelectric material causes a change in the crystal structure, with expansion in some directions and contraction in others. A net change in volume also occurs [23.153]. The first STM used a piezo tripod for scanning [23.1]. The piezo tripod is one way to generate three-dimensional movement of a tip attached to its center. However, the tripod needs to be fairly large (≈ 50 mm) to get a suitable range. Its size and asymmetric shape makes it susceptible to thermal drift. Tube scanners are widely used in AFMs [23.154]. These provide ample scanning range within a small size. Control electronics systems for AFMs can use either analog or digital feedback. Digital feedback circuits are better suited for ultralow noise operation.

Images from AFMs need to be processed. An ideal AFM is a noise-free device that images a sample with perfect tips of known shape and has perfect linear scanning piezo. In reality, scanning devices are affected by distortions for which corrections must be made. The distortions can be linear and nonlinear. Linear distortions mainly result from imperfections in the machining of the piezo translators, causing cross talk from the z-piezo to the x- and y-piezos, and vice versa. Nonlinear distortions mainly result because of the presence of a hysteresis loop in piezoelectric ceramics. These may also result if the scan frequency approaches the upper frequency limit of the x- and y-drive amplifiers or the upper frequency limit of the feedback loop (z-component). In addition, electronic noise may be present in the system. The noise is removed by digital filtering in the real space [23.155] or in the spatial frequency domain (Fourier space) [23.156].

Processed data consists of many tens of thousands of points per plane (or data set). The output of the first STM and AFM images were recorded on an x–y chart recorder, with the z-value plotted against the tip position in the fast scan direction. Chart recorders have slow response so computers are used for display of the data. The data are displayed as a wire mesh display or a gray scale display (with at least 64 shades of gray).

23.2.1 The AFM Design of Binnig et al.

In the first AFM design developed by *Binnig* et al. [23.2], AFM images were obtained by measurement of the force on a sharp tip created by the proximity to the surface of the sample mounted on a 3-D piezoelectric scanner. Tunneling current between STM tip and the backside of the cantilever beam with attached tip was measured to obtain the normal force. This force was kept at a constant level with a feedback mechanism. The STM tip was also mounted on a piezoelectric element to maintain the tunneling current at a constant level.

23.2.2 Commercial AFM

A review of early AFM designs is presented by *Bhushan* [23.10]. There are a large number of commercial AFMs available on the market. Major manufacturers of AFMs for use in an ambient environment are: Bruker Instruments, Inc. (formerly Digital Instruments Inc. and later Veeco Instruments Inc.), Santa Barbara, California; Agilent Technologies, Santa Clara, California, Park Systems Corp., Suwon, Korea; Asylum Research, Santa Clara, California; NT-MDT Spectrum Instruments, Moscow, Russia; Nanosurf AF, Liestal, Switzerland; Seiko Instruments, Japan; and Olympus, Japan. A major manufacturer of AFM/STMs for use in UHV (ultra-high vacuum) and low-temperature (LT) environments is Scienta Omicron GMBH, Taunusstein, Germany.

We describe here two typical commercial AFMs – small-sample and large-sample AFMs – for operation in the contact mode, produced by Bruker Instruments, Santa Barbara, CA, with scanning lengths ranging from about 0.7 μm (for atomic resolution) to about 125 μm [23.8, 132, 135, 157]. The original design of these AFMs comes from [23.62]. Basically, the AFM scans the sample in a raster pattern while outputting the cantilever deflection error signal to the control station. The cantilever deflection (or the force) is measured using the laser deflection technique, Fig. 23.9. The DSP in the workstation controls the z-position of the piezo based on the cantilever deflection error signal. The AFM operates in both the *constant height* and *constant force* modes. The DSP always adjusts the height of the sample under the tip based on the cantilever deflection error signal, but if the feedback gains are low, the piezo remains at a nearly *constant height* and the cantilever deflection data is collected. With high gains, the piezo height changes to keep the cantilever deflection nearly constant (therefore the force is constant) and the change in piezo height is collected by the system.

To describe further the operation principles of the small-sample commercial AFM shown in Fig. 23.9a, the sample, generally no larger than 10 mm × 10 mm, is mounted on a PZT tube scanner which consists of separate electrodes to precisely scan the sample in the x–y plane in a raster pattern, and to move the sample in the vertical (z) direction. A sharp tip at the free end of a flexible cantilever is brought in contact with the sample. Features on the sample surface cause the cantilever to deflect in the vertical and lateral directions as the sample moves under the tip. A laser beam from a diode laser (5 mW max peak output at 670 nm)

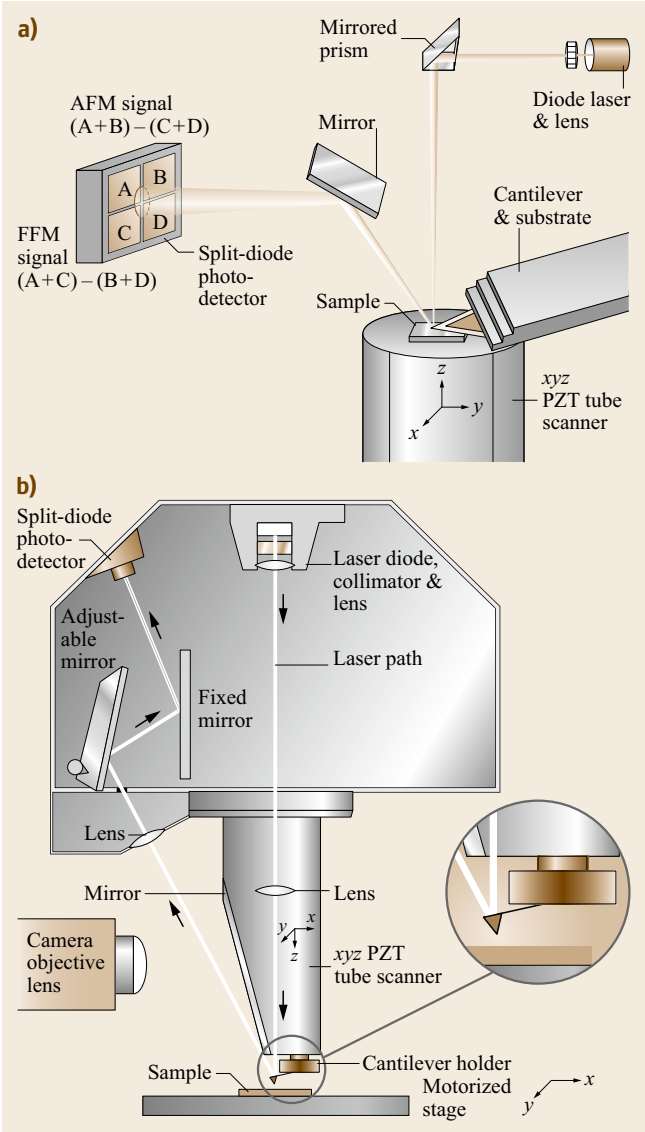

Fig. 23.9a,b Principles of operation of **(a)** a commercial small-sample AFM/FFM, and **(b)** a large-sample AFM/FFM

is directed by a prism onto the back of a cantilever near its free end, tilted downward at about 10° with respect to the horizontal plane. The reflected beam from the vertex of the cantilever is directed through a mirror onto a quad photodetector (split photodetector with four quadrants) (commonly called a position-sensitive detector (PSD), produced by Silicon Detector Corp., Camarillo, California). The differential signal from the top and bottom photodiodes provides the AFM signal, which is a sensitive measure of the cantilever vertical deflection. Topographic features of the sample cause the tip to deflect in the vertical direction as the sample is scanned under the tip. This tip deflection will change the direction of the reflected laser beam, changing the intensity difference between the top and bottom sets of photodetectors (AFM signal). In the AFM operating mode called the height mode, for topographic imaging or for any other operation in which the applied normal force is to be kept constant, a feedback circuit is used to modulate the voltage applied to the PZT scanner to adjust the height of the PZT. This ensures that the cantilever vertical deflection (given by the intensity difference between the top and bottom detector), and consequently normal load, will remain constant during scanning. The PZT height variation is thus a direct measure of the surface roughness of the sample.

In a large-sample AFM, both force sensors using the optical deflection method and scanning unit are mounted on the microscope head, Fig. 23.9b. Because of vibrations added by cantilever movement, lateral resolution of this design is somewhat poorer than the design in Fig. 23.9a in which the sample is scanned instead of the cantilever beam. The advantage of the large-sample AFM is that large samples can be measured readily.

Most AFMs can be used for topography measurements in the so-called tapping mode (intermittent contact mode), also referred to as dynamic force microscopy in the amplitude mode (AM) mentioned earlier. In the tapping mode, during scanning over the surface, the cantilever/tip assembly is sinusoidally vibrated by a piezo mounted above it, and the oscillating tip slightly taps the surface at the resonant frequency of the cantilever (70–400 kHz) with a constant (20–100 nm) oscillating amplitude introduced in the vertical direction with a feedback loop keeping the average normal force constant, Fig. 23.10. The oscillating amplitude is kept large enough so that the tip does not get stuck to the sample because of adhesive attractions. The tapping mode is used in topography measurements to minimize effects of friction and other lateral forces to measure topography of soft surfaces.

Topographic measurements are made at any scanning angle. At a first instance, scanning angle may not appear to be an important parameter. However, the friction force between the tip and the sample will affect the topographic measurements in a parallel scan (scanning along the long axis of the cantilever). Therefore, a perpendicular scan may be more desirable. Generally, one picks a scanning angle that gives the same topographic data in both directions. This angle may be slightly different than that for the perpendicular scan.

For measurement of friction force being applied at the tip surface during sliding, left hand and right hand sets of quadrants of the photodetector are used. In the so-called friction mode, the sample is scanned back and

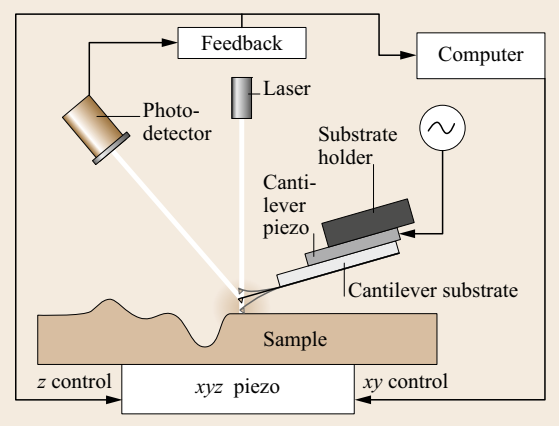

Fig. 23.10 Schematic of tapping mode used for surface roughness measurements

forth in a direction orthogonal to the long axis of the cantilever beam. A friction force between the sample and the tip will produce a twisting of the cantilever. As a result, the laser beam will be reflected out of the plane defined by the incident beam and the beam reflected vertically from an untwisted cantilever. This produces an intensity difference of the laser beam received in the left hand and right hand sets of quadrants of the photodetector. The intensity difference between the two sets of detectors (FFM signal) is directly related to the degree of twisting and hence to the magnitude of the friction force. This method provides three-dimensional maps of friction force. One problem associated with this method is that any misalignment between the laser beam and the photodetector axis introduces error in the measurement. However, by following the procedures developed by *Ruan* and *Bhushan* [23.157] in which the average FFM signal for the sample scanned in two opposite directions is subtracted from the friction profiles of each of the two scans, the misalignment effect is eliminated. By following the friction force calibration procedures developed by *Ruan* and *Bhushan* [23.157], voltages corresponding to friction forces can be converted to force units. The coefficient of friction is obtained from the slope of friction force data measured as a function of normal loads typically ranging from 10 to 150 nN. This approach eliminates any contributions due to adhesive forces [23.36]. For calculation of the coefficient of friction based on a single point measurement, friction force should be divided by the sum of applied normal load and intrinsic adhesive force. Furthermore, note that for a single asperity contact, the coefficient of friction is not independent of load. For further details, refer to a later section.

The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern, Fig. 23.11. Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. Scan sizes ranging from less than 1 nm × 1 nm to 125 μm × 125 μm and scan rates from less than 0.5 to 122 Hz typically can be used. Higher scan rates are used for smaller scan lengths. For example, scan rates in the fast and slow scan directions for an area of 10 μm × 10 μm scanned at 0.5 Hz are 10 μm/s and 20 nm/s, respectively.

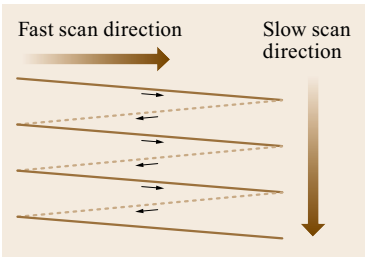

Fig. 23.11 Schematic of triangular pattern trajectory of the AFM tip as the sample is scanned in two dimensions. During imaging, data are recorded only during scans along the *solid scan lines*

We now describe the construction of a small sample AFM in more detail. It consists of three main parts: the optical head that senses the cantilever deflection, a PZT tube scanner that controls the scanning motion of the sample mounted on its one end, and the base that supports the scanner and head and includes circuits for the deflection signal, Fig. 23.12a. The AFM connects directly to a control system. The optical head consists of a laser diode stage, a photodiode stage preamp board, a cantilever mount and its holding arm, and a deflection beam reflecting mirror, Fig. 23.12b. The laser diode stage is a tilt stage used to adjust the position of the laser beam relative to the cantilever. It consists of the laser diode, collimator, focusing lens, baseplate, and the x and y laser diode positioners. The positioners are used to place the laser spot on the end of the cantilever. The photodiode stage is an adjustable stage used to position the photodiode elements relative to the reflected laser beam. It consists of the split photodiode, the base plate, and the photodiode positioners. The deflection beam reflecting mirror is mounted on the upper left in the interior of the head which reflects the deflected beam toward the photodiode. The cantilever mount is a metal (for operation in air) or glass (for operation in water) block which holds the cantilever firmly at the proper angle, Fig. 23.12d. Next, the tube scanner consists of an Invar cylinder holding a single tube made of piezoelectric crystal which provides the necessary three-dimensional motion to the sample. Mounted on top of the tube is a magnetic cap on which the steel sample puck is placed. The tube is rigidly held at one end with the sample mounted on the other end of the tube. The scanner also contains three fine-pitched screws which form the mount for the optical head. The optical head rests on the tips of the screws which are used to adjust the position of the head relative to the sample.

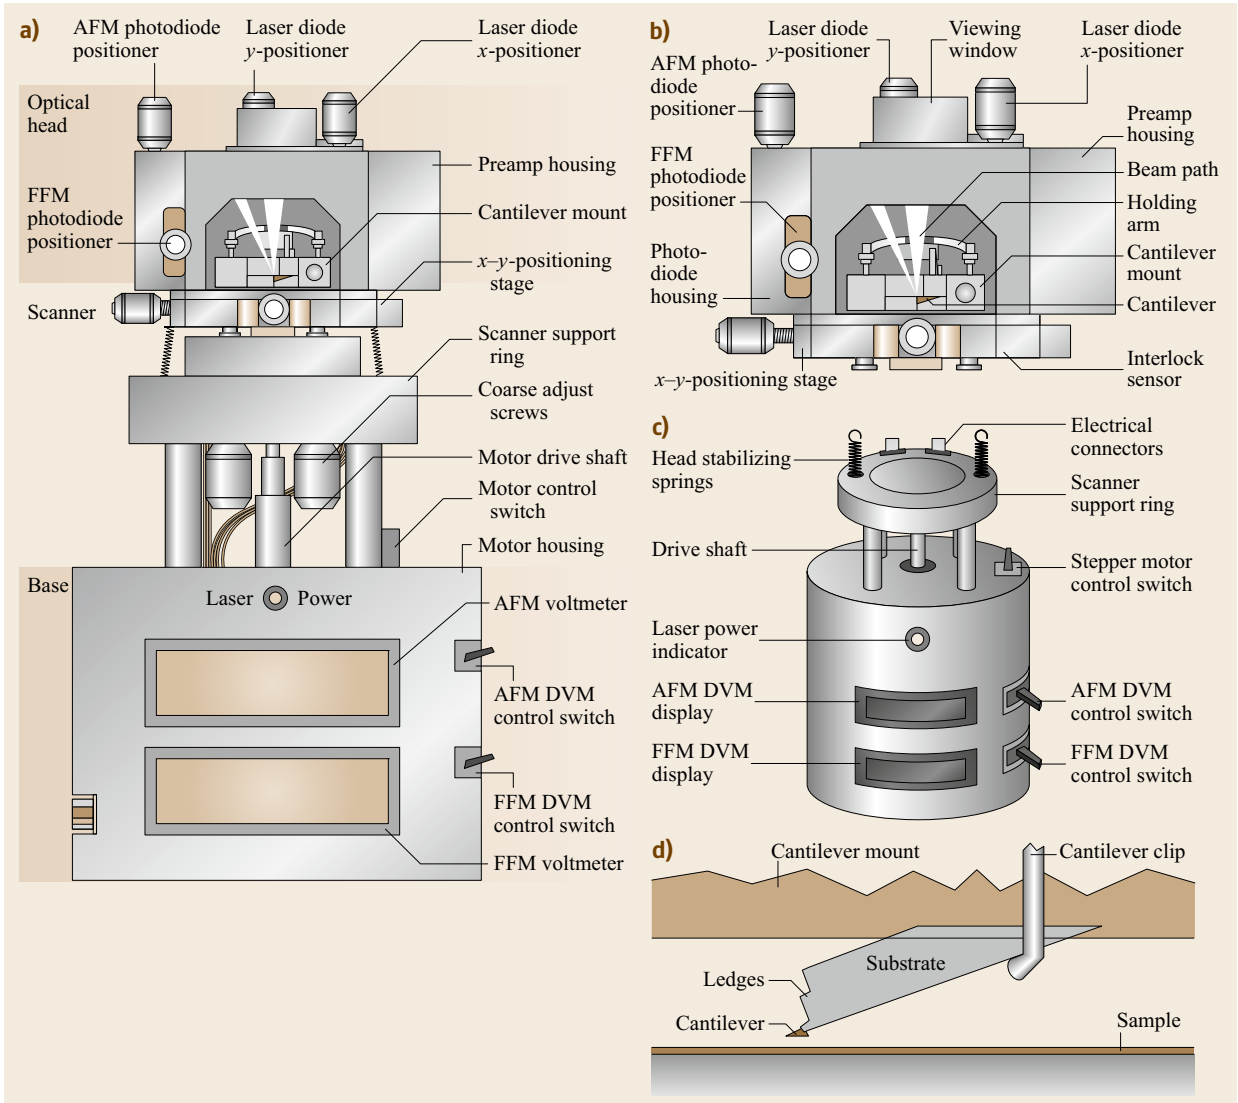

Fig. 23.12a–d Schematics of a commercial multimode AFM/FFM made by Bruker Instruments Inc. **(a)** Front view, **(b)** optical head, **(c)** base, and **(d)** cantilever substrate mounted on cantilever mount (not to scale)

The scanner fits into the scanner support ring mounted on the base of the microscope, Fig. 23.12c. The stepper motor is controlled manually with the switch on the upper surface of the base and automatically by the computer during the tip-engage and tip-withdraw processes.

The scan sizes available for these instruments are 0.7 μm, 12 μm, and 125 μm. The scan rate must be decreased as the scan size is increased. A maximum scan rate of 122 Hz can be used. Scan rates of about 60 Hz should be used for small scan lengths (0.7 μm). Scan rates of 0.5–2.5 Hz should be used for large scans on samples with tall features. High scan rates help reduce drift, but they can only be used on flat samples with small scan sizes. Scan rate, or scanning speed in length/time in the fast scan direction, is equal to twice the scan length times the scan rate in Hz, and in the slow direction, it is equal to scan length times the scan rate in Hz divided by the number of data points in the transverse direction. For example, for $10\,\mu m \times 10\,\mu m$ scan size scanned at 0.5 Hz, the scan rates in the fast and slow scan directions are 10 μm/s and 20 nm/s, respectively. Normally 256×256 data points are taken for each image. The lateral resolution at larger scans is approximately equal to scan length divided by 256. The piezo tube requires *x*–*y* calibration, which is carried out by imaging an appropriate calibration standard.

Cleaved graphite is used for small scan heads while two-dimensional grids (with a gold plating rule) can be used for longer range heads.

Examples of AFM images of freshly cleaved highly oriented pyrolytic (HOP) graphite and mica surfaces are shown in Fig. 23.13 [23.59, 131, 135]. Images with near atomic resolution are obtained.

Force calibration mode is used to study interaction between the cantilever and the sample surface. In the force calibration mode, the x and y voltages applied to the piezo tube are held at zero, and a sawtooth voltage is applied to the z-electrode of the piezo tube, Fig. 23.14a. The force measurement starts with the sample far away and the cantilever in its rest position. As a result of the applied voltage, the sample is moved up and down relative to the stationary cantilever tip. As the piezo moves the sample up and down, the cantilever deflection signal from the photodiode is monitored. The force–distance curve, a plot of the cantilever tip deflection signal as a function of the voltage applied to the piezo tube, is obtained. Figure 23.14b shows a typical force–distance curve showing the various features of the curve. The arrow heads reveal the direction of piezo travel. As the piezo extends, it approaches the tip, which is at this point in free air and hence shows no deflection. This is indicated by the flat portion of the curve. As the tip approaches the sample within a few nanometers (point A), an attractive force exists between the atoms of the tip surface and the atoms of the sample surface. The tip is pulled towards the sample and contact occurs at point B on the graph. From this point on, the tip is in contact with the surface and as the piezo further extends, the tip gets further deflected. This is represented by the sloped portion of the curve. As the piezo retracts, the tip goes beyond the zero deflection (flat) line into the adhesive regime because of attractive forces (van der Waals forces and long-range meniscus forces). At point C in the graph, the tip snaps free of the adhesive forces, and is in free air again. The horizontal distance between points B and C along the retrace line gives the distance moved by the tip in the adhesive regime. This distance multiplied by the stiffness of the cantilever gives the adhesive force. Incidentally, the horizontal shift between the loading and unloading curves results from the hysteresis in the PZT tube [23.10].

Multimode Capabilities

The multimode AFM can be used for topography measurements in the contact mode and AM or tapping mode as described earlier. It can also be used for measurements of lateral (friction) force, electric force gradients, and magnetic force gradients.

The multimode AFM using a grounded conducting tip can measure electric field gradients by oscillating the tip near its resonant frequency. When the lever encoun-

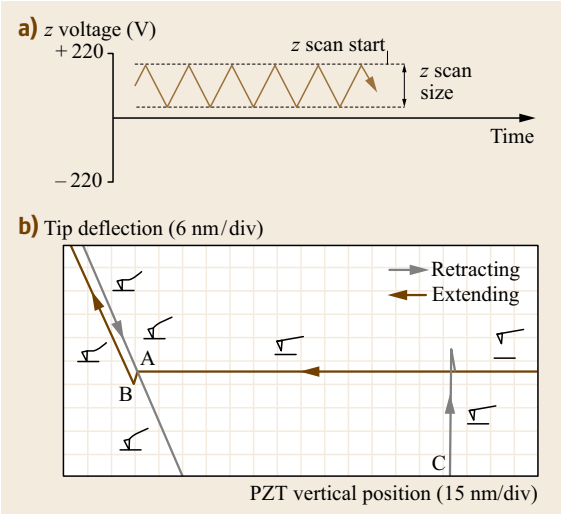

Fig. 23.14 **(a)** Force calibration z-waveform, and **(b)** a typical force–distance curve for a tip in contact with a sample. Contact occurs at point B; tip breaks free of adhesive forces at point C as the sample moves away from the tip

ters a force gradient from the electric field, the effective spring constant of the cantilever is altered, changing its resonant frequency. Depending on which side of the resonance curve is chosen, the oscillation amplitude of the cantilever increases or decreases due to the shift in the resonant frequency. By recording the amplitude of the cantilever, an image revealing the strength of the electric field gradient is obtained.

In a magnetic force microscope (MFM) used with a magnetically coated tip, static cantilever deflection is detected that occurs when a magnetic field exerts a force on the tip and the MFM images of magnetic materials can be produced. MFM sensitivity can be enhanced by oscillating the cantilever near its resonant frequency. When the tip encounters a magnetic force gradient, the effective spring constant, and hence the resonant frequency, is shifted. By driving the cantilever above or below the resonant frequency, the oscillation amplitude varies as the resonance shifts. An image of magnetic field gradients is obtained by recording the oscillation amplitude as the tip is scanned over the sample.

Topographic information is separated from the electric field gradients and magnetic field images by using a so-called lift mode. Measurements in lift mode are taken in two passes over each scan line. On the first pass, topographical information is recorded in the standard tapping mode where the oscillating cantilever lightly taps the surface. On the second pass, the tip is lifted to a user-selected separation (typically 20–200 nm) between the tip and local surface topography. By using the stored topographical data instead of the standard feedback, the separation remains constant without sensing the surface. At this height, cantilever amplitudes are sensitive to electric field force gradients or relatively weak but long-range magnetic forces without being influenced by topographic features. Two-pass measurements are taken for every scan line, producing separate topographic and magnetic force images.

Electrochemical AFM

This option allows study of electrochemical reactions in the AFM. It includes a potentiostat, a fluid cell with a transparent cantilever holder and electrodes, and the software required to operate the potentiostat and display the results of the electrochemical reaction.

23.2.3 AFM Probe Construction

Various probes (cantilevers and tips) are used for AFM studies. The cantilever stylus used in the AFM should meet the following criteria:

1. Low normal spring constant (stiffness)
2. A high resonant frequency
3. A high quality factor of the cantilever Q
4. High lateral spring constant (stiffness)
5. Short cantilever length
6. Incorporation of components (such as mirror) for deflection sensing
7. A sharp protruding tip [23.158].

In order to register a measurable deflection with small forces, the cantilever must flex with a relatively low force (on the order of a few nN) requiring vertical spring constants of 10^{-2}–$10^{2}\,\mathrm{N/m}$ for atomic resolution in the contact profiling mode. The data rate or imaging rate in the AFM is limited by the mechanical resonant frequency of the cantilever. To achieve a large imaging bandwidth, the AFM cantilever should have resonant frequency greater than about 10 kHz (preferably 30–100 kHz) in order to make the cantilever the least sensitive part of the system. Fast imaging rates are not just a matter of convenience, since the effects of thermal drifts are more pronounced with slow scanning speeds. The combined requirements of a low spring constant and a high resonant frequency is met by reducing the mass of the cantilever. The quality factor Q ($= \omega_\mathrm{R}/(c/m)$ where ω_R is the resonant frequency of the damped oscillator, c is the damping constant, and m is the mass of the oscillator) should have a high value for some applications. For example, resonance curve detection is a sensitive modulation technique for measuring small force gradients in noncontact imaging. Increasing the Q increases the sensitivity of the measurements. Mechanical Q values of 100–1000 are typical. In contact modes, Q is less important. A high lateral spring constant in the cantilever is desirable to reduce the effect of lateral forces in the AFM as frictional forces can cause appreciable lateral bending of the cantilever. Lateral bending results in error in the topography measurements. For friction measurements, cantilevers with less lateral rigidity are preferred. A sharp protruding tip must be formed at the end of the cantilever to provide a well-defined interaction with the sample over a small area. The tip radius should be much smaller than the radii of corrugations in the sample in order for these to be measured accurately. The lateral spring constant depends critically on the tip length. Additionally, the tip should be centered at the free end.

In the past, cantilevers have been cut by hand from thin metal foils or formed from fine wires. Tips for these cantilevers were prepared by attaching diamond fragments to the ends of the cantilevers by hand, or, in the case of wire cantilevers, electrochemically etching the wire to a sharp point. Several cantilever geometries for wire cantilevers have been used. The simplest geometry is the L-shaped cantilever, usually made by bending a wire at a 90° angle. Other geometries include single-

Table 23.2 Relevant properties of commonly used materials for cantilevers and diamond used in the some tips

Property	Young's modulus (E) (GPa)	Density (ρg) (kg/m^3)	Microhardness (GPa)	Speed of sound $\left(\sqrt{E/\rho}\right)$ (m/s)

V and double-V geometries with a sharp tip attached at the apex of V, and double-X configuration with a sharp tip attached at the intersection [23.34, 159]. These cantilevers can be constructed with high vertical spring constants. For example, a double-cross cantilever with an effective spring constant of 250 N/m was used by *Burnham* and *Colton* [23.34]. The small size and low mass needed in the AFM make hand fabrication of the cantilever a difficult process with poor reproducibility. Conventional microfabrication techniques are ideal for constructing planar thin-film structures which have submicron lateral dimensions. Triangular (V-shaped) cantilevers have improved (higher) lateral spring constants in comparison to rectangular cantilevers. In terms of spring constants, triangular cantilevers are approximately equivalent to two rectangular cantilevers in parallel [23.158]. Although the macroscopic radius of a photolithographically patterned corner is seldom much less than about 50 nm, microscopic asperities on the etched surface provide tips with near atomic dimensions.

Cantilevers and tips have been used from a whole range of materials. Most common are cantilevers/tips made of Si_3N_4, Si, and stainless steel/diamond. Besides the geometry, the material parameters that determine the resonant frequency of the cantilever are Young's modulus and density. Table 23.2 shows the relevant properties of commonly used materials and the speed of sound, indicative of the resonant frequency for a cantilever beam. Hardness is important to judge the durability of the tips, and is also listed in the table. Materials used for STM cantilevers are also included.

Silicon nitride cantilevers with integrated tips are less expensive than those made of other materials. They are very rugged and well suited to imaging in almost all environments. They are especially compatible to organic and biological materials. Microfabricated silicon nitride triangular beams with integrated square pyramidal tips made using plasma-enhanced chemical vapor deposition (PECVD) are the most commonly used [23.158]. Figure 23.15a shows a schematic example of four cantilever beams, each with different sizes and spring constants, arranged in pairs, attached to a borosilicate glass substrate (Pyrex) and marketed by various manufacturers including Bruker Instruments, Inc. Each pair of triangular cantilevers measures 115 and 193 μm from the substrate to the apex, with base widths of 122 and 205 μm, respectively. These cantilevers are commercially available with wide (top) and narrow (bottom) legs, all in the same thickness of 0.6 μm. Calculated spring constant and measured natural frequencies for each of the configurations are listed in Table 23.3. The most commonly used cantilever beam is the 115 μm long, wide-legged cantilever (vertical spring constant = 0.58 N/m). Cantilevers with smaller spring constants should be used on softer samples. Pyramidal tips are highly symmetric with ends having a radius of about 20–50 nm. The tip side walls have a slope of 35°, and the length of the edges of the tip at the cantilever base is about 4 μm.

An alternative to silicon nitride cantilevers with integrated tips are microfabricated single-crystal silicon cantilevers with integrated tips. Si tips are sharper than Si_3N_4 tips because they are directly formed by the anisotropic etch in single-crystal Si rather than using an etch pit as a mask for deposited materials [23.160]. Etched single-crystal n-type silicon rectangular cantilevers with square pyramidal tips with a lower radius of less than 10 nm for contact and tapping mode (tapping mode etched silicon probe or TESP) AFMs are commercially available from various manufacturers in-

cluding Bruker Instruments, Inc., Fig. 23.15b. Spring constants and resonant frequencies are also presented in Fig. 23.15b.

Commercial triangular Si_3N_4 cantilevers have a typical width-thickness ratio of 10–30, which results in 100 to 1000 times stiffer spring constants in the lateral direction compared to the normal direction. Therefore, these cantilevers are not well suited for torsion. For friction measurements, the torsional spring constant should be minimized in order to be sensitive to lateral forces. Rather long cantilevers with small thicknesses and large tip lengths are most suitable. Rectangular beams have lower torsional spring constants in comparison to the triangular (V-shaped) cantilevers. Table 23.4 lists the spring constants (with full length of the beam used) in three directions of typical rectangular beams. We note that lateral and torsional spring constants are about two orders of magnitude larger than the normal spring constants. A cantilever beam required for the tapping mode is quite stiff and may not be sensitive enough for friction measurements. *Meyer* et al. [23.161] used a specially designed rectangular silicon cantilever with length $= 200\,\mu m$, width $= 21\,\mu m$, thickness $=$

Table 23.4 Vertical (k_z), lateral (k_y), and torsional (k_{yT}) spring constants of rectangular cantilevers made of Si (IBM) and PECVD Si_3N_4 (Bruker Instruments, Inc.)

Dimensions/stiffness	Si cantilever	Si_3N_4 cantilever
Length L (µm)	100	100
Width b (µm)	10	20
Thickness h (µm)	1	0.6
Tip length ℓ (µm)	5	3
k_z (N/m)	0.4	0.15
k_y (N/m)	40	175
k_{yT} (N/m)	120	116
ω_0 (kHz)	≈ 90	≈ 65

Note: $k_z = Ebh^3/4L^3$, $k_y = Eb^3h/4\ell^3$, $k_{yT} = Gbh^3/3L\ell^2$, and $\omega_0 = [k_z/(m_c + 0.24\,bhL\rho)]^{1/2}$ where E is Young's modulus, G is the modulus of rigidity $[= E/2(1+\nu)$, where ν is the Poisson's ratio], ρ is the mass density of the cantilever, and m_c is the concentrated mass of the tip (≈ 4 ng) [23.113]. For Si, $E = 130$ GPa, $\rho g = 2300\,kg/m^3$, and $\nu = 0.3$. For Si_3N_4, $E = 150$ GPa, $\rho g = 3100\,kg/m^3$, and $\nu = 0.3$.

0.4 μm, tip length = 12.5 μm, and shear modulus = 50 GPa, giving a normal spring constant of 0.007 N/m and torsional spring constant of 0.72 N/m which gives a lateral force sensitivity of 10 pN and an angle of resolution of 10^{-7} rad. With this particular geometry, sensitivity to lateral forces could be improved by about a factor of 100 compared with commercial V-shaped Si_3N_4 or rectangular Si or Si_3N_4 cantilevers used by *Meyer* and *Amer* [23.7] with torsional spring constant of ≈ 100 N/m. *Ruan* and *Bhushan* [23.157] and *Bhushan* and *Ruan* [23.8] used 115 μm long, wide-legged V-shaped cantilevers made of Si_3N_4 for friction measurements.

For scratching, wear, and indentation studies, single-crystal natural diamond tips ground to the shape of a three-sided pyramid with an apex angle of either 60 or 80° whose point is sharpened to a radius of about 100 nm are commonly used [23.10, 36] (Fig. 23.15c). The tips are bonded with conductive epoxy to a gold-plated 304 stainless steel spring sheet (length = 20 mm, width = 0.2 mm, thickness = 20–60 μm) which acts as a cantilever. Free length of the spring is varied to change the beam stiffness. The normal spring constant of the beam ranges from about 5–600 N/m for a 20 μm thick beam. The tips are produced by various manufacturers including R-DEC Co., Tsukuba, Japan. Scanning electron microscopy (SEM) micrographs of silicon nitride, single-crystal silicon, and natural diamond tips are shown in Fig. 23.16.

For imaging within trenches by AFM, high aspect ratio tips are used. Examples of the two probes are shown in Fig. 23.17. The high aspect ratio tip (HART) probes are produced by starting with a conventional Si_3N_4 pyramidal probe. Through a combination of focused ion beam (FIB) and high-resolution SEM techniques, a thin filament is grown at the apex of the pyramid. The probe filament is approximately 1 μm long and 0.1 μm in diameter. It tapers to an extremely sharp point (radius better than the resolution of most SEMs). The long thin shape and sharp radius make it ideal for imaging features of microstructures and trenches (> 0.25 μm). Because of flexing of the probe, it is unsuitable for imaging structures at the atomic level since the flexing of the probe can create image artifacts. For atomic-scale imaging, a FIB-milled probe is used which is relatively stiff yet allows for closely spaced topography. These probes start out as conventional Si_3N_4 pyramidal probes but the pyramid is FIB milled until a small cone shape is formed which has a high aspect ratio with 0.2–0.3 μm length. The milled probes allow nanostructure resolution without sacrificing rigidity.

Carbon nanotube tips having small diameter and high aspect ratio are used for high-resolution imaging of surfaces and deep trenches, in the tapping mode or noncontact mode. Single-walled carbon nanotubes (SWNTs) are microscopic graphitic cylinders that are

0.7–3 nm in diameter and up to many microns in length. Larger structures called multiwalled carbon nanotubes (MWNTs) consist of nested, concentrically arranged SWNT and have diameters ranging from 3 to 50 nm. MWNT carbon nanotube AFM tips are produced by manual assembly [23.162], chemical vapor deposition (CVD) synthesis, and hybrid fabrication processes [23.163]. Figure 23.18 shows a TEM micrograph of a carbon nanotube tip, ProbeMax, commercially produced using mechanical assembly by Piezomax Technologies, Inc., Middleton, Wisconsin. For production of these tips, MWNT nanotubes are produced by the carbon arc method. They are physically attached on single-crystal silicon square-pyramidal tips in the SEM using a manipulator and the SEM stage to control the nanotubes and the tip independently. Once the nanotube is attached to the tip, it is usually too long to image with. It is shortened using an AFM applying voltage between the tip and the sample. Nanotube tips are also commercially produced by CVD synthesis by NanoDevices, Santa Barbara, California.

23.2.4 Friction Measurement Methods

On the basis of the work by *Ruan* and *Bhushan* [23.157], the two methods for friction measurements are now described in more detail (also see [23.7, 164]). A scanning angle is defined as the angle relative to the y-axis in Fig. 23.19a. This is also the long axis of the cantilever. A zero degree scanning angle corresponds to the sample scanning in the y-direction, and a 90° scanning angle corresponds to the sample scanning perpendicular to this axis in the xy-plane (along the x-axis). If the scanning direction is in both y- and $-y$-directions, we call this a *parallel scan*. Similarly, a *perpendicular scan* means the scanning direction is in x- and $-x$-directions. The sample traveling direction for each of these two methods is illustrated in Fig. 23.19b.

Fig. 23.18 SEM micrograph of a multiwalled carbon nanotube (MWNT) tip physically attached on the single-crystal silicon, square-pyramidal tip (Courtesy Piezomax Technologies, Inc.)

In method 1 (using the *height* mode with parallel scans) in addition to topographic imaging, it is also possible to measure friction force when the scanning direction of the sample is parallel to the y-direction (parallel scan). If there were no friction force between the tip and the moving sample, the topographic feature would be the only factor to cause the cantilever to deflect vertically. However, friction force does exist on all contact surfaces where one object is moving relative to another. The friction force between the sample and the tip will also cause a cantilever deflection. We assume that the normal force between the sample and the tip is W_0 when the sample is stationary (W_0

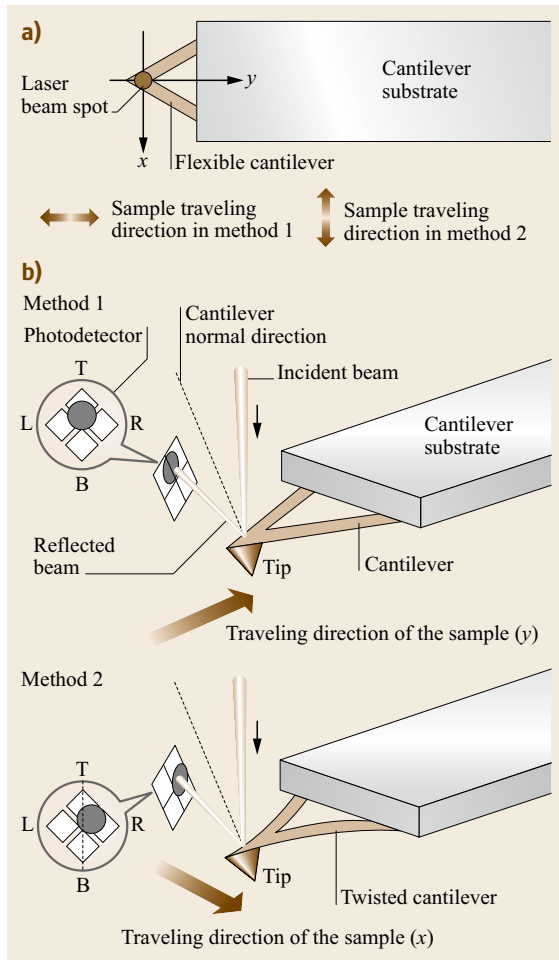

Fig. 23.19 **(a)** Schematic defining the x- and y-directions relative to the cantilever, and showing the sample traveling direction in the two different measurement methods discussed in the text. **(b)** Schematic of deformation of the tip and cantilever shown as a result of sliding in the x- and y-directions. A twist is introduced to the cantilever if the scanning is in the x-direction (Method 2) (after [23.157])

is typically in the range 10–200 nN), and the friction force between the sample and the tip is W_f as the sample scans against the tip. The direction of friction force (W_f) is reversed as the scanning direction of the sample is reversed from the positive (y) to the negative ($-y$) direction $\vec{W}_{f(y)} = -\vec{W}_{f(-y)}$.

When the vertical cantilever deflection is set at a constant level, it is the total force (normal force and friction force) applied to the cantilever that keeps the cantilever deflection at this level. Since the friction force is in opposite directions as the traveling direction of the sample is reversed, the normal force will have to be adjusted accordingly when the sample reverses its traveling direction, so that the total deflection of the cantilever will remain the same. We can calculate the difference of the normal force between the two traveling directions for a given friction force W_f. First, by means of a constant deflection, the total moment applied to the cantilever is constant. If we take the reference point to be the point where the cantilever joins the cantilever holder (substrate), point P in Fig. 23.20, we have the following relationship

$$(W_0 - \Delta W_1)\, L + W_f \ell = (W_0 + \Delta W_2)\, L - W_f \ell \tag{23.1}$$

or

$$(\Delta W_1 + \Delta W_2)\, L = 2 W_f \ell\,. \tag{23.2}$$

Thus,

$$W_f = \frac{(\Delta W_1 + \Delta W_2)\, L}{2\ell}\,, \tag{23.3}$$

where ΔW_1 and ΔW_2 are the absolute value of the changes of normal force when the sample is traveling in $-y$- and y-directions, respectively, as shown in Fig. 23.20; L is the length of the cantilever; and ℓ is the vertical distance between the end of the tip and point P. The coefficient of friction (μ) between the tip and the sample is then given as

$$\mu = \frac{W_f}{W_0} = \left(\frac{\Delta W_1 + \Delta W_2}{W_0}\right)\left(\frac{L}{2\ell}\right)\,. \tag{23.4}$$

In all circumstances, there are adhesive and interatomic attractive forces between the cantilever tip and the sample. The adhesive force can be due to water from the capillary condensation and other contaminants present at the surface which form meniscus bridges [23.10, 165, 166] and the interatomic attractive force includes van der Waals attraction [23.18]. If these forces (and the indentation effect as well, which is usually small for rigid samples) can be neglected, the normal force W_0 is then equal to the initial cantilever deflection H_0 multiplied by the spring constant of the cantilever. $(\Delta W_1 + \Delta W_2)$ can be measured by multiplying the same spring constant by the height difference of the piezo tube between the two traveling directions (y- and $-y$-directions) of the sample. This height difference is denoted as $(\Delta H_1 + \Delta H_2)$, shown schematically in Fig. 23.21. Thus, (23.4) can be rewritten as

$$\mu = \frac{W_f}{W_0} = \left(\frac{\Delta H_1 + \Delta H_2}{H_0}\right)\left(\frac{L}{2\ell}\right)\,. \tag{23.5}$$

Since the vertical position of the piezo tube is affected by the surface topographic profile of the sample in addition to the friction force being applied at the tip, this difference has to be taken point-by-point at the same location on the sample surface as shown in Fig. 23.21. Subtraction of point-by-point measurements may introduce errors, particularly for rough samples. We will come back to this point later. In addition, precise measurement of L and ℓ (which should include the cantilever angle) are also required.

If the adhesive forces between the tip and the sample are large enough that it can not be neglected, one should include it in the calculation. However, there could be a large uncertainty in determining this force, thus an uncertainty in using (23.5). An alternative approach is to make the measurements at different normal loads and to use $\Delta(H_0)$ and $\Delta(\Delta H_1 + \Delta H_2)$ from the measurements in (23.5). Another comment on (23.5) is that, since only the ratio between $(\Delta H_1 + \Delta H_2)$ and H_0 comes into this equation, the piezo tube vertical position H_0 and its position difference $(\Delta H_1 + \Delta H_2)$ can be

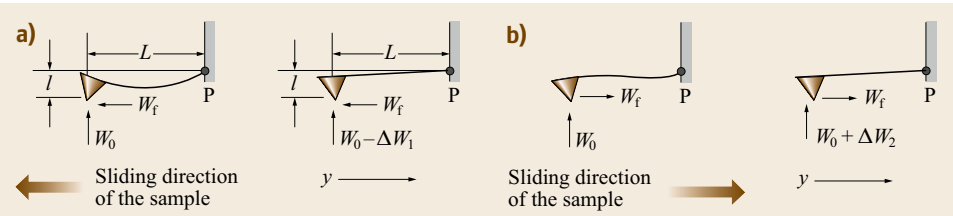

Fig. 23.20 **(a)** Schematic showing an additional bending of the cantilever – due to friction force when the sample is scanned in the y- or $-y$-direction (*left*). **(b)** This effect will be canceled by adjusting the piezo height by a feedback circuit (*right*) (after [23.157])

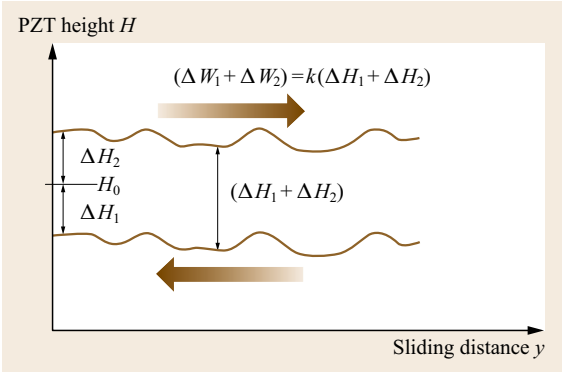

Fig. 23.21 Schematic illustration of the height difference of the piezoelectric tube scanner as the sample is scanned in y- and $-y$-directions

in the units of volts as long as the vertical traveling distance of the piezo tube and the voltage applied to it has a linear relationship. However, if there is a large nonlinearity between the piezo tube traveling distance and the applied voltage, this nonlinearity must be included in the calculation.

It should also be pointed out that (23.4) and (23.5) are derived under the assumption that the friction force W_f is the same for the two scanning directions of the sample. This is an approximation since the normal force is slightly different for the two scans and there may also be a directionality effect in friction. However, this difference is much smaller than W_0 itself. We can ignore the second-order correction.

Method 2 (*aux* mode with perpendicular scan) to measure friction was suggested by *Meyer* and *Amer* [23.7]. The sample is scanned perpendicular to the long axis of the cantilever beam (i. e., to scan along the x- or $-x$-direction in Fig. 23.19a) and the output of the two horizontal quadrants of the photodiode detector is measured. In this arrangement, as the sample moves under the tip, the friction force will cause the cantilever to twist. Therefore, the light intensity between the left and right (L and R in Fig. 23.19b, right) detectors will be different. The differential signal between the left and right detectors is denoted as FFM signal $[(L-R)/(L+R)]$. This signal can be related to the degree of twisting, hence to the magnitude of friction force. Again, because of a possible error in determining normal force due to the presence of an adhesive force at the tip–sample interface, the slope of the friction data (FFM signal versus normal load) needs to be taken for an accurate value of coefficient of friction.

While friction force contributes to the FFM signal, friction force may not be the only contributing factor in commercial FFM instruments. One can notice this fact by simply engaging the cantilever tip with the sample. Before engaging, the left and right detectors can be balanced by adjusting the position of the detectors so that the intensity difference between these two detectors is zero (FFM signal is zero). Once the tip is engaged with the sample, this signal is no longer zero even if the sample is not moving in the xy-plane with no friction force applied. This would be a detrimental effect. It has to be understood and eliminated from the data acquisition before any quantitative measurement of friction force becomes possible.

One of the fundamental reasons for this observation is the following. The detectors may not have been properly aligned with respect to the laser beam. To be precise, the vertical axis of the detector assembly (the line joining T–B in Fig. 23.22) is not in the plane defined by the incident laser beam and the beam reflected from an untwisted cantilever (we call this the *beam plane*). When the cantilever vertical deflection changes due to a change of applied normal force (without having the sample scanned in the xy-plane), the laser beam will be reflected up and down and form a projected trajectory on the detector. (Note that this trajectory is in the defined beam plane). If this trajectory is not coincident with the vertical axis of the detector, the laser beam will not evenly bisect the left and right quadrants of the detectors, even under the condition of no torsional motion of the cantilever, see Fig. 23.22. Thus, when the laser beam is reflected up and down due to a change of the normal force, the intensity difference between the left and right detectors will also change. In other words, the FFM signal will change as the normal force applied to the tip is changed, even if the tip is not experiencing any friction force. This (FFM) signal is unrelated to friction force or to the actual twisting of the cantilever. We will call this part of the FFM signal $\mathrm{FFM_F}$, and the part which is truly related to friction force $\mathrm{FFM_T}$.

The $\mathrm{FFM_F}$ signal can be eliminated. One way of doing this is as follows. First the sample is scanned in both x- and $-x$-directions and the FFM signal for scans in each direction is recorded. Since friction force reverses its direction when the scanning direction is reversed from x- to $-x$-direction, the $\mathrm{FFM_T}$ signal will have opposite signs as the scanning direction of the sample is reversed ($\mathrm{FFM_T}(x) = -\mathrm{FFM_T}(-x)$). Hence, the $\mathrm{FFM_T}$ signal will be canceled out if we take the sum of the FFM signals for the two scans. The average value of the two scans will be related to $\mathrm{FFM_F}$ due to the misalignment,

$$\mathrm{FFM}(x) + \mathrm{FFM}(-x) = 2\mathrm{FFM_F}\,. \tag{23.6}$$

This value can therefore be subtracted from the original FFM signals of each of these two scans to obtain the true FFM signal ($\mathrm{FFM_T}$). Or, alternately, by

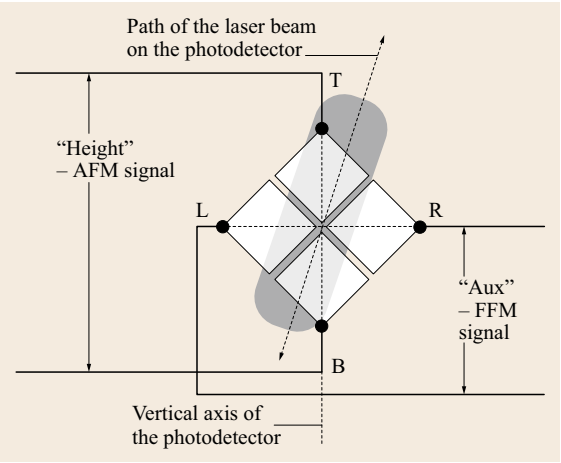

Fig. 23.22 The trajectory of the laser beam on the photodetectors as the cantilever is vertically deflected (with no torsional motion) for a misaligned photodetector with respect to the laser beam. For a change of normal force (vertical deflection of the cantilever), the laser beam is projected at a different position on the detector. Because of a misalignment, the projected trajectory of the laser beam on the detector is not parallel with the detector's vertical axis (the line T–B) (after [23.157])

taking the difference of the two FFM signals, one directly gets the $\mathrm{FFM_T}$ value

$$\begin{aligned}\mathrm{FFM}(x) - \mathrm{FFM}(-x) &= \mathrm{FFM_T}(x) - \mathrm{FFM_T}(-x) \\ &= 2\mathrm{FFM_T}(x)\,.\end{aligned} \tag{23.7}$$

Ruan and *Bhushan* [23.157] have shown that the error signal ($\mathrm{FFM_F}$) can be very large compared to friction signal $\mathrm{FFM_T}$, thus correction is required.

Now we compare the two methods. The method using the *height* mode with a parallel scan (method 1) is very simple to use. Technically, this method can provide 3-D friction profiles and the corresponding topographic profiles. However, there are some problems with this method. Under most circumstances, the piezo scanner displays a hysteresis when the traveling direction of the sample is reversed. Therefore, the measured surface topographic profiles will be shifted relative to each other along the y-axis for the two opposite (y and $-y$) scans. This would make it difficult to measure the local height difference of the piezo tube for the two scans. However, the average height difference between the two scans and hence the average friction can still be measured. The measurement of average friction can serve as an internal means of friction force calibration. Method 2 is the more desirable approach. The subtraction of the $\mathrm{FFM_F}$ signal from FFM for the two scans does not introduce error to local friction force data. An ideal approach in using this method would be to add the average value of the two profiles in order to get the error component ($\mathrm{FFM_F}$) and then subtract this component from either profile to get true friction profiles in either direction. By making measurements at various loads, we can obtain the average value of the coefficient of friction which then can be used to convert the friction profile to the coefficient of friction profile. Thus, any directionality and local variations in friction can be easily measured. In this method, since topography data are not affected by friction, accurate topography data can be measured simultaneously with friction data and a better localized relationship between the two can be established.

23.2.5 Normal Force and Friction Force Calibrations of Cantilever Beams

On the basis of [23.157], we now discuss normal force and friction force calibrations. In order to calculate the absolute value of normal and friction forces in Newtons using the measured AFM and $\mathrm{FFM_T}$ voltage signals, it is necessary to first have an accurate value of the spring constant of the cantilever (k_c). The spring constant can be calculated using the geometry and the physical properties of the cantilever material [23.7, 113, 158]. However, the properties of the PECVD Si_3N_4 (used in fabricating cantilevers) could be different from those of the bulk material. For example, by using an ultrasonic measurement, we found the Young's modulus of the cantilever beam to be about 238 ± 18 GPa, which is less than that of bulk Si_3N_4 (310 GPa). Furthermore, the thickness of the beam is nonuniform and difficult to measure precisely. Since the stiffness of a beam is proportional to the cube of thickness, minor errors in precise measurements of thickness can introduce substantial stiffness errors. Thus, one should experimentally measure the spring constant of the cantilever. *Cleveland* et al. [23.167] measured the normal spring constant by measuring resonant frequencies of the beams.

For normal spring constant measurement, *Ruan* and *Bhushan* [23.157] used a stainless steel spring sheet of known stiffness (width = 1.35 mm, thickness = 15 μm, free hanging length = 5.2 mm). One end of the spring was attached to the sample holder and the other end was made to contact with the cantilever tip during the measurement, see Fig. 23.23. They measured the piezo traveling distance for a given cantilever deflection. For a rigid sample (such as diamond), the piezo traveling distance Z_t (measured from the point where the tip touches the sample) should equal the cantilever deflection. To keep the cantilever deflection at the same level using a flexible spring sheet, the new piezo traveling

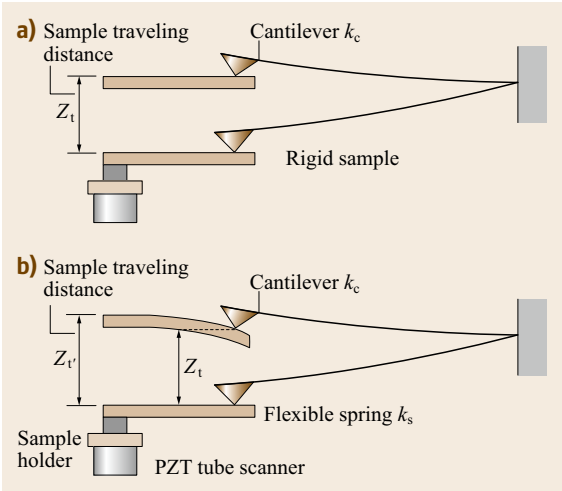

Fig. 23.23a,b Illustration showing the deflection of a cantilever as it is pushed by **(a)** a rigid sample or by **(b)** a flexible spring sheet (after [23.157])

distance $Z_{t'}$ would be different from Z_t. The difference between $Z_{t'}$ and Z_t corresponds to the deflection of the spring sheet. If the spring constant of the spring sheet is k_c, the spring constant of the cantilever k_c can be calculated by

$$(Z_{t'} - Z_t)\, k_s = Z_t k_c$$

or

$$k_c = \frac{k_S\,(Z_{t'} - Z_t)}{Z_t}\,. \tag{23.8}$$

The spring constant of the spring sheet (k_s) used in this study is calculated to be 1.54 N/m. For the wide-legged cantilever used in our study (length = 115 μm, base width = 122 μm, leg width = 21 μm, and thickness = 0.6 μm), k_c was measured to be 0.40 N/m instead of 0.58 N/m reported by its manufacturer – Digital Instruments Inc. To relate photodiode detector output to the cantilever deflection in nm, they used the same rigid sample to push against the AFM tip. Since for a rigid sample the cantilever vertical deflection equals the sample traveling distance measured from the point where the tip touches the sample, the photodiode output as the tip is pushed by the sample can be converted directly to cantilever deflection. For these measurements, they found the conversion factor to be 20 nm/V.

The normal force applied to the tip can be calculated by multiplying the cantilever vertical deflection by the cantilever spring constant for samples which have very small adhesive force with the tip. If the adhesive force between the sample and the tip is large, it should be included in the normal force calculation. This is particularly important in atomic-scale force measurement because in this region, the typical normal force that is measured is in the range of a few hundreds of nN to a few mN. The adhesive force could be comparable to the applied force.

The conversion of friction signal (from FFM_T to friction force) is not as straightforward. For example, one can calculate the degree of twisting for a given friction force using the geometry and the physical properties of the cantilever [23.62, 166]. One would need information on the detectors such as the quantum efficiency of the detector, the laser power, the instrument's gain, etc. in order to be able to convert the signal into the degree of twisting. Generally speaking, this procedure cannot be accomplished without having some detailed information about the instrument. This information is not usually provided by the manufacturers. Even if this information is readily available, error may still occur in using this approach because there will always be variations as a result of the instrumental set up. For example, it has been noticed that the measured FFM_T signal could be different for the same sample when different AFM microscopes of the same kind are used. The essence is that, one cannot calibrate the instrument experimentally using this calculation. *O'Shea* et al. [23.166] did perform a calibration procedure in which the torsional signal was measured as the sample is displaced a known distance laterally while ensuring that the tip does not slide over the surface. However, it is difficult to verify if the tip sliding does not occur.

Apparently, a new method of calibration is required. There is a more direct and simpler way of doing this. The first method described (method 1) to measure friction can directly provide an absolute value of coefficient of friction. It can therefore be used just as an internal means of calibration for the data obtained using method 2. Or, if for method 1 one uses a polished sample which introduces the least error in friction measurements, the method can then be used to obtain a calibration for friction force for method 2. This calibration can in turn be used for measurement of all samples using method 2. In method 1, the length of the cantilever required can be measured using an optical microscope; the length of the tip can be measured using a scanning electron microscope. The relative angle between the cantilever and the horizontal sample surface can be measured directly. Thus, the coefficient of friction can be measured with few unknown parameters. The friction force can then be calculated by multiplying the coefficient of friction by the normal load. The FFM_T signal obtained using method 2 can then be converted into friction force. For their instrument, they found the conversion to be 8.6 nN/V.

23.3 AFM Instrumentation and Analyses

The performance of AFMs and the quality of AFM images greatly depend on the instrument available and the probes (cantilever and tips) in use. This section describes the mechanics of cantilevers, instrumentation and analysis of force detection systems for cantilever deflections, and scanning and control systems.

23.3.1 The Mechanics of Cantilevers

Stiffness and Resonances of Lumped Mass Systems

Any one of the building blocks of an AFM, be it the body of the microscope itself or the force-measuring cantilevers, are mechanical resonators. These resonances can be excited either by the surrounding or by the rapid movement of the tip or the sample. To avoid problems due to building- or air-induced oscillations, it is of paramount importance to optimize the design of the AFMs for high resonant frequencies. This usually means to decrease the size of the microscope [23.168]. By using cube-like or sphere-like structures for the microscope, one can considerably increase the lowest eigen-frequency. The fundamental natural frequency, ω_0, of any spring is given by

$$\omega_0 = \frac{1}{2\pi}\sqrt{\frac{k}{m_{\text{eff}}}}\,, \tag{23.9}$$

where k is the spring constant (stiffness) in the normal direction and m_{eff} is the effective mass. The spring constant k of a cantilever beam with uniform cross section (Fig. 23.24) is given by [23.169]

$$k = \frac{3EI}{L^3}\,, \tag{23.10}$$

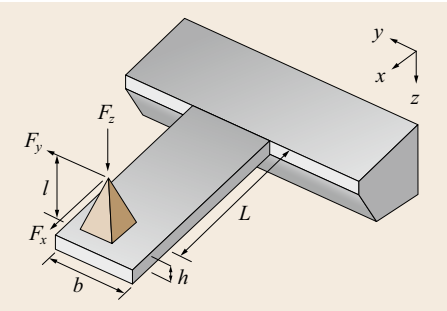

Fig. 23.24 A typical AFM cantilever with length L, width b, and height h. The height of the tip is l. The material is characterized by Young's modulus E, the shear modulus G, and a mass density ρ. Normal (F_z), axial (F_x), and lateral (F_y) forces exist at the end of the tip

where E is the Young's modulus of the material, L is the length of the beam, and I is the moment of inertia of the cross section. For a rectangular cross section with width b (perpendicular to the deflection) and height h one obtains an expression for I

$$I = \frac{bh^3}{12}\,. \tag{23.11}$$

Combining (23.9)–(23.11) we get an expression for ω_0

$$\omega_0 = \sqrt{\frac{Ebh^3}{4L^3 m_{\text{eff}}}}\,. \tag{23.12}$$

The effective mass can be calculated using Raleigh's method. The general formula using Raleigh's method for the kinetic energy T of a bar is

$$T = \frac{1}{2}\int_0^L \frac{m}{L}\left(\frac{\partial z(x)}{\partial t}\right)^2 \mathrm{d}x\,. \tag{23.13}$$

For the case of a uniform beam with a constant cross section and length L one obtains for the deflection

$$z(x) = z_{\max}\left[1 - \left(\frac{3x}{2L}\right) + \left(\frac{x^3}{2L^3}\right)\right]\,.$$

Inserting $z_{\max}$ into (23.13) and solving the integral gives

$$\begin{aligned} T &= \frac{1}{2}\int_0^L \frac{m}{L}\left[\frac{\partial z_{\max}(x)}{\partial t}\left(1 - \frac{3x}{2L}\right) + \left(\frac{x^3}{L^3}\right)\right]^2 \mathrm{d}x \\ &= \frac{1}{2} m_{\text{eff}}\,(z_{\max} t)^2 \end{aligned}$$

which gives

$$m_{\text{eff}} = \frac{9}{20}m\,. \tag{23.14}$$

Substituting (23.14) into (23.12) and noting that $m = \rho Lbh$, where ρ is the mass density, one obtains the following expression

$$\omega_0 = \left(\frac{\sqrt{5}}{3}\sqrt{\frac{E}{\rho}}\right)\frac{h}{L^2}\,. \tag{23.15}$$

It is evident from (23.15), that one way to increase the natural frequency is to choose a material with a high ratio E/ρ; see Table 23.2 for typical values of $\sqrt{E/\rho}$

of various commonly used materials. Another way to increase the lowest eigen-frequency is also evident in (23.15). By optimizing the ratio h/L^2, one can increase the resonant frequency. However, it does not help to make the length of the structure smaller than the width or height. Their roles will just be interchanged. Hence, the optimum structure is a cube. This leads to the design rule, that long, thin structures like sheet metal should be avoided. For a given resonant frequency, the quality factor Q should be as low as possible. This means that an inelastic medium such as rubber should be in contact with the structure to convert kinetic energy into heat.

Stiffness and Resonances of Cantilevers

Cantilevers are mechanical devices specially shaped to measure tiny forces. The analysis given in the previous section is applicable. However, to understand better the intricacies of force detection systems we will discuss the example of a cantilever beam with uniform cross section, Fig. 23.24. The bending of a beam due to a normal load on the beam is governed by the Euler equation [23.169]

$$M = EI(x)\frac{\mathrm{d}^2 z}{\mathrm{d}x^2}\,, \tag{23.16}$$

where M is the bending moment acting on the beam cross section. $I(x)$, the moment of inertia of the cross section with respect to the neutral axis, is defined by

$$I(x) = \int_z \int_y z^2 \mathrm{d}y\mathrm{d}z\,. \tag{23.17}$$

For a normal force F_z acting at the tip,

$$M(x) = (L-x)F_z \tag{23.18}$$

since the moment must vanish at the endpoint of the cantilever. Integrating (23.16) for a normal force F_z acting at the tip and observing that EI is a constant for beams with a uniform cross section, one gets

$$z(x) = \frac{L^3}{6EI}\left(\frac{x}{L}\right)^2\left(3-\frac{x}{L}\right)F_z\,. \tag{23.19}$$

The slope of the beam is

$$z'(x) = \frac{Lx}{2EI}\left(2-\frac{x}{L}\right)F_z\,. \tag{23.20}$$

From (23.19) and (23.20), at the end of the cantilever, i. e., for $x = L$, for a rectangular beam, and by using an expression for I in (23.11), one gets,

$$z(L) = \frac{4}{Eb}\left(\frac{L}{h}\right)^3 F_z\,, \tag{23.21}$$

$$z'(L) = \frac{3}{2}\left(\frac{z}{L}\right)\,. \tag{23.22}$$

Now the stiffness in the normal (z) direction, k_z, is

$$k_z = \frac{F_z}{z(L)} = \frac{Eb}{4}\left(\frac{h}{L}\right)^3 \tag{23.23}$$

and a change in angular orientation of the end of the cantilever beam is

$$\Delta\alpha = \frac{3}{2}\frac{z}{L} = \frac{6}{Ebh}\left(\frac{L}{h}\right)^2 F_z\,. \tag{23.24}$$

Now we ask what will, to first order, happen if we apply a lateral force F_y to the end of the tip (Fig. 23.24. The cantilever will bend sideways and it will twist. The stiffness in the lateral (y) direction, k_y, can be calculated with (23.23) by exchanging b and h

$$k_y = \frac{Eh}{4}\left(\frac{b}{L}\right)^3\,. \tag{23.25}$$

Therefore, the bending stiffness in the lateral direction is larger than the stiffness for bending in the normal direction by $(b/h)^2$. The twisting or torsion on the other side is more complicated to handle. For a wide, thin cantilever ($b \gg h$) we obtain torsional stiffness along the y-axis, $k_{y\mathrm{T}}$

$$k_{y\mathrm{T}} = \frac{Gbh^3}{3L\ell^2}\,, \tag{23.26}$$

where G is the modulus of rigidity [$= E/2(1+\nu)$, where ν is Poisson's ratio]. The ratio of the torsional stiffness to the lateral bending stiffness is

$$\frac{k_{y\mathrm{T}}}{k_y} = \frac{1}{2}\left(\frac{\ell b}{hL}\right)^2\,, \tag{23.27}$$

where we assume $\nu = 0.333$. We see that thin, wide cantilevers with long tips favor torsion while cantilevers with square cross sections and short tips favor bending. Finally, we calculate the ratio between the torsional stiffness and the normal bending stiffness,

$$\frac{k_{y\mathrm{T}}}{k_z} = 2\left(\frac{L}{\ell}\right)^2\,. \tag{23.28}$$

Equations (23.26) to (23.28) hold in the case where the cantilever tip is exactly in the middle axis of the cantilever. Triangular cantilevers and cantilevers with tips not on the middle axis can be dealt with by finite element methods.

The third possible deflection mode is the one from the force on the end of the tip along the cantilever axis, F_x (Fig. 23.24). The bending moment at the free end of

the cantilever is equal to $F_x\ell$. This leads to the following modification of (23.18) for the case of forces F_z and F_x

$$M(x) = (L-x)F_z + F_x\ell \,. \tag{23.29}$$

Integration of (23.16) now leads to

$$z(x) = \frac{1}{2EI}\left[Lx^2\left(1-\frac{x}{3L}\right)F_z + \ell x^2 F_x\right] \tag{23.30}$$

and

$$z'(x) = \frac{1}{EI}\left[\frac{Lx}{2}\left(2-\frac{x}{L}\right)F_z + \ell x F_x\right] \,. \tag{23.31}$$

Evaluating (23.30) and (23.31) at the end of the cantilever, we get the deflection and the tilt

$$\begin{aligned} z(L) &= \frac{L^2}{EI}\left(\frac{L}{3}F_z - \frac{\ell}{2}F_x\right) \,, \\ z'(x) &= \frac{L}{EI}\left(\frac{L}{2}F_z + \ell F_x\right) \,. \end{aligned} \tag{23.32}$$

From these equations, one gets

$$\begin{aligned} F_z &= \frac{12EI}{L^3}\left(z(L) - \frac{Lz'(L)}{2}\right) \,, \\ F_x &= \frac{2EI}{\ell L^2}\left(2Lz'(L) - 3z(L)\right) \,. \end{aligned} \tag{23.33}$$

A second class of interesting properties of cantilevers is their resonance behavior. For cantilever beams one can calculate the resonant frequencies [23.169, 170]

$$\omega_n^{\text{free}} = \frac{\lambda_n^2}{2\sqrt{3}}\frac{h}{L^2}\sqrt{\frac{E}{\rho}} \tag{23.34}$$

with $\lambda_0 = (0.596864\ldots)\pi$, $\lambda_1 = (1.494175\ldots)\pi$, $\lambda_n \to (n+1/2)\pi$. The subscript n represents the order of the frequency, e.g., fundamental, second mode, and the n-th mode.

A similar equation as (23.34) holds for cantilevers in rigid contact with the surface. Since there is an additional restriction on the movement of the cantilever, namely the location of its end point, the resonant frequency increases. Only the λ_n's terms change to [23.170]

$$\begin{aligned} \lambda_0' &= (1.2498763\ldots)\pi \,, \\ \lambda_1' &= (2.2499997\ldots)\pi \,, \\ \lambda_n' &\to \left(n+\frac{1}{4}\right)\pi \,. \end{aligned} \tag{23.35}$$

The ratio of the fundamental resonant frequency in contact to the fundamental resonant frequency not in contact is 4.3851.

For the torsional mode we can calculate the resonant frequencies as

$$\omega_0^{\text{tors}} = 2\pi\frac{h}{Lb}\sqrt{\frac{G}{\rho}} \,. \tag{23.36}$$

For cantilevers in rigid contact with the surface, we obtain the expression for the fundamental resonant frequency [23.170]

$$\omega_0^{\text{tors,contact}} = \frac{\omega_0^{\text{tors}}}{\sqrt{1+3\left(\frac{2L}{b}\right)^2}} \,. \tag{23.37}$$

The amplitude of the thermally induced vibration can be calculated from the resonant frequency using

$$\Delta z_{\text{therm}} = \sqrt{\frac{k_B T}{k}} \,, \tag{23.38}$$

where k_B is Boltzmann's constant and T is the absolute temperature. Since AFM cantilevers are resonant structures, sometimes with rather high Q, the thermal noise is not evenly distributed as (23.38) suggests. The spectral noise density below the peak of the response curve is [23.170]

$$z_0 = \sqrt{\frac{4k_B T}{k\omega_0 Q}} \quad \left\{\text{in m}/\sqrt{\text{Hz}}\right\} \,, \tag{23.39}$$

where Q is the quality factor of the cantilever, described earlier.

23.3.2 Instrumentation and Analyses of Detection Systems for Cantilever Deflections

A summary of selected detection systems was provided in Fig. 23.8. Here we discuss in detail the pros and cons of various systems.

Optical Interferometer Detection Systems

Interferometers. Soon after the first papers on the AFM [23.2], which used a tunneling sensor, an instrument based on an interferometer was presented [23.171]. The sensitivity of the interferometer depends on the wavelength of the light employed in the apparatus. Figure 23.25 shows the principle of such an interferometric design. The light incident from the left is

focused by a lens on the cantilever. The reflected light is collimated by the same lens and interferes with the light reflected at the flat. To separate the reflected light from the incident light a $\lambda/4$ plate converts the linear polarized incident light to circular polarization. The reflected light is made linearly polarized again by the $\lambda/4$ plate, but with a polarization orthogonal to that of the incident light. The polarizing beam splitter then deflects the reflected light to the photodiode.

Homodyne Interferometer. To improve the signal-to-noise ratio of the interferometer the cantilever is driven by a piezo near its resonant frequency. The amplitude Δz of the cantilever as a function of driving frequency Ω is

$$\Delta z(\Omega) = \Delta z_0 \frac{\Omega_0^2}{\sqrt{\left(\Omega^2 - \Omega_0^2\right)^2 + \frac{\Omega^2 \Omega_0^2}{Q^2}}} , \qquad (23.40)$$

where Δz_0 is the constant drive amplitude and Ω_0 the resonant frequency of the cantilever. The resonant frequency of the cantilever is given by the effective potential

$$\Omega_0 = \sqrt{\left(k + \frac{\partial^2 U}{\partial z^2}\right) \frac{1}{m_{\text{eff}}}} \qquad (23.41)$$

where U is the interaction potential between the tip and the sample. Equation (23.41) shows that an attractive potential decreases Ω_0. The change in Ω_0 in turn results in a change of the Δz (see (23.40)). The movement of the cantilever changes the path difference in the interferometer. The light reflected from the cantilever with the amplitude $A_{\ell,0}$ and the reference light with the amplitude $A_{r,0}$ interfere on the detector. The detected

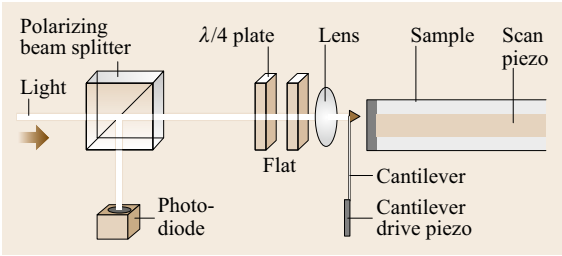

Fig. 23.25 Principle of an interferometric AFM. The light of the laser light source is polarized by the polarizing beam splitter and focused on the back of the cantilever. The light passes twice through a quarter wave plate and is hence orthogonally polarized to the incident light. The second arm of the interferometer is formed by the flat. The interference pattern is modulated by the oscillating cantilever

intensity

$$I(t) = \{A_\ell(t) + A_r(t)\}^2$$

consists of two constant terms and a fluctuating term

$$2A_\ell(t)A_r(t) = A_{\ell,0}A_{r,0} \sin\left[\omega t + \frac{4\pi\delta}{\lambda} + \frac{4\pi\Delta z}{\lambda} \sin(\Omega t)\right] \sin(\omega t) . \qquad (23.42)$$

Here ω is the frequency of the light, λ is the wavelength of the light, δ is the path difference in the interferometer, and Δz is the instantaneous amplitude of the cantilever, given according to (23.40) and (23.41) as a function of Ω, k, and U. The time average of (23.42) then becomes

$$\begin{aligned}\langle 2A_\ell(t)A_r(t)\rangle_{\text{T}} &\propto \cos\left[\frac{4\pi\delta}{\lambda} + \frac{4\pi\Delta z}{\lambda} \sin(\Omega t)\right] \\ &\approx \cos\left(\frac{4\pi\delta}{\lambda}\right) - \sin\left[\frac{4\pi\Delta z}{\lambda} \sin(\Omega t)\right] \\ &\approx \cos\left(\frac{4\pi\delta}{\lambda}\right) - \frac{4\pi\Delta z}{\lambda} \sin(\Omega t) .\end{aligned} \qquad (23.43)$$

Here all small quantities have been omitted and functions with small arguments have been linearized. The amplitude of Δz can be recovered with a lock-in technique. However, (23.43) shows that the measured amplitude is also a function of the path difference δ in the interferometer. Hence this path difference δ must be very stable. The best sensitivity is obtained when $\sin(4\delta/\lambda) \approx 0$.

Heterodyne Interferometer. This influence is not present in the heterodyne detection scheme shown in Fig. 23.26. Light incident from the left with a frequency ω is split into a reference path (upper path in Fig. 23.26) and a measurement path. Light in the measurement path is shifted in frequency to $\omega_1 = \omega + \Delta\omega$ and focused on the cantilever. The cantilever oscillates at the frequency Ω, as in the homodyne detection scheme. The reflected light $A_\ell(t)$ is collimated by the same lens and interferes on the photodiode with the reference light $A_r(t)$. The fluctuating term of the intensity is given by

$$2A_\ell(t)A_r(t) = A_{\ell,0}A_{r,0} \sin\left[(\omega + \Delta\omega)t + \frac{4\pi\delta}{\lambda} + \frac{4\pi\Delta z}{\lambda} \sin(\Omega t)\right] \sin(\omega t) , \qquad (23.44)$$

where the variables are defined as in (23.42). Setting the path difference $\sin(4\pi\delta/\lambda) \approx 0$ and taking the time average, omitting small quantities and linearizing functions with small arguments we get

$$
\begin{aligned}
&\langle 2A_\ell(t)A_r(t)\rangle_\mathrm{T} \\
&\propto \cos\left[\Delta\omega t + \frac{4\pi\delta}{\lambda} + \frac{4\pi\Delta z}{\lambda}\sin(\Omega t)\right] \\
&= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\cos\left[\frac{4\pi\Delta z}{\lambda}\sin(\Omega t)\right] \\
&\quad - \sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin\left[\frac{4\pi\Delta z}{\lambda}\sin(\Omega t)\right] \\
&\approx \cos\left(\frac{4\pi\delta}{\lambda}\right) - \sin\left[\frac{4\pi\Delta z}{\lambda}\sin(\Omega t)\right] \\
&\approx \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\left[1 - \frac{8\pi^2\Delta z^2}{\lambda^2}\sin(\Omega t)\right] \\
&\quad - \frac{4\pi\Delta z}{\lambda}\sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin(\Omega t) \\
&= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right) - \frac{8\pi^2\Delta z^2}{\lambda^2} \\
&\quad \times \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin(\Omega t) \\
&\quad - \frac{4\pi\Delta z}{\lambda}\sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin(\Omega t) \\
&= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right) - \frac{4\pi^2\Delta z^2}{\lambda^2} \\
&\quad \times \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right) \\
&\quad + \frac{4\pi^2\Delta z^2}{\lambda^2}\cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\cos(2\Omega t) \\
&\quad - \frac{4\pi\Delta z}{\lambda}\sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin(\Omega t) \\
&= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\left(1 - \frac{4\pi^2\Delta z^2}{\lambda^2}\right) \\
&\quad + \frac{2\pi^2\Delta z^2}{\lambda^2}\left(\cos\left[(\Delta\omega + 2\Omega)\,t + \frac{4\pi\delta}{\lambda}\right]\right. \\
&\quad \left. + \cos\left[(\Delta\omega - 2\Omega)\,t + \frac{4\pi\delta}{\lambda}\right]\right) \\
&\quad + \frac{2\pi\Delta z}{\lambda}\left(\cos\left[(\Delta\omega + \Omega)\,t + \frac{4\pi\delta}{\lambda}\right]\right. \\
&\quad \left. + \cos\left[(\Delta\omega - \Omega)\,t + \frac{4\pi\delta}{\lambda}\right]\right) .
\end{aligned}
\tag{23.45}
$$

Multiplying electronically the components oscillating at $\Delta\omega$ and $\Delta\omega + \Omega$ and rejecting any product except the one oscillating at Ω we obtain

$$
\begin{aligned}
A &= \frac{2\Delta z}{\lambda}\left(1 - \frac{4\pi^2\Delta z^2}{\lambda^2}\right) \\
&\quad \times \cos\left[(\Delta\omega + 2\Omega)\,t + \frac{4\pi\delta}{\lambda}\right] \\
&\quad \times \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right) \\
&= \frac{\Delta z}{\lambda}\left(1 - \frac{4\pi^2\Delta z^2}{\lambda^2}\right) \\
&\quad \times \left(\cos\left[(2\Delta\omega + \Omega)\,t + \frac{8\pi\delta}{\lambda}\right] + \cos(\Omega t)\right) \\
&\approx \frac{\pi\Delta z}{\lambda}\cos(\Omega t) \ .
\end{aligned}
\tag{23.46}
$$

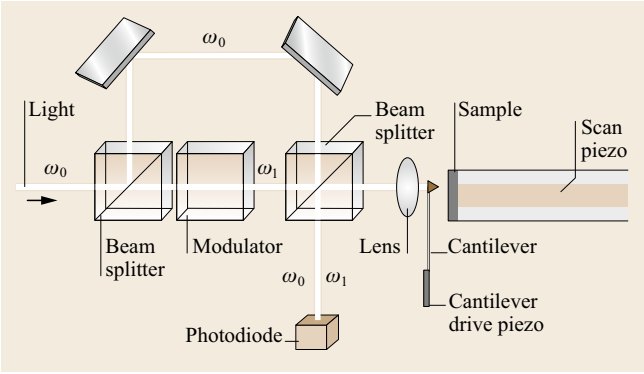

Fig. 23.26 Principle of a heterodyne interferometric AFM. Light with the frequency ω_0 is split into a reference path (upper path) and a measurement path. The light in the measurement path is frequency shifted to ω_1 by an acousto-optical modulator (or an electro-optical modulator). The light reflected from the oscillating cantilever interferes with the reference beam on the detector

Unlike in the homodyne detection scheme the recovered signal is independent from the path difference δ of the interferometer. Furthermore, a lock-in amplifier with the reference set $\sin(\Delta\omega t)$ can measure the path difference δ independent of the cantilever oscillation. If necessary, a feedback circuit can keep $\delta = 0$.

Fiber-optical Interferometer. The fiber-optical interferometer [23.150] is one of the simplest interferometers to build and use. Its principle is sketched in Fig. 23.27. The light of a laser is fed into an optical fiber. Laser diodes with integrated fiber pigtails are convenient light sources. The light is split in a fiber-optic beam splitter into two fibers. One fiber is terminated by index matching oil to avoid any reflections back into the fiber. The end of the other fiber is brought close to the

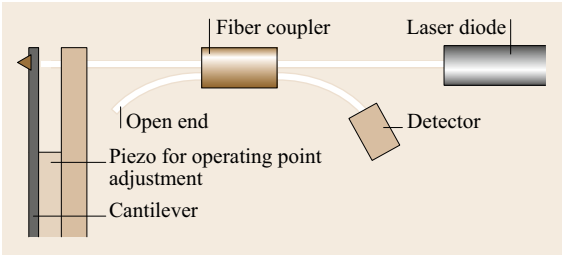

Fig. 23.27 A typical setup for a fiber-optic interferometer readout

cantilever in the AFM. The emerging light is partially reflected back into the fiber by the cantilever. Most of the light, however, is lost. This is not a big problem since only 4% of the light is reflected at the end of the fiber, at the glass-air interface. The two reflected light waves interfere with each other. The product is guided back into the fiber coupler and again split into two parts. One half is analyzed by the photodiode. The other half is fed back into the laser. Communications-grade laser diodes are sufficiently resistant against feedback to be operated in this environment. They have, however, a bad coherence length, which in this case does not matter, since the optical path difference is in any case no larger than 5 μm. Again the end of the fiber has to be positioned on a piezo drive to set the distance between the fiber and the cantilever to $\lambda(n+1/4)$.

Nomarski Interferometer. Another solution to minimize the optical path difference is to use the Nomarski interferometer [23.151]. Figure 23.28 shows a schematic of the microscope. The light of a laser is focused on the cantilever by a lens. A birefringent crystal (for instance calcite) between the cantilever and the lens with its optical axis 45° off the polarization direction of the light splits the light beam into two paths, offset by a distance given by the length of the crystal. Birefringent crystals have varying indexes of refraction. In calcite, one crystal axis has a lower index than the other two. This means, that certain light rays will propagate at a different speed through the crystal than the others. By choosing a correct polarization, one can select the ordinary ray, the extraordinary ray or one can get any distribution of the intensity amongst those two rays. A detailed description of birefringence can be found in textbooks (e.g., [23.172]). A calcite crystal deflects the extraordinary ray at an angle of 6° within the crystal. By choosing a suitable length of the calcite crystal, any separation can be set.

The focus of one light ray is positioned near the free end of the cantilever while the other is placed close to the clamped end. Both arms of the interferometer pass

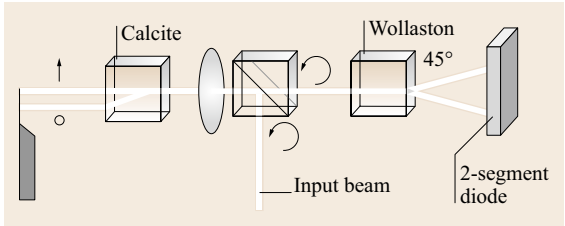

Fig. 23.28 Principle of the Nomarski AFM. The circular polarized input beam is deflected to the left by a nonpolarizing beam splitter. The light is focused onto a cantilever. The calcite crystal between the lens and the cantilever splits the circular polarized light into two spatially separated beams with orthogonal polarizations. The two light beams reflected from the lever are superimposed by the calcite crystal and collected by the lens. The resulting beam is again circular polarized. A Wollaston prism produces two interfering beams with $\pi/2$ phase shift between them. The minimal path difference accounts for the excellent stability of this microscope

through the same space, except for the distance between the calcite crystal and the lever. The closer the calcite crystal is placed to the lever, the less influence disturbances like air currents have.

Sensitivity. *Sarid* [23.137] has given values for the sensitivity of the different interferometric detection systems. Table 23.5 presents a summary of his results.

Optical Lever

The most common cantilever deflection detection system is the optical lever [23.62, 132]. This method, depicted in Fig. 23.29, employs the same technique as light beam deflection galvanometers. A fairly well collimated light beam is reflected off a mirror and projected to a receiving target. Any change in the angular position of the mirror will change the position at which the light ray hits the target. Galvanometers use optical path lengths of several meters and scales projected to the target wall as a read-out aid.

For the AFM using the optical lever method a photodiode segmented into two (or four) closely spaced devices detects the orientation of the end of the cantilever. Initially, the light ray is set to hit the photodiodes in the middle of the two subdiodes. Any deflection of the cantilever will cause an imbalance of the number of photons reaching the two halves. Hence, the electrical currents in the photodiodes will be unbalanced too. The difference signal is further amplified and is the input signal to the feedback loop. Unlike the interferometric AFMs, where often a modulation technique is necessary to get a sufficient signal-to-noise ratio, most AFMs employing the optical lever

Table 23.5 Noise in interferometers. F is the finesse of the cavity in the homodyne interferometer, P_i the incident power, P_d is the power on the detector, η is the sensitivity of the photodetector, and RIN is the relative intensity noise of the laser. P_R and P_S are the power in the reference and sample beam in the heterodyne interferometer. P is the power in the Nomarski interferometer, $\delta\theta$ is the phase difference between the reference and the probe beam in the Nomarski interferometer. B is the bandwidth, e is the electron charge, λ is the wavelength of the laser, k the cantilever stiffness, ω_0 is the resonant frequency of the cantilever, Q is the quality factor of the cantilever, T is the temperature, and δi is the variation of current i

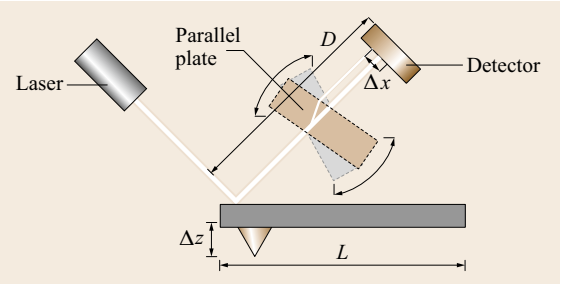

Fig. 23.29 The setup of the optical lever detection microscope

method are operated in a static mode. AFMs based on the optical lever method are universally used. It is the simplest method to construct an optical readout and it can be confined in volumes smaller than 5 cm on the side.

The optical lever detection system is a simple yet elegant way to detect normal and lateral force signals simultaneously [23.6, 7, 62, 132]. It has the additional advantage that it is a remote detection system.

Implementations. Light from a laser diode or from a super luminescent diode is focused on the end of the cantilever. The reflected light is directed onto a quadrant diode that measures the direction of the light beam. A Gaussian light beam far from its waist is characterized by an opening angle β. The deflection of the light beam by the cantilever surface tilted by an angle α is 2α. The intensity on the detector then shifts to the side by the product of 2α and the separation between the detector and the cantilever. The readout electronics calculates the difference of the photocurrents. The photocurrents in turn are proportional to the intensity incident on the diode.

The output signal is hence proportional to the change in intensity on the segments

$$I_\mathrm{sig} \propto 4\frac{\alpha}{\beta} I_\mathrm{tot} \,. \tag{23.47}$$

For the sake of simplicity, we assume that the light beam is of uniform intensity with its cross section increasing proportional to the distance between the cantilever and the quadrant detector. The movement of the center of the light beam is then given by

$$\Delta x_\mathrm{Det} = \Delta z \frac{D}{L} \,. \tag{23.48}$$

The photocurrent generated in a photodiode is proportional to the number of incoming photons hitting it. If the light beam contains a total number of N_0 photons then the change in difference current becomes

$$\Delta \left(I_\mathrm{R} - I_\mathrm{L}\right) = \Delta I = \mathrm{const}\, \Delta z D N_0 \,. \tag{23.49}$$

Combining (23.48) and (23.49), one obtains that the difference current ΔI is independent of the separation of the quadrant detector and the cantilever. This relation is true, if the light spot is smaller than the quadrant detector. If it is greater, the difference current ΔI becomes smaller with increasing distance. In reality the light beam has a Gaussian intensity profile. For small movements Δx (compared to the diameter of the light spot at the quadrant detector), (23.49) still holds. Larger movements Δx, however, will introduce a nonlinear response. If the AFM is operated in a constant force mode, only small movements Δx of the light spot will occur. The feedback loop will cancel out all other movements.

The scanning of a sample with an AFM can twist the microfabricated cantilevers because of lateral

forces [23.4, 6, 7] and affect the images [23.141]. When the tip is subjected to lateral forces, it will twist the cantilever and the light beam reflected from the end of the cantilever will be deflected perpendicular to the ordinary deflection direction. For many investigations this influence of lateral forces is unwanted. The design of the triangular cantilever stems from the desire to minimize the torsion effects. However, lateral forces open up a new dimension in force measurements. They allow, for instance, a distinction between two materials because of the different friction coefficient, or the determination of adhesion energies. To measure lateral forces the original optical lever AFM has to be modified. The only modification compared with Fig. 23.29 is the use of a quadrant detector photodiode instead of a two-segment photodiode and the necessary readout electronics, see Fig. 23.9a. The electronics calculates the following signals

$$\begin{aligned} U_{\text{NormalForce}} &= \alpha\left[\left(I_{\text{UpperLeft}} + I_{\text{UpperRight}}\right) - \right. \\ &\quad \left.\left(I_{\text{LowerLeft}} + I_{\text{LowerRight}}\right)\right] , \\ U_{\text{LateralForce}} &= \beta\left[\left(I_{\text{UpperLeft}} + I_{\text{LowerLeft}}\right) - \right. \\ &\quad \left.\left(I_{\text{UpperRight}} + I_{\text{LowerRight}}\right)\right] . \end{aligned} \tag{23.50}$$

The calculation of the lateral force as a function of the deflection angle does not have a simple solution for cross sections other than circles. An approximate formula for the angle of twist for rectangular beams is [23.173]

$$\theta = \frac{M_t L}{\beta G b^3 h} , \tag{23.51}$$

where $M_t = F_y \ell$ is the external twisting moment due to lateral force, F_y, and β a constant determined by the value of h/b. For the equation to hold, h has to be larger than b.

Inserting the values for a typical microfabricated cantilever with integrated tips

$$\begin{aligned} b &= 6\times10^{-7}\,\text{m} \\ h &= 10^{-5}\,\text{m} \\ L &= 10^{-4}\,\text{m} \\ \ell &= 3.3\times10^{-6}\,\text{m} \\ G &= 5\times10^{10}\,\text{Pa} \\ \beta &= 0.333 \end{aligned} \tag{23.52}$$

into (23.51) we obtain the relation

$$F_y = 1.1\times10^{-4} N\times\theta . \tag{23.53}$$

Typical lateral forces are of order 10^{-10} N.

Sensitivity. The sensitivity of this setup has been calculated in various papers [23.137, 170, 174]. Assuming a Gaussian beam the resulting output signal as a function of the deflection angle is dispersion-like. (23.47) shows that the sensitivity can be increased by increasing the intensity of the light beam I_{tot} or by decreasing the divergence of the laser beam. The upper bound of the intensity of the light I_{tot} is given by saturation effects on the photodiode. If we decrease the divergence of a laser beam we automatically increase the beam waist. If the beam waist becomes larger than the width of the cantilever we start to get diffraction. Diffraction sets a lower bound on the divergence angle. Hence, one can calculate the optimal beam waist w_{opt} and the optimal divergence angle β [23.170, 174]

$$\begin{aligned} w_{\text{opt}} &\approx 0.36b \\ \theta_{\text{opt}} &\approx 0.89\frac{\lambda}{b} . \end{aligned} \tag{23.54}$$

The optimal sensitivity of the optical lever then becomes

$$\varepsilon\left[\frac{\text{mW}}{\text{rad}}\right] = 1.8\frac{b}{\lambda} I_{\text{tot}}\,[\text{mW}] . \tag{23.55}$$

The angular sensitivity of the optical lever can be measured by introducing a parallel plate into the beam. A tilt of the parallel plate results in a displacement of the beam, mimicking an angular deflection.

An additional noise source can be considered. Of little importance is the quantum mechanical uncertainty of the position [23.170, 174], which is for typical cantilevers at room temperature

$$\Delta z = \sqrt{\frac{\hbar}{2m\omega_0}} = 0.05\,\text{fm} , \tag{23.56}$$

where $\hbar$ is the Planck constant ($= 6.626\times10^{-34}$ Js). At very low temperatures and for high-frequency cantilevers this could become the dominant noise source. A second noise source is the shot noise of the light. The shot noise is related to the particle number. We can calculate the number of photons incident on the detector

$$n = \frac{I\tau}{\hbar\omega} = \frac{I\lambda}{2\pi B\hbar c} = 1.8\times10^{9}\frac{I\,[\text{W}]}{B\,[\text{Hz}]} , \tag{23.57}$$

where I is the intensity of the light, τ the measurement time, $B = 1/\tau$ the bandwidth, and c the speed of light. The shot noise is proportional to the square root of the number of particles. Equating the shot noise signal with the signal resulting for the deflection of the cantilever

one obtains

$$\Delta z_{\text{shot}} = 68\frac{L}{w}\sqrt{\frac{B\,[\text{kHz}]}{I\,[\text{mW}]}}[\text{fm}]\,, \tag{23.58}$$

where w is the diameter of the focal spot. Typical AFM setups have a shot noise of 2 pm. The thermal noise can be calculated from the equipartition principle. The amplitude at the resonant frequency is

$$\Delta z_{\text{therm}} = 129\sqrt{\frac{B}{k\,[\text{N/m}]\omega_0 Q}}[\text{pm}]\,. \tag{23.59}$$

A typical value is 16 pm. Upon touching the surface, the cantilever increases its resonant frequency by a factor of 4.39. This results in a new thermal noise amplitude of 3.2 pm for the cantilever in contact with the sample.

Piezoresistive Detection

Implementations. An alternative detection system which is not as widely spread as the optical detection schemes are piezoresistive cantilevers [23.146, 147, 153]. These cantilevers are based on the fact that the resistivity of certain materials, in particular of Si, changes with the applied stress. Figure 23.30 shows a typical implementation of a piezoresistive cantilever. Four resistances are integrated on the chip, forming a Wheatstone bridge. Two of the resistors are in unstrained parts of the cantilever, the other two measure the bending at the point of maximal deflection. For instance, when an AC voltage is applied between terminals a and c one can measure the detuning of the bridge between terminals b and d. With such a connection the output signal varies only due to bending, but not due to changing the ambient temperature and thus the coefficient of piezoresistance.

Sensitivity. The resistance change is [23.147]

$$\frac{\Delta R}{R_0} = \Pi\delta\,, \tag{23.60}$$

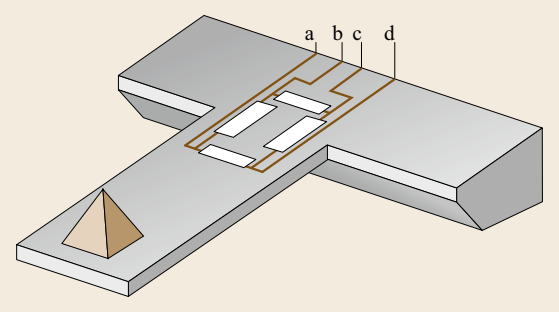

Fig. 23.30 A typical setup for a piezoresistive readout

where Π is the tensor element of the piezoresistive coefficients, δ the mechanical stress tensor element, and R_0 the equilibrium resistance. For a single resistor they separate the mechanical stress and the tensor element in longitudinal and transversal components

$$\frac{\Delta R}{R_0} = \Pi_{\text{t}}\delta_{\text{t}} + \Pi_{\text{l}}\delta_{\text{l}}\,. \tag{23.61}$$

The maximum value of the stress components are $\Pi_{\text{t}} = -64.0\times10^{-11}\,\text{m}^2/\text{N}$ and $\Pi_{\text{l}} = -71.4\times10^{-11}\,\text{m}^2/\text{N}$ for a resistor oriented along the (110)-direction in silicon [23.147]. In the resistor arrangement of Fig. 23.30, two of the resistors are subject to the longitudinal piezoresistive effect and two of them are subject to the transverse piezoresistive effect. The sensitivity of that setup is about four times that of a single resistor, with the advantage that temperature effects cancel to first order. The resistance change is then calculated as

$$\frac{\Delta R}{R_0} = \Pi\frac{3Eh}{2L^2}\Delta z = \Pi\frac{6L}{bh^2}F_z\,, \tag{23.62}$$

where $\Pi = 67.7\times10^{-11}\,\text{m}^2/\text{N}$ is the averaged piezoresistive coefficient. Plugging in typical values for the dimensions (Fig. 23.24) ($L = 100\,\mu\text{m}$, $b = 10\,\mu\text{m}$, $h = 1\,\mu\text{m}$) one obtains

$$\frac{\Delta R}{R_0} = \frac{4\times10^{-5}}{nN}F_z\,. \tag{23.63}$$

The sensitivity can be tailored by optimizing the dimensions of the cantilever.

Capacitance Detection

The capacitance of an arrangement of conductors depends on the geometry. Generally speaking, the capacitance increases for decreasing separations. Two parallel plates form a simple capacitor (see Fig. 23.31, upper left), with the capacitance

$$C = \frac{\varepsilon\varepsilon_0 A}{x} \tag{23.64}$$

where A is the area of the plates, assumed equal, and x is the separation. Alternatively, one can consider a sphere versus an infinite plane (see Fig. 23.31, lower left). Here the capacitance is [23.137]

$$C = 4\pi\varepsilon_0 R\sum_{n=2}^{\infty}\frac{\sinh(\alpha)}{\sinh(n\alpha)}\,, \tag{23.65}$$

where R is the radius of the sphere, and α is defined by

$$\alpha = \ln\left(1+\frac{z}{R}+\sqrt{\frac{z^2}{R^2}+2\frac{z}{R}}\right)\,. \tag{23.66}$$

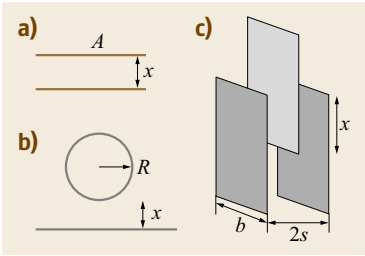

Fig. 23.31a–c Three possible arrangements of a capacitive readout. The **(a)** shows the cross section through a parallel plate capacitor. The **(b)** shows the geometry sphere versus plane. The **(c)** shows the more complicated, but linear capacitive readout

One has to keep in mind that capacitance of a parallel plate capacitor is a nonlinear function of the separation. Using a voltage divider one can circumvent this problem. Figure 23.32a shows a low-pass filter. The output voltage is given by

$$U_{\text{out}} = U_{\approx}\frac{\frac{1}{\mathrm{i}\omega C}}{R+\frac{1}{\mathrm{i}\omega C}} = U_{\approx}\frac{1}{J\omega CR+1} \cong \frac{U_{\approx}}{J\omega CR}\,. \tag{23.67}$$

Here, $U_{\approx}$ is the driving voltage, C is given by (23.64), ω is the excitation frequency, and i is the imaginary unit. The approximate relation in the end is true when $\omega CR \gg 1$. This is equivalent to the statement that C is fed by a current source, since R must be large in this setup. Plugging (23.64) into (23.67) and neglecting the phase information one obtains

$$U_{\text{out}} = \frac{U_{\approx}x}{\omega R\varepsilon\varepsilon_0 A} \tag{23.68}$$

which is linear in the displacement x.

Figure 23.32b shows a capacitive divider. Again the output voltage U_{out} is given by

$$U_{\text{out}} = U_{\approx}\frac{C_1}{C_2+C_1} = U_{\approx}\frac{C_1}{\frac{\varepsilon\varepsilon_0 A}{x}+C_1}\,. \tag{23.69}$$

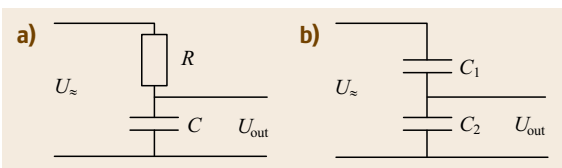

Fig. 23.32a,b Measuring the capacitance. The *left side*, **(a)**, shows a low-pass filter, the *right side*, **(b)**, shows a capacitive divider. C (*left*) or C_2 (*right*) are the capacitances under test

If there is a stray capacitance C_{s} then (23.69) is modified as

$$U_{\text{out}} = U_{\approx}\frac{C_1}{\frac{\varepsilon\varepsilon_0 A}{x}+C_{\text{s}}+C_1}\,. \tag{23.70}$$

Provided $C_{\text{s}}+C_1 \ll C_2$ one has a system which is linear in x. The driving voltage $U_{\approx}$ has to be large (more than 100 V) to have the output voltage in the range of 1 V. The linearity of the readout depends on the capacitance C_1 (Fig. 23.33).

Another idea is to keep the distance constant and to change the relative overlap of the plates (see Fig. 23.31, right side). The capacitance of the moving center plate versus the stationary outer plates becomes

$$C = C_{\text{s}} + 2\frac{\varepsilon\varepsilon_0 bx}{S}\,, \tag{23.71}$$

where the variables are defined in Fig. 23.31. The stray capacitance comprises all effects, including the capacitance of the fringe fields. When length x is comparable to the width b of the plates one can safely assume that the stray capacitance is constant, independent of x. The main disadvantage of this setup is that it is not as easily incorporated in a microfabricated device as the others.

Sensitivity. The capacitance itself is not a measure of the sensitivity, but its derivative is indicative of the signals one can expect. Using the situation described in Fig. 23.31, upper left, and in (23.64) one obtains for the

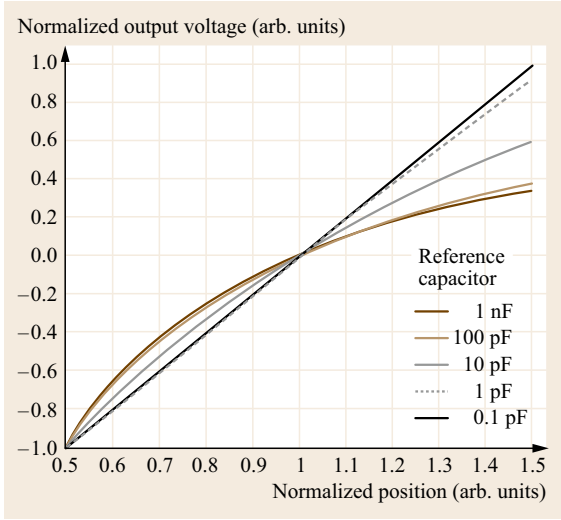

Fig. 23.33 Linearity of the capacitance readout as a function of the reference capacitor

parallel plate capacitor

$$\frac{\mathrm{d}C}{\mathrm{d}x} = -\frac{\varepsilon\varepsilon_0 A}{x^2} \,. \tag{23.72}$$

Assuming a plate area A of 20 µm by 40 µm and a separation of 1 µm one obtains a capacitance of 31 fF (neglecting stray capacitance and the capacitance of the connection leads) and a $\mathrm{d}C/\mathrm{d}x$ of $3.1\times10^{-8}\,\mathrm{F/m} = 31\,\mathrm{fF/\mu m}$. Hence, it is of paramount importance to maximize the area between the two contacts and to minimize the distance x. The latter however is far from being trivial. One has to go to the limits of microfabrication to achieve a decent sensitivity.

If the capacitance is measured by the circuit shown in Fig. 23.32 one obtains for the sensitivity

$$\frac{\mathrm{d}U_{\mathrm{out}}}{U_{\approx}} = \frac{\mathrm{d}x}{\omega R\varepsilon\varepsilon_0 A} \,. \tag{23.73}$$

Using the same value for A as above, setting the reference frequency to 100 kHz, and selecting $R = 1\,\mathrm{G\Omega}$, we get the relative change of the output voltage U_{out} to

$$\frac{\mathrm{d}U_{\mathrm{out}}}{U_{\approx}} = \frac{22.5\times10^{-6}}{\text{Å}}\mathrm{d}x \,. \tag{23.74}$$

A driving voltage of 45 V then translates to a sensitivity of 1 mV/Å. A problem in this setup is the stray capacitances. They are in parallel to the original capacitance and decrease the sensitivity considerably.

Alternatively one could build an oscillator with this capacitance and measure the frequency. RC-oscillators typically have an oscillation frequency of

$$f_{\mathrm{res}} \propto \frac{1}{RC} = \frac{x}{R\varepsilon\varepsilon_0 A} \,. \tag{23.75}$$

Again the resistance R must be of the order of 1 GΩ, when stray capacitances C_{s} are neglected. However C_{s} is of the order of 1 pF. Therefore, one gets $R = 10\,\mathrm{M\Omega}$. Using these values the sensitivity becomes

$$\mathrm{d}f_{\mathrm{res}} = \frac{C\mathrm{d}x}{R\,(C+C_{\mathrm{s}})^2\,x} \approx \frac{0.1\,\mathrm{Hz}}{\text{Å}}\mathrm{d}x \,. \tag{23.76}$$

The bad thing is that the stray capacitances have made the signal nonlinear again. The linearized setup in Fig. 23.31 has a sensitivity of

$$\frac{\mathrm{d}C}{\mathrm{d}x} = 2\frac{\varepsilon\varepsilon_0 b}{s} \,. \tag{23.77}$$

Substituting typical values, $b = 10\,\mu\mathrm{m}$, $s = 1\,\mu\mathrm{m}$ one gets $\mathrm{d}C/\mathrm{d}x = 1.8\times10^{-10}\,\mathrm{F/m}$. It is noteworthy that the sensitivity remains constant for scaled devices.

Implementations. The readout of the capacitance can be done in different ways [23.144, 145]. All include an alternating current or voltage with frequencies in the 100 kHz to 100 MHz range. One possibility is to build a tuned circuit with the capacitance of the cantilever determining the frequency. The resonance frequency of a high-quality Q-tuned circuit is

$$\omega_0 = (LC)^{-\frac{1}{2}} \,, \tag{23.78}$$

where L is the inductance of the circuit. The capacitance C includes not only the sensor capacitance but also the capacitance of the leads. The precision of a frequency measurement is mainly determined by the ratio of L and C

$$Q = \left(\frac{L}{C}\right)^{\frac{1}{2}} \frac{1}{R} \,. \tag{23.79}$$

Here R symbolizes the losses in the circuit. The higher the quality the more precise the frequency measurement. For instance, a frequency of 100 MHz and a capacitance of 1 pF gives an inductance of 250 µH. The quality then becomes 2.5×10^8. This value is an upper limit, since losses are usually too high.

Using a value of $\mathrm{d}C/\mathrm{d}x = 31\,\mathrm{fF/\mu m}$ one gets $\Delta C/\text{Å} = 3.1\,\mathrm{aF/Å}$. With a capacitance of 1 pF one gets

$$\frac{\Delta\omega}{\omega} = \frac{1}{2}\frac{\Delta C}{C} \,,$$
$$\Delta\omega = 100\,\mathrm{MHz}\times\frac{1}{2}\frac{3.1\,\mathrm{aF}}{1\,\mathrm{pF}} = 155\,\mathrm{Hz} \,. \tag{23.80}$$

This is the frequency shift for 1 Å deflection. The calculation shows, that this is a measurable quantity. The quality also indicates that there is no physical reason why this scheme should not work.

23.3.3 Combinations for 3-D-Force Measurements

Three-dimensional force measurements are essential if one wants to know all the details of the interaction between the tip and the cantilever. The straightforward attempt to measure three forces is complicated, since force sensors such as interferometers or capacitive sensors need a minimal detection volume, which often is too large. The second problem is that the force-sensing tip has to be held by some means. This implies that one of the three Cartesian axes is stiffer than the others.

However, through the combination of different sensors one can achieve this goal. Straight cantilevers are employed for these measurements, because they can be

handled analytically. The key observation is that the optical lever method does not determine the position of the end of the cantilever; it measures the orientation. In the previous sections, one has always made use of the fact that for a force along one of the orthogonal symmetry directions at the end of the cantilever (normal force, lateral force, force along the cantilever beam axis) there is a one-to-one correspondence of the tilt angle and the deflection. The problem is that the force along the cantilever beam axis and the normal force create a deflection in the same direction. Hence, what is called the normal force component is actually a mixture of two forces. The deflection of the cantilever is the third quantity, which is not considered in most of the AFMs. A fiber-optic interferometer in parallel with the optical lever measures the deflection. Three measured quantities then allow the separation of the three orthonormal force directions, as is evident from (23.27) and (23.33) [23.12–16].

Alternatively one can put the fast scanning direction along the axis of the cantilever. Forward and backward scans then exert opposite forces F_x. If the piezo movement is linearized, both force components in AFM based on the optical lever detection can be determined. In this case, the normal force is simply the average of the forces in the forward and backward direction. The force from the front, F_x, is the difference of the forces measured in forward and backward direction.

23.3.4 Scanning and Control Systems

Almost all SPMs use piezo translators to scan the tip or the sample. Even the first STM [23.1, 122] and some of the predecessor instruments [23.175, 176] used them. Other materials or setups for nanopositioning have been proposed, but were not successful [23.177, 178].

Piezo Tubes

A popular solution is tube scanners (Fig. 23.34). They are now widely used in SPMs due to their simplicity and their small size [23.154, 179]. The outer electrode is segmented in four equal sectors of 90°. Opposite sectors are driven by signals of the same magnitude, but opposite sign. This gives, through bending, a two-dimensional movement on, approximately, a sphere. The inner electrode is normally driven by the z-signal. It is possible, however, to use only the outer electrodes for scanning and for the z-movement. The main drawback of applying the z-signal to the outer electrodes is that the applied voltage is the sum of both the x- or y-movement and the z-movement. Hence, a larger scan size effectively reduces the available range for the z-control.

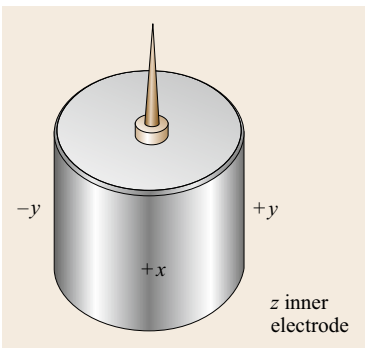

Fig. 23.34 Schematic drawing of a piezoelectric tube scanner. The piezo ceramic is molded into a tube form. The outer electrode is separated into four segments and connected to the scanning voltages. The z-voltage is applied to the inner electrode

Piezo Effect

An electric field applied across a piezoelectric material causes a change in the crystal structure, with expansion in some directions and contraction in others. Also, a net volume change occurs [23.153]. Many SPMs use the transverse piezoelectric effect, where the applied electric field $\boldsymbol{E}$ is perpendicular to the expansion/contraction direction.

$$\Delta L = L\,(\boldsymbol{E}\cdot\boldsymbol{n})\,d_{31} = L\frac{V}{t}d_{31}\,, \tag{23.81}$$

where d_{31} is the transverse piezoelectric constant, V is the applied voltage, t is the thickness of the piezo slab or the distance between the electrodes where the voltage is applied, L is the free length of the piezo slab, and $\boldsymbol{n}$ is the direction of polarization. Piezo translators based on the transverse piezoelectric effect have a wide range of sensitivities, limited mainly by mechanical stability and breakdown voltage.

Scan Range

The calculation of the scanning range of a piezo tube is difficult [23.179–181]. The bending of the tube depends on the electric fields and the nonuniform strain induced. A finite element calculation where the piezo tube was divided into 218 identical elements was used [23.180] to calculate the deflection. On each node the mechanical stress, stiffness, strain, and piezoelectric stress was calculated when a voltage was applied on one electrode. The results were found to be linear on the first iteration and higher order corrections were very small even for large electrode voltages. It was found that to first order the x- and z-movement of the tube could be reasonably well approximated by assuming that the piezo tube is a segment of a torus. Using this model one obtains

$$dx = (V_+ - V_-)\,|d_{31}|\,\frac{L^2}{2td}\,, \tag{23.82}$$

$$dz = (V_+ + V_- - 2V_z)\,|d_{31}|\,\frac{L}{2t}\,, \tag{23.83}$$

where $|d_{31}|$ is the coefficient of the transversal piezoelectric effect, L is the tube's free length, t is the tube's

wall thickness, d is the tube's diameter, V_+ is the voltage on the positive outer electrode while V_- is the voltage of the opposite quadrant negative electrode, and V_z is voltage of the inner electrode. The cantilever or sample mounted on the piezo tube has an additional lateral movement because the point of measurement is not in the end plane of the piezo tube. The additional lateral displacement of the end of the tip is $\ell \sin\varphi \approx \ell\varphi$, where ℓ is the tip length and φ is the deflection angle of the end surface. Assuming that the sample or cantilever are always perpendicular to the end of the walls of the tube and calculating with the torus model one gets for the angle

$$\varphi = \frac{L}{R} = \frac{2dx}{L} \tag{23.84}$$

where R is the radius of curvature of the piezo tube. Using the result of (23.84) one obtains for the additional x-movement

$$dx_{\text{add}} = \ell\varphi = \frac{2dx\ell}{L} = (V_+ - V_-)\,|d_{31}|\,\frac{\ell L}{td} \tag{23.85}$$

and for the additional z-movement due to the x-movement

$$dz_{\text{add}} = \ell - \ell\cos\varphi = \frac{\ell\varphi^2}{2} = \frac{2\ell\,(dx)^2}{L^2} = (V_+ - V_-)^2\,|d_{31}|^2\,\frac{\ell L^2}{2t^2d^2}\,. \tag{23.86}$$

Carr [23.180] assumed for his finite element calculations that the top of the tube was completely free to move and, as a consequence, the top surface was distorted, leading to a deflection angle about half that of the geometrical model. Depending on the attachment of the sample or the cantilever this distortion may be smaller, leading to a deflection angle in-between that of the geometrical model and the one of the finite element calculation.

Nonlinearities and Creep

Piezo materials with a high conversion ratio, i. e., a large d_{31} or small electrode separations, with large scanning ranges are hampered by substantial hysteresis resulting in a deviation from linearity by more than 10%. The sensitivity of the piezo ceramic material (mechanical displacement divided by driving voltage) decreases with reduced scanning range, whereas the hysteresis is reduced. A careful selection of the material for the piezo scanners, the design of the scanners, and of the operating conditions is necessary to get optimum performance.

Linearization Strategies

Passive Linearization: Calculation. The analysis of images affected by piezo nonlinearities [23.182–185] shows that the dominant term is

$$x = AV + BV^2\,, \tag{23.87}$$

where x is the excursion of the piezo, V the applied voltage, and A and B two coefficients describing the sensitivity of the material. Equation (23.87) holds for scanning from $V = 0$ to large V. For the reverse direction the equation becomes

$$x = \tilde{A}V - \tilde{B}\,(V - V_{\max})^2\,, \tag{23.88}$$

where $\tilde{A}$ and $\tilde{B}$ are the coefficients for the back scan, and $V_{\max}$ is the applied voltage at the turning point. Both equations demonstrate the true x-travel is small at the beginning of the scan and becomes larger towards the end. Therefore, images are stretched at the beginning and compressed at the end.

Similar equations hold for the slow scan direction. The coefficients, however, are different. The combined action causes a greatly distorted image. This distortion can be calculated. The data acquisition systems record the signal as a function of V. However, the data is measured as a function of x. Therefore, we have to distribute the x-values evenly across the image and this can be done by inverting an approximation of (23.87). First we write

$$x = AV\left(1 - \frac{B}{A}V\right)\,. \tag{23.89}$$

For $B \ll A$ we can approximate

$$V = \frac{x}{A}\,. \tag{23.90}$$

We now substitute (23.90) into the nonlinear term of (23.89). This gives

$$x = AV\left(1 + \frac{Bx}{A^2}\right)\,,$$
$$V = \frac{x}{A}\,\frac{1}{(1 + Bx/A^2)} \approx \frac{x}{A}\left(1 - \frac{Bx}{A^2}\right)\,. \tag{23.91}$$

Hence an equation of the type

$$x_{\text{true}} = x\left(\alpha - \frac{\beta x}{x_{\max}}\right) \quad \text{with } 1 = \alpha - \beta \tag{23.92}$$

takes out the distortion of an image. α and β are dependent on the scan range, scan speed, and scan history and have to be determined with exactly the same settings

as for the measurement. x_{max} is the maximal scanning range. The condition for α and β guarantees that the image is transformed onto itself.

Similar equations as the empirical one shown above (23.92) can be derived by analyzing the movements of domain walls in piezo ceramics.

Passive Linearization: Measuring the Position. An alternative strategy is to measure the position of the piezo translators. Several possibilities exist:

1. The interferometers described above can be used to measure the elongation of the piezo elongation. Especially the fiber-optic interferometer is easy to implement. The coherence length of the laser only limits the measurement range. However, the signal is of periodic nature. Hence, a direct use of the signal in a feedback circuit for the position is not possible. However, as a measurement tool and, especially, as a calibration tool the interferometer is without competition. The wavelength of the light, for instance in a HeNe laser is so well defined that the precision of the other components determines the error of the calibration or measurement.
2. The movement of the light spot on the quadrant detector can be used to measure the position of a piezo [23.186]. The output current changes by $0.5\,\mathrm{A/cm} \times (P\,[\mathrm{W}]/R\,[\mathrm{cm}])$. Typical values ($P = 1\,\mathrm{mW}$, $R = 0.001\,\mathrm{cm}$) give $0.5\,\mathrm{A/cm}$. The noise limit is typically

$$0.15\,\mathrm{nm} \times \sqrt{(\Delta f\,[Hz])/(H\,[\mathrm{W/cm^2}])}.$$

   Again this means that the laser beam above would have a 0.1 nm noise limitation for a bandwidth of 21 Hz. The advantage of this method is that, in principle, one can linearize two axes with only one detector.
3. A knife-edge blocking part of a light beam incident on a photodiode can be used to measure the position of the piezo. This technique, commonly used in optical shear force detection [23.86, 187], has a sensitivity of better than 0.1 nm.
4. The capacitive detection [23.188, 189] of the cantilever deflection can be applied to the measurement of the piezo elongation. Equations (23.64)–(23.79) apply to the problem. This technique is used in some commercial instruments. The difficulties lie in the avoidance of fringe effects at the borders of the two plates. While conceptually simple, one needs the latest technology in surface preparation to obtain a decent linearity. The electronic circuits used for the readout are often proprietary.
5. Linear variable differential transformers (LVDTs) are a convenient means to measure positions down to 1 nm. They can be used together with a solid-state joint setup, as often used for large scan-range stages. Unlike the capacitive detection there are few difficulties to implementation. The sensors and the detection circuits for LVDTs are available commercially.
6. A popular measurement technique is the use of strain gauges. They are especially sensitive when mounted on a solid-state joint where the curvature is maximal. The resolution depends mainly on the induced curvature. A precision of 1 nm is attainable. The signals are low – a Wheatstone bridge is needed for the readout.

Active Linearization. Active linearization is done with feedback systems. Sensors need to be monotonic. Hence all the systems described above, with the exception of the interferometers are suitable. The most common solutions include the strain gauge approach, the capacitance measurement or the LVDT, which are all electronic solutions. Optical detection systems have the disadvantage that the intensity enters into the calibration.

Alternative Scanning Systems

The first STMs were based on piezo tripods [23.1]. The piezo tripod (Fig. 23.35) is an intuitive way to generate the three-dimensional movement of a tip attached to its center. However, to obtain a suitable stability and scanning range, the tripod needs to be fairly large (about 50 mm). Some instruments use piezo stacks instead of monolithic piezoactuators. They have the tripod arrangement. Piezo stacks are thin layers of piezoactive materials glued together to form a device with up to 200 µm of actuation range. Preloading with a suitable metal casing reduces the nonlinearity.

If one tries to construct a home-built scanning system, the use of linearized scanning tables is recommended. They are built around solid state joints and actuated by piezo stacks. The joints guarantee that the movement is parallel with little deviation from the predefined scanning plane. Because of the construction it

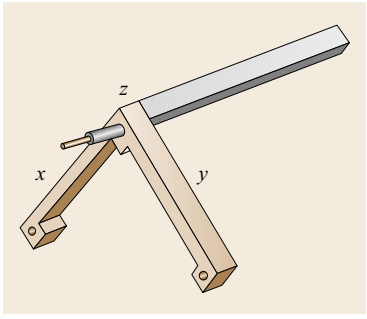

Fig. 23.35 An alternative type of piezo scanner: the tripod

is easy to add measurement devices such as capacitive sensors, LVDTs, or strain gauges which are essential for a closed-loop linearization. Two-dimensional tables can be bought from several manufacturers. They have a linearity of better than 0.1% and a noise level of 10^{-4}–10^{-5} of the maximal scanning range.

Control Systems

Basics. The electronics and software play an important role in the optimal performance of an SPM. Control electronics and software are supplied with commercial SPMs. Control electronic systems can use either analog or digital feedback. While digital feedback offers greater flexibility and the ease of configuration, analog feedback circuits might be better suited for ultralow noise operation. We will describe here the basic setups for AFM.

Figure 23.36 shows a block schematic of a typical AFM feedback loop. The signal from the force transducer is fed into the feedback loop consisting mainly of a subtraction stage to get an error signal and an integrator. The gain of the integrator (high gain corresponds to short integration times) is set as high as possible without generating more than 1% overshoot. High gain minimizes the error margin of the current and forces the tip to follow the contours of constant density of states as precisely as possible. This operating mode is known as constant force mode. A high voltage amplifier amplifies the outputs of the integrator. As AFMs using piezo tubes usually require ± 150 V at the output, the output of the integrator needs to be amplified by a high-voltage amplifier.

In order to scan the sample, additional voltages at high tension are required to drive the piezo. For example, with a tube scanner, four scanning voltages are required, namely $+V_x$, $-V_x$, $+V_y$, and $-V_y$. The x- and y-scanning voltages are generated in a scan generator (analog or computer-controlled). Both voltages are input to the two respective power amplifiers. Two inverting amplifiers generate the input voltages for the other two power amplifiers. The topography of the sample surface is determined by recording the input voltage to the high voltage amplifier for the z-channel as a function of x and y (Constant Force Mode).

Another operating mode is the variable force mode. The gain in the feedback loop is lowered and the scanning speed increased such that the force on the cantilever is no longer constant. Here the force is recorded as a function of x and y.

Force Spectroscopy. Four modes of spectroscopic imaging are in common use with force microscopes: measuring lateral forces, $\partial F/\partial z$, $\partial F/\partial x$ spatially resolved, and measuring force versus distance curves.

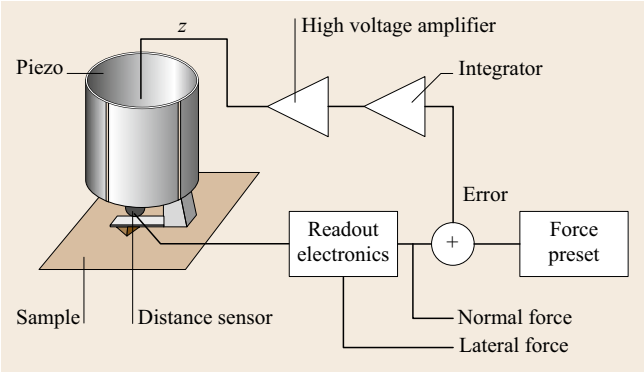

Fig. 23.36 Block schematic of the feedback control loop of an AFM

Lateral forces can be measured by detecting the deflection of a cantilever in a direction orthogonal to the normal direction. The optical lever deflection method most easily does this. Lateral force measurements give indications of adhesion forces between the tip and the sample.

$\partial F/\partial z$ measurements probe the local elasticity of the sample surface. In many cases the measured quantity originates from a volume of a few cubic nanometers. The $\partial F/\partial z$ or local stiffness signal is proportional to Young's modulus, as far as one can define this quantity. Local stiffness is measured by vibrating the cantilever by a small amount in the z-direction. The expected signal for very stiff samples is zero: for very soft samples one obtains, independent of the stiffness, also a constant signal. This signal is again zero for the optical lever deflection and equal to the driving amplitude for interferometric measurements. The best sensitivity is obtained when the compliance of the cantilever matches the stiffness of the sample.

A third spectroscopic quantity is the lateral stiffness. It is measured by applying a small modulation in the x-direction on the cantilever. The signal is again optimal when the lateral compliance of the cantilever matches the lateral stiffness of the sample. The lateral stiffness is, in turn, related to the shear modulus of the sample.

Detailed information on the interaction of the tip and the sample can be gained by measuring force versus distance curves. It is necessary to have cantilevers with high enough compliance to avoid instabilities due to the attractive forces on the sample.

Using the Control Electronics as a 2-D-Measurement Tool. Usually the control electronics of an AFM is used to control the x- and y-piezo signals while several data acquisition channels record the position-dependent signals. The control electronics can be used

in another way: it can be viewed as a two-dimensional function generator. What is normally the x- and y-signal can be used to control two independent variables of an experiment. The control logic of the AFM then ensures that the available parameter space is systematically probed at equally spaced points. An example is friction force curves measured along a line across a step on graphite.

Figure 23.37 shows the connections. The z-piezo is connected as usual, like the x-piezo. However, the y-output is used to command the desired input parameter. The offset of the y-channel determines the position of the tip on the sample surface, together with the x-channel.

Some Imaging Processing Methods

The visualization and interpretation of images from AFMs is intimately connected to the processing of these images. An ideal AFM is a noise-free device that images a sample with perfect tips of known shape and has perfect linear scanning piezos. In reality, AFMs are not that ideal. The scanning device in AFMs is affected by distortions. The distortions are both linear and nonlinear. Linear distortions mainly result from imperfections in the machining of the piezo translators causing crosstalk from the z-piezo to the x- and y-piezos, and vice versa. Among the linear distortions, there are two kinds that are very important. First, scanning piezos invariably have different sensitivities along the different scan axes due to the variation of the piezo material and uneven sizes of the electrode areas. Second, the same reasons might cause the scanning axes not to be orthogonal. Furthermore, the plane in which the piezo scanner moves for constant height z is hardly ever coincident with the sample plane. Hence, a linear ramp is added to the sample data. This ramp is especially bothersome when the height z is displayed as an intensity map.

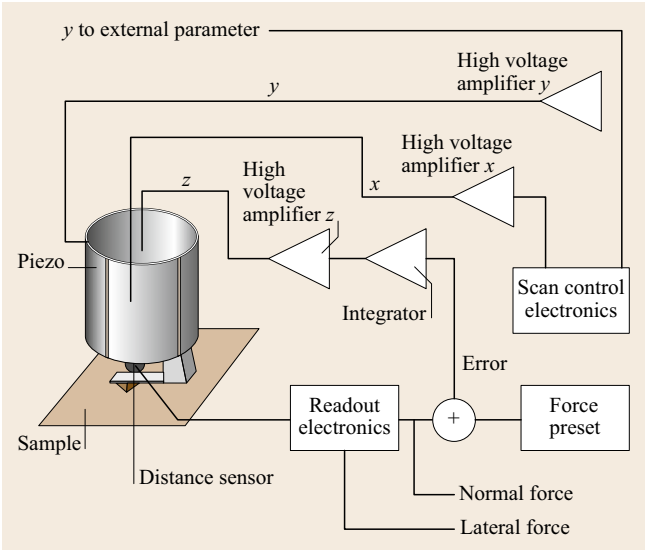

Fig. 23.37 Wiring of an AFM to measure friction force curves along a line

The nonlinear distortions are harder to deal with. They can affect AFM data for a variety of reasons. First, piezoelectric ceramics do have a hysteresis loop, much like ferromagnetic materials. The deviations of piezoceramic materials from linearity increase with increasing amplitude of the driving voltage. The mechanical position for one voltage depends on the previously applied voltages to the piezo. Hence, to obtain the best position accuracy, one should always approach a point on the sample from the same direction. Another type of nonlinear distortion of the images occurs when the scan frequency approaches the upper frequency limit of the x- and y-drive amplifiers or the upper frequency limit of the feedback loop (z-component). This distortion, due to the feedback loop, can only be minimized by reducing the scan frequency. Conversely, there is a simple way to reduce distortions due to the x- and y-piezo drive amplifiers. To keep the system as simple as possible, one normally uses a triangular waveform for driving the scanning piezos. However, triangular waves contain frequency components as multiples of the scan frequency. If the cutoff frequency of the x- and y-drive electronics or of the feedback loop is too close to the scanning frequency (two or three times the scanning frequency), the triangular drive voltage is rounded off at the turning points. This rounding error causes, first, a distortion of the scan linearity and, second, through phase lags, the projection of part of the backward scan onto the forward scan. This type of distortion can be minimized by carefully selecting the scanning frequency and by using driving voltages for the x- and y-piezos with waveforms like trapezoidal waves, which are closer to a sine wave. The values measured for x-, y-, or z-piezos are affected by noise. The origin of this noise can be either electronic, some disturbances, or a property of the sample surface due to adsorbates. In addition to this incoherent noise, interference with the main and other equipment nearby might be present. Depending on the type of noise, one can filter it in the real space or in Fourier space. The most important part of image processing is to visualize the measured data. Typical AFM data sets can consist of many thousands to over a million points per plane. There may be more than one image plane present. The AFM data represents a topography in various data spaces.

Most commercial data acquisition systems use implicitly some kind of data processing. Since the original data is commonly subject to slopes on the surface,

most programs use some kind of slope correction. The least disturbing way is to substrate a plane $z(x, y) = Ax + By + C$ from the data. The coefficients are determined by fitting $z(x, y)$ to the data. Another operation is to subtract a second-order function such as $z(x, y) = Ax^2 + By^2 + Cxy + Dx + Ey + F$. Again, the parameters are determined with a fit. This function is appropriate for almost plane data, where the nonlinearity of the piezos caused such a distortion.

In the image processing software from Digital Instruments, up to three operations are performed on the raw data. First, a zero-order flatten is applied. The flatten operation is used to eliminate image bow in the slow scan direction (caused by a physical bow in the instrument itself), slope in the slow scan direction, and bands in the image (caused by differences in the scan height from one scan line to the next). The flatten operation takes each scan line and subtracts the average value of the height along each scan line from each point in that scan line. This brings each scan line to the same height. Next, a first-order planefit is applied in the fast scan direction. The planefit operation is used to eliminate bow and slope in the fast scan direction. The planefit operation calculates a best-fit plane for the image and subtracts it from the image. This plane has a constant nonzero slope in the fast scan direction. In some cases, a higher order polynomial *plane* may be required. Depending upon the quality of the raw data, the flatten operation and/or the planefit operation may not be required at all.

23.4 Conclusion

Since introduction of the STM in 1981 and AFM in 1985, many variations of probe-based microscopies, referred to as SPMs, have been developed. While the pure imaging capabilities of SPM techniques are dominated by the application of these methods at their early development stages, the physics of probe-sample interactions and the quantitative analyses of tribological, electronic, magnetic, biological, and chemical surfaces have now become of increasing interest. Nanoscale science and technology are strongly driven by SPMs which allow investigation and manipulation of surfaces down to the atomic scale. With growing understanding of the underlying interaction mechanisms, SPMs have found application in many fields outside basic research fields. In addition, various derivatives of all these methods have been developed for special applications, some of them with targets far beyond microscopy.

24. Low-Temperature Scanning Probe Microscopy

Mehmet Z. Baykara, Markus Morgenstern, Alexander Schwarz, Udo D. Schwarz

This chapter is dedicated to scanning probe microscopy (SPM) operated at cryogenic temperatures, where the more fundamental aspects of phenomena important in the fields of nanoscience and nanotechnology can be investigated with high sensitivity under well-defined conditions. In general, scanning probe techniques allow the measurement of physical properties down to the nanometer scale. Some techniques, such as scanning tunneling microscopy (STM) and scanning force microscopy (SFM), even go down to the atomic scale. Various properties are accessible. Most importantly, one can image the arrangement of atoms on conducting surfaces by STM and on insulating samples by SFM. However, electronic states (scanning tunneling spectroscopy), force interaction between different atoms (scanning force spectroscopy), magnetic domains (magnetic force microscopy), magnetic exchange interactions (magnetic exchange force microscopy and spectroscopy), local capacitance (scanning capacitance microscopy), local contact potential differences (Kelvin probe force microscopy), local temperature (scanning thermal microscopy), and local light-induced excitations (scanning near-field microscopy) can also be measured with high spatial resolution, among others. In addition, some modern techniques even allow the controlled manipulation of individual atoms/molecules and the visualization of the internal structure of individual molecules. Moreover, combined STM/SFM experiments are now possible, mainly thanks to the advent of tuning forks as sensing elements in low-temperature (LT) SPM systems.

Probably the most important advantage associated with the low-temperature operation of scanning probes is that it leads to a significantly better signal-to-noise ratio than measuring at room temperature. This is why many researchers work below 100 K. However, there are also physical reasons to use low-temperature equipment. For example, visualizing the internal structure of molecules with SFM or the utilization of scanning tunneling spectroscopy with high energy resolution can only be realized at low temperatures. Moreover, some physical effects such as superconductivity or the Kondo effect are restricted to low temperatures. Here, we describe the advantages of low-temperature scanning probe operation and the basics of related instrumentation. Additionally, some of the important results achieved by low-temperature scanning probe microscopy are summarized. We first focus on the STM, giving examples of atomic manipulation and the analysis of electronic properties in different material arrangements, among others. Afterwards, we describe results obtained by SFM, reporting on atomic-scale and submolecular imaging, as well as three-dimensional (3-D) force spectroscopy. Results obtained with the method of Kelvin probe force microscopy (KPFM) that is used to study variations in local contact potential difference (LCPD) are briefly discussed. Magnetic force microscopy (MFM), magnetic exchange force microscopy (MExFM), and magnetic resonance force microscopy (MRFM) are also introduced. Although the presented selection of results is far from complete, we feel that it gives an adequate impression of the fascinating possibilities of low-temperature scanning probe instruments.

In this chapter low temperatures are defined as lower than about 100 K and are normally achieved by cooling with liquid nitrogen or liquid helium. Applications in which SPMs are operated close to 0 °C are not covered in this chapter.

Three decades ago, the first design of an experimental setup was presented where a sharp tip was systematically scanned over a sample surface in order to acquire local information on the tip–sample interaction down to the atomic scale. This original instrument used the tunneling current between a conducting tip and a conducting sample as a feedback signal and was thus named the *scanning tunneling microscope* [24.1]. Soon after this historic breakthrough, it became widely recognized that virtually any type of tip–sample interaction could be used to obtain local information on the sample by applying the same general principle, provided that the selected interaction was reasonably short-ranged. Thus, a whole variety of new methods has been introduced, which are denoted collectively as *scanning probe methods*. Overviews are provided in [24.2] and more recently [24.3].

The various methods, especially the above-mentioned scanning tunneling microscopy (STM) and scanning force microscopy (SFM) – which is often further classified into subdisciplines such as topography-reflecting atomic force microscopy (AFM), Kelvin probe force microscopy (KPFM), or magnetic force microscopy (MFM) – have been established as standard methods for surface characterization on the nanometer scale. The reason is that they feature extremely high resolution (often down to the atomic scale for STM and AFM), despite a principally simple, compact, and comparatively inexpensive design.

An important advantage of the simple working principle and the compact design of many scanning probe microscopes (SPMs) is that they can be adapted to different environments such as air, all kinds of gaseous atmospheres, liquids, or vacuum with reasonable effort. Another advantage is their ability to work within a wide temperature range. Microscope operation at higher temperatures is chosen to study surface diffusion, surface reactivity, surface reconstructions that only manifest at elevated temperatures, high-temperature phase transitions, or to simulate conditions as they occur, e.g., in engines, catalytic converters or reactors. Ultimately, the upper limit for the operation of an SPM is determined by the stability of the sample. However, thermal drift, which limits the ability to move the tip in a controlled manner with respect to the sample, as well as the depolarization temperature of the piezoelectric positioning elements might further restrict successful measurements.

Conversely, low-temperature (LT) application of SPMs is much more widespread than operation at high temperatures. Essentially five reasons make researchers adapt their experimental setups to low-temperature compatibility. These are:

1. Reduced thermal drift
2. Lower noise levels
3. Enhanced stability of tip and sample
4. Reduction in piezo hysteresis/creep
5. Probably the most obvious, the fact that many physical effects are restricted to low temperature.

Reasons 1–4 only apply unconditionally if the whole microscope body is kept at low temperature (typically by employing a bath cryostat, Sect. 24.2). Conversely, setups in which only the sample or the tip is cooled (typically those that employ flow cryostats) may show considerably less favorable operating characteristics. As a result of 1–4, ultrahigh resolution and long-term stability can be achieved on a level that significantly exceeds what can be accomplished at room temperature even under the most favorable circumstances. Typical examples of (5) are superconductivity [24.4] and the Kondo effect [24.5].

This chapter is organized such that the advantages associated with low-temperature microscope operation are introduced first, followed by an overview of instrumentational aspects. Subsequently, certain exemplary results of low-temperature STM and SFM operation are presented and the chapter is concluded with a summary.

24.1 Microscope Operation at Low Temperatures

24.1.1 Drift

Thermal drift originates from thermally activated movements of individual atoms, which are reflected by the thermal expansion coefficient. At room temperature, typical values for solids are in the order of $(1-50) \times 10^{-6}\,\mathrm{K}^{-1}$. If the temperature could be kept precisely constant, any thermal drift would vanish, regardless of the absolute temperature of the system. The close coupling of the microscope to a large temperature bath that maintains a constant temperature therefore ensures a significant reduction in thermal drift and allows for distortion-free long-term measurements. As such, microscopes that are efficiently attached to sufficiently large bath cryostats show a one- to two-order-of-magnitude increase in thermal stability compared with nonstabilized setups operated at room temperature.

A second effect also helps suppress thermally induced drift of the probing tip relative to a specific location on the sample surface: The thermal expansion coefficients of materials at liquid-helium temperatures are two or more orders of magnitude smaller than at room temperature. Consequently, thermal drift during low-temperature operation decreases significantly.

For some specific scanning probe methods, there may be additional ways in which a change in temperature can affect the quality of the data. In *frequency-modulation SFM* (FM-SFM), for example, the measurement principle relies on the accurate determination of the eigenfrequency of the cantilever, which is determined by its spring constant and its effective mass. However, the spring constant changes with temperature due to both thermal expansion (i. e., the resulting change in cantilever dimensions) and the variation of the Young's modulus with temperature. Assuming temperature drift rates of about 2 mK/min, as is typical for room-temperature measurements, this effect might have a significant influence on the obtained data.

It should be mentioned that software-based correction of thermal drift to a certain extent in SPM experiments is now a possibility [24.6, 7]. Despite this fact, low-temperature operation currently provides the most direct and reliable route to the elimination of thermal-drift-related effects.

24.1.2 Noise

The theoretically achievable resolution in SPM often increases with decreasing temperature due to a decrease in thermally induced noise. An example is the thermal noise in SFM, which is proportional to the square root of the temperature [24.8, 9]. Lowering the temperature from $T = 300$ to 10 K thus results in a reduction of the thermal frequency noise by more than a factor of five, enabling, e.g., three-dimensional force fields to be acquired with atomic resolution on low-corrugation surfaces such as graphite [24.10].

Another, even more striking, example is the spectroscopic resolution in *scanning tunneling spectroscopy* (STS). This depends linearly on the temperature [24.2] and is consequently reduced even more at LT than the thermal noise in AFM. This provides the opportunity to study structures or physical effects not accessible at room temperature such as Landau levels in semiconductors [24.11].

Finally, it might be worth mentioning that the enhanced stiffness of most materials at low temperatures (increased Young's modulus) leads to a reduced coupling to external noise. Even though this effect is considered small [24.9], it should not be ignored, especially when combined with the fact that artifacts in atomic-resolution SPM experiments due to tip elasticity [24.12, 13] are also expected to decrease at low temperatures due to the increase in stiffness.

24.1.3 Stability

There are two major stability issues that considerably improve at low temperature. First, low temperatures close to the temperature of liquid helium inhibit most of the thermally activated diffusion processes. As a consequence, the sample surfaces show a significantly increased long-term stability since defect motion and/or adatom diffusion is massively suppressed. Most strikingly, even single xenon atoms deposited on suitable substrates can be successfully imaged [24.14, 15] or even manipulated [24.16]. In the same way, low temperatures also stabilize the atomic configuration at the tip end by preventing sudden jumps of the most loosely bound, foremost tip atom(s). Moreover, the large cryostat that usually surrounds the microscope acts as an effective cryo-pump. Thus, samples can be kept clean for several weeks, which is a multiple of the corresponding time at room temperature (about 3–4 h).

24.1.4 Piezo Relaxation and Hysteresis

The last important benefit of low-temperature operation of SPMs is that artifacts from the response of the piezoelectric scanners are substantially reduced. After applying a voltage ramp to one electrode of a piezoelectric scanner, its immediate initial deflection, l_0, is followed by a much slower relaxation, Δl, with a loga-

rithmic time dependence. This effect, known as piezo relaxation or *creep*, diminishes substantially at low temperatures, typically by a factor of ten or more. As a consequence, piezo nonlinearities and piezo hysteresis decrease accordingly. Additional information is given in [24.17].

24.2 Instrumentation

The two main design criteria for all ultrahigh vacuum (UHV)-based SPM systems (which we are exclusively focusing on) are: (1) to provide an efficient decoupling of the microscope from the UHV system and other sources of external vibrations, and (2) to avoid most internal noise sources through the high mechanical rigidity of the microscope body itself. In vacuum systems designed for low-temperature applications, a significant degree of complexity is added, since, on the one hand, close thermal contact of the SPM and cryogen is necessary to ensure the (nearly) drift-free conditions described above, while, on the other hand, good vibration isolation (both from the outside world, as well as from the boiling or flowing cryogen) has to be maintained.

During the last couple of decades, a considerable number of both home-built and commercial SPM designs have been presented for low-temperature operation. Because of the variety of different approaches, it is not possible to cover all related aspects here. Instead, we will briefly discuss a home-built combined STM/SFM system that is specifically geared toward atomic-resolution imaging and spectroscopy at low temperatures that relies on a bath cryostat [24.18] rather than a flow cryostat. The main advantage of using bath cryostats instead of flow cryostats for low-temperature operation is the fact that the *whole microscope* is kept at the same cryogenic temperature which thus (nearly) eliminates the occurrence of thermal drift between the tip and the sample.

Drawings of the (i) UHV system that houses the specific microscope to be discussed here, (ii) the cryostat to which the microscope is attached, and (iii) the microscope itself, are provided in Fig. 24.1. The UHV system (Fig. 24.1a) is partially based on a commercial design by *Omicron Nanotechnology* (Germany) and features two individual chambers for sample preparation (via sputtering, annealing, oxygen plasma deposition, etc.) and surface analysis (via conventional surface science techniques such as low-energy electron diffraction (LEED) and Auger spectroscopy) as well as a third chamber (the SPM chamber) that houses the microscope attached to the on-top bath cryostat. Samples are introduced into the UHV system via a fast entry load lock pumped by a turbo pump and sample transfer between different chambers occurs in situ via magnetic transfer arms. All chambers are equipped with ion getter and titanium sublimation pumps that allow base pressures on the order of 10^{-11} mbar to be reached. Additionally, the SPM and preparation chambers are equipped with turbo pumps for the bakeout process and pump-down from ambient pressure. For vibration isolation purposes, the whole UHV system is situated on 12 active vibration isolation units in a sound-proofed room on a basement floor.

The bath cryostat employed in the present design (Fig. 24.1b) has been fabricated by *Cryovac* and consists of a central dewar for liquid helium with a capacity of 8.5 l and a *shielding* dewar that can contain up to 18 l of liquid nitrogen. This setup allows low liquid helium consumption ($\approx 3\,\mathrm{l/day}$). The cryostat features, on the vacuum chamber side, a double set of thermal radiation shields (gold-coated copper) that are cooled by the liquid helium and liquid nitrogen dewars, respectively. The microscope is situated inside the thermal shields and may be suspended on a set of three springs for vibrational isolation from the cryostat during measurements. Thanks to a set of sliding doors on the shields, sample and tip transfer occur in situ (as the microscope is cold and under vacuum) and cool-down times after transfer are on the order of 2 h. During operation, the whole microscope is at a typical temperature of $\approx 5\,\mathrm{K}$.

The microscope itself (Fig. 24.1c) allows combined STM/SFM operation thanks to the fact that it employs quartz tuning forks rather than the conventional micromachined SFM cantilevers. While the particular details associated with using tuning forks as sensing elements for atomic-resolution SFM (often combined with STM) are explained elsewhere [24.19], the main advantages involve (i) *self-sensing* thanks to the piezoelectric character of the quartz and (ii) enhanced sensitivity to short-range forces due to high mechanical stiffness. The main body of the microscope is manufactured out of Macor and is cylindrical with a height of 80 mm and a diameter of 40 mm. To minimize thermal drift, a (mostly) symmetric structural design has been employed and most metallic parts are made out of titanium which has a similar thermal expansion coefficient to Macor. In this particular design, the tip is stationary and for the *coarse* approach, the sample is moved vertically with respect to the tip by using a *pan-style* motor that is based on a sapphire prism in point-contact with several shear-piezo-stacks (see [24.18] for details).

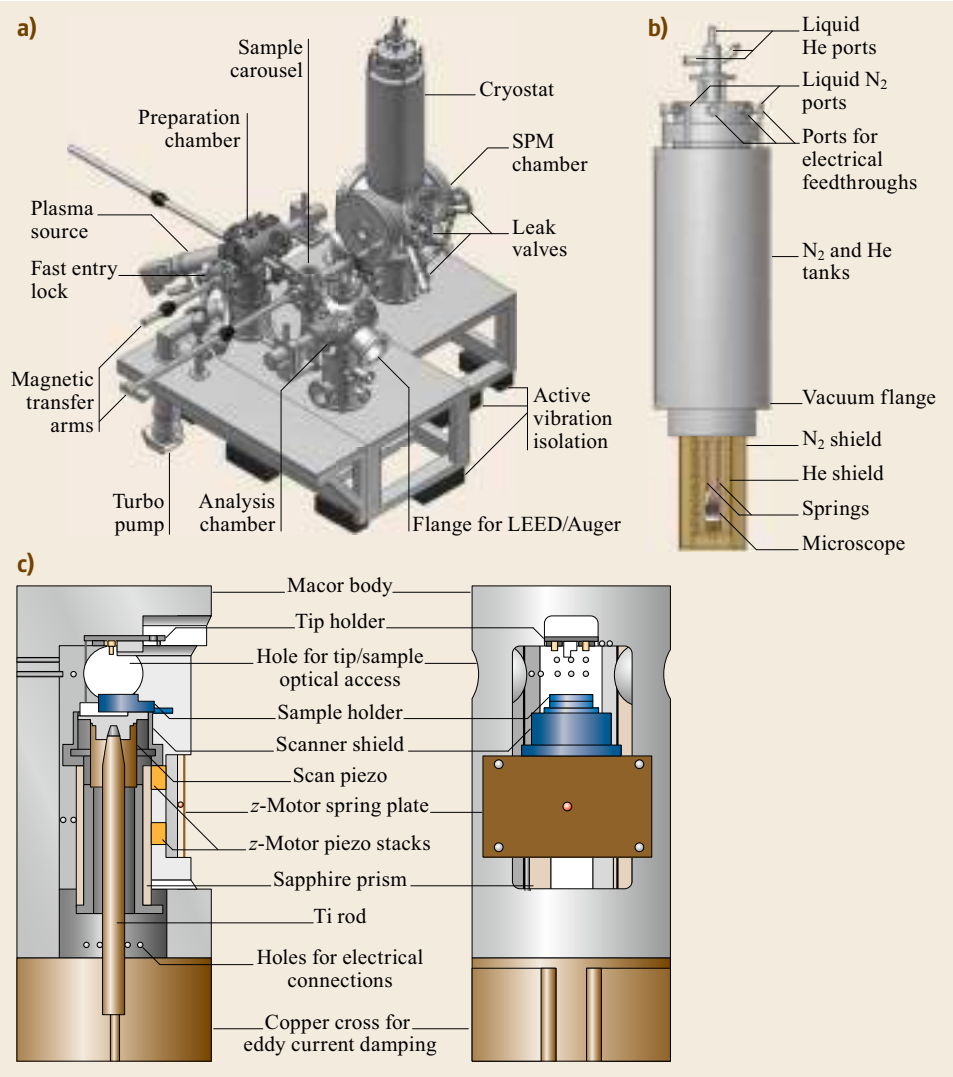

Fig. 24.1 Schematic drawings of the **(a)** UHV system that houses the low-temperature microscope described in this chapter, **(b)** the cryostat to which the microscope is attached and **(c)** the microscope itself (*left*: section view, *right*: front view). Adapted from [24.18]

For precise three-dimensional positioning of the sample with respect to the tip during the *fine* approach and data acquisition, a piezoelectric element in the shape of a cylinder (the *scan piezo*) is employed.

To conclude this section, one should re-iterate that careful instrumentational design for low-temperature scanning probe microscopy allows imaging and spectroscopy experiments with ultrahigh resolution and stability to be successfully performed. In particular, the 3-D force spectroscopy data on surface-oxidized copper and titanium dioxide surfaces discussed in Sect. 24.4 have been obtained with the specific microscope presented here. Finally, rapidly increasing prices for liquid helium have recently led to the development of cryogen-free designs for low-temperature SPM with promising results (e.g., by *RHK technology*). It is projected that this trend in SPM instrumentation will accelerate in the near future.

24.3 Scanning Tunneling Microscopy and Spectroscopy

In this section, we review some of the most important results achieved by low-temperature scanning tunneling microscopy (LT-STM). After summarizing the results, placing emphasis on the necessity of LT equipment, we turn to the details of the different experiments and the physical meaning of the results obtained.

As described in Sect. 24.1, the LT equipment has basically *three* advantages for scanning tunneling microscopy (STM) and spectroscopy (STS): First, the instruments are much more stable with respect to thermal drift and the coupling to external noise, allowing the establishment of new functionalities for the instrument. In particular, LT-STM has been used to move atoms on a surface [24.16], cut molecules into pieces [24.20], reform bonds [24.21], charge individual atoms [24.22], and, consequently, establish new structures on the nanometer scale. Also, the detection of light resulting from tunneling into a particular molecule [24.23, 24], the visualization of thermally induced atomic movements [24.25], and the detection of hysteresis curves of individual atoms [24.26] require LT instrumentation. More recent accomplishments achieved with LT-STM include the measurement of electron spin relaxation times of individual atoms [24.27] and the detection of magnetic remanence in single atoms [24.28].

Second, the spectroscopic resolution in STS depends linearly on temperature and is, therefore, considerably reduced at LT. This provides the opportunity to study physical effects inaccessible at room temperature. Examples are the resolution of spin and Landau levels in semiconductors [24.11], or the investigation of lifetime-broadening effects on the nanometer scale [24.29]. Also the imaging of distinct electronic wavefunctions in real space requires LT-STM [24.30]. More recently, vibrational levels, spin-flip excitations and phonons have been detected with high spatial resolution at LT using the additional inelastic tunneling channel [24.31–33].

Third, many physical effects, in particular effects guided by electronic correlations, are restricted to low temperature. Typical examples are superconductivity [24.4], the Kondo effect [24.5], and many of the electron phases found in semiconductors [24.34]. Here, LT-STM provides the possibility to study electronic effects on a local scale, and intensive work has been done in this field, the most elaborate with respect to high-temperature superconductivity [24.35–37].

24.3.1 Atomic Manipulation

Although manipulation of surfaces on the atomic scale can be achieved at room temperature [24.38, 39], only the use of LT-STM allows the placement of individual atoms at desired atomic positions [24.40]. The main reason is that rotation, diffusion, or charge transfer of entities could be excited at higher temperature, making the intentionally produced configurations unstable.

The usual technique to manipulate atoms is to increase the current above a certain atom, which reduces the tip–atom distance, then to move the tip with the atom to a desired position and finally to reduce the current again in order to decouple atom and tip. The first demonstration of this technique was performed by *Eigler* and *Schweizer* [24.16], who used Xe atoms on a Ni(110) surface to write the three letters *IBM* (their employer) on the atomic scale (Fig. 24.2a). Nowadays, many laboratories are able to move different kinds of atoms and molecules on different surfaces with high precision. An example featuring CO molecules on Cu(110) is shown in Fig. 24.2b–g. Even more complex structures than the "2000" shown in the figure, such as cascades of CO molecules that by mutual repulsive interaction mimic different kinds of logic gates, have been assembled and their functionality tested [24.41]. Although these devices are slow and restricted to low temperature, they nicely demonstrate the high degree of control achieved on the atomic scale.

The basic modes of controlled motion of atoms and molecules by the tip are pushing, pulling, and sliding. The selection of the particular mode depends on the tunneling current, i. e., the distance between tip and molecule, as well as on the particular molecule–substrate combination [24.42]. It has been shown experimentally that the potential landscape for the adsorbate movement is modified by the presence of the tip [24.43, 44] and that excitations induced by the tunneling current can trigger atomic or molecular motion [24.45, 46]. Other sources of motion are the electric field between tip and molecule or electromigration caused by the high current density [24.40]. The required lateral tip force for atomic motion has been measured for typical adsorbate–substrate combinations to be on the order of 0.1 nN [24.47]. Other types of manipulation on the atomic scale are feasible. Some of them require selective inelastic tunneling into vibrational or rotational modes of the molecules [24.48]. This leads to controlled desorption [24.49], diffusion [24.50], molecular rotation [24.51, 52], conformational change [24.53], or even the controlled pick-up of molecules by the tip [24.21]. Dissociation can be achieved by voltage pulses [24.20] inducing local heating, even if the pulse is applied at distances of 100 nm away from the molecule [24.54]. Also, association of individual molecules [24.21, 55–57] can require voltage pulses in order to overcome local energy barriers. The process of controlled bond formation can even be used for doping of single C_{60} molecules by up to four potassium atoms [24.58]. As an example of controlled manipulation, Fig. 24.2h–m shows the production of biphenyl from two iodobenzene molecules [24.59]. The iodine is abstracted by voltage pulses (Fig. 24.2i,j), then the iodine is moved to the terrace by the pulling mode (Fig. 24.2k,l), and finally the two phenyl parts are slid along the step edge until they are close enough to react (Fig. 24.2m). The

Eigler, Almaden); **(b–f)** STM images recorded after different positioning processes of CO molecules on a Cu(110) surface; **(g)** final artwork greeting the new millennium on the atomic scale (**(b–g)** © G. Meyer, Zürich). **(h–m)** Synthesis of biphenyl from two iodobenzene molecules on Cu(111): First, iodine is abstracted from both molecules **(i,j)**; then the iodine between the two phenyl groups is removed from the step **(k)**, and finally one of the phenyls is slid along the Cu step **(l)** until it reacts with the other phenyl **(m)**; the line drawings symbolize the actual status of the molecules (**(h–m)** © S. W. Hla and K. H. Rieder, Berlin)

chemical identification of the product is not straightforward and partly requires detailed vibrational STM spectroscopy [24.60].

Finally, also the charge state of a single atom or molecule can be manipulated, tested, and read out. A Au atom has been switched reversibly between two charge states using an insulating thin film as the substrate [24.22]. In addition, the carrier capture rate of a single impurity level within the bandgap of a semiconductor has been quantified [24.61], and the point conductance of a single atom has been measured and turned out to be a reproducible quantity [24.62]. These promising results might trigger a novel electronic field of manipulation of matter on the atomic scale, which is tightly related to the currently very popular field of molecular electronics.

24.3.2 High-Resolution Spectroscopy

One of the most important modes of LT-STM is STS, which detects the differential conductivity $\mathrm{d}I/\mathrm{d}V$ as a function of the applied voltage V and the position (x, y). The $\mathrm{d}I/\mathrm{d}V$ signal is basically proportional to the local density of states (LDOS) of the sample, the sum

over squared single particle wavefunctions Ψ_i [24.2],

$$\frac{\mathrm{d}I}{\mathrm{d}V}(V,x,y) \propto \mathrm{LDOS}\,(E,x,y) = \sum_{\Delta E} |\Psi_i(E,x,y)|^2\,, \tag{24.1}$$

where ΔE is the energy resolution of the experiment. In simple terms, each state corresponds to a tunneling channel, if it is located between the Fermi levels (E_F) of the tip and the sample. Thus, all states located in this energy interval contribute to I, while $\mathrm{d}I/\mathrm{d}V(V)$ detects only the states at the energy E corresponding to V. The local intensity of each channel depends further on the LDOS of the state at the corresponding surface position and its decay length into vacuum. For s-like tip states, *Tersoff* and *Hamann* have shown that it is simply proportional to the LDOS at the position of the tip [24.63]. Therefore, as long as the decay length is spatially constant, one measures the LDOS at the surface (24.1). Note that the contributing states are not only surface states, but also bulk states. However, surface states usually dominate if present. *Chen* has shown that higher orbital tip states lead to the so-called derivation rule [24.64]: p_z-type tip states detect $\mathrm{d(LDOS)}/\mathrm{d}z$, d_z^2-states detect $\mathrm{d}^2(\mathrm{LDOS})/\mathrm{d}z^2$, and so on. As long as the decay into vacuum is exponential and spatially constant, this leads only to an additional, spatially constant factor in $\mathrm{d}I/\mathrm{d}V$. Thus, it is still the LDOS that is measured (24.1). The requirement of a spatially constant decay is usually fulfilled on larger length scales, but not on the atomic scale [24.64]. There, states located close to the atoms show a stronger decay into vacuum than the less localized states in the interstitial region. This effect can lead to STS corrugations that are larger than the real LDOS corrugations [24.65].

The voltage dependence of $\mathrm{d}I/\mathrm{d}V$ is sensitive to a changing decay length with V, which increases with V. This influence can be reduced at higher V by displaying $\mathrm{d}I/\mathrm{d}V/(I/V)$ [24.66]. Additionally, $\mathrm{d}I/\mathrm{d}V(V)$ curves might be influenced by possible structures in the density of states (DOS) of the tip, which also contribute to the number of tunneling channels [24.67]. However, these structures can usually be identified, and only tips free of characteristic DOS structures are used for quantitative experiments.

Importantly, the energy resolution ΔE is largely determined by temperature. It is defined as the smallest energy distance of two δ-peaks in the LDOS that can still be resolved as two individual peaks in $\mathrm{d}I/\mathrm{d}V(V)$ curves and is $\Delta E = 3.3\,k_\mathrm{B}T$ [24.2]. The temperature dependence is nicely demonstrated in Fig. 24.3, where the tunneling gap of the superconductor Nb is measured at different temperatures [24.68]. The peaks at the rim of the gap get wider at temperatures well below the critical temperature of the superconductor ($T_\mathrm{c} = 9.2\,\mathrm{K}$).

Different temperatures are indicated; the *lines* are fits according to the superconducting gap of Nb folded with the temperature-broadened Fermi distribution of the Au (© S.H. Pan, Houston)

Lifetime Broadening

Besides ΔE, intrinsic properties of the sample lead to a broadening of spectroscopic features. Basically, the finite lifetime of the electron or hole in the corresponding state broadens its energetic width. Any kind of interaction such as electron–electron interaction can be responsible. Lifetime broadening has usually been measured by photoemission spectroscopy (PES), but it turned out that lifetimes of surface states on noble-metal surfaces determined by STS (Fig. 24.4a,b) are up to a factor of three larger than those measured by PES [24.69]. The reason is probably that defects broaden the PES spectrum. Defects are unavoidable in a spatially integrating technique such as PES, thus STS has the advantage of choosing a particularly clean area for lifetime measurements. The STS results can be successfully compared with theory, highlighting the dominating influence of intraband transitions for the surface-state lifetime on Au(111) and Cu(111), at least close to the onset of the surface band [24.29].

With respect to band electrons, the analysis of the width of the band onset on $\mathrm{d}I/\mathrm{d}V(V)$ curves has the disadvantage of being restricted to the onset energy. Another method circumvents this problem by mea-

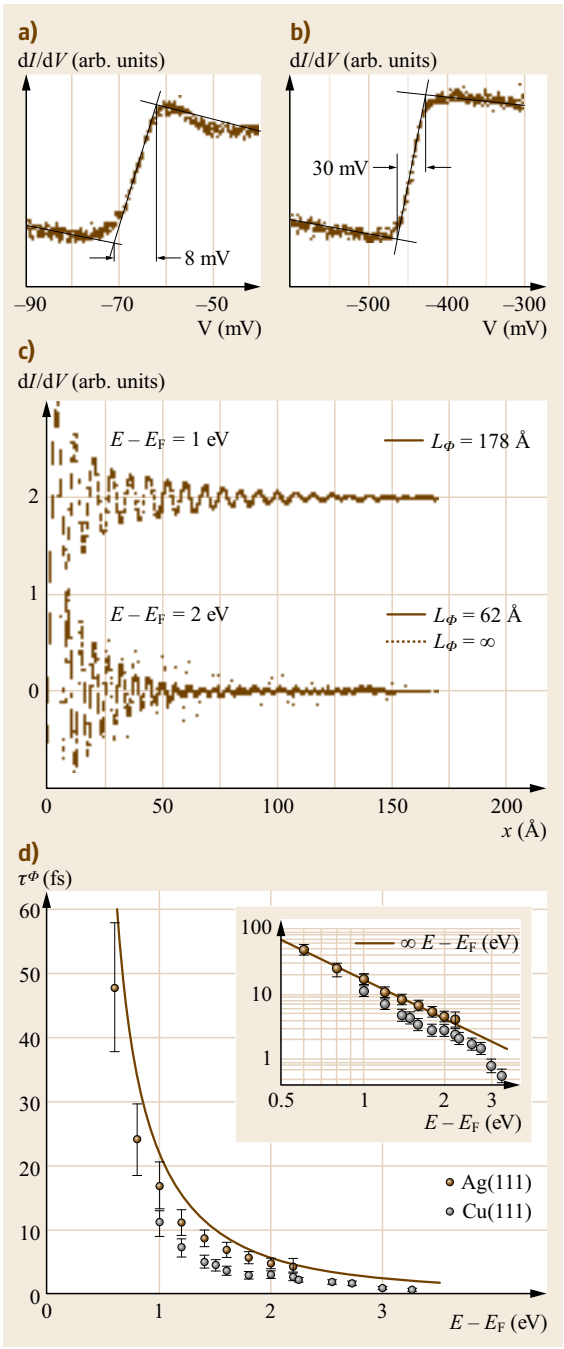

Fig. 24.4 (a,b) Spatially averaged dI/dV curves of Ag(111) and Cu(111); both surfaces exhibit a surface state with parabolic dispersion, starting at −65 and −430 meV, respectively. The *lines* are drawn to determine the energetic width of the onset of these surface bands (**(a,b)** © R. Berndt, Kiel); **(c)** dI/dV intensity as a function of position away from a step edge of Cu(111) measured at the voltages $(E - E_F)$, as indicated (*points*); the *lines* are fits assuming standing electron waves with a phase coherence length L_Φ as marked; **(d)** resulting phase coherence time as a function of energy for Ag(111) and Cu(111). *Inset* shows the same data on a double-logarithmic scale, evidencing the E^{-2} dependence (*line*) (**(c,d)** © H. Brune, Lausanne) ◀

suring the decay of standing electron waves scattered from a step edge as a function of energy [24.70]. Figure 24.4c,d shows the resulting oscillating dI/dV signal measured for two different energies. To deduce the coherence length L_Φ, which is inversely proportional to the lifetime τ_Φ, one has to consider that the finite energy resolution ΔE in the experiment also leads to a decay of the standing wave away from the step edge. The dotted fit line using $L_\Phi = \infty$ indicates this effect and, more importantly, shows a discrepancy from the measured curve. Only including a finite coherence length of 6.2 nm results in good agreement, which in turn determines L_Φ and thus τ_Φ, as displayed in Fig. 24.4c. The determined $1/E^2$ dependence of τ_Φ points to a dominating influence of electron–electron interactions at higher energies in the surface band.

Landau and Spin Levels

Moreover, the increased energy resolution at LT allows the resolution of electronic states that are not resolvable at room temperature (RT); for example, Landau and spin quantization appearing in a magnetic field B have been probed on InAs(110) [24.11, 71]. The corresponding quantization energies are given by $E_{\text{Landau}} = \hbar eB/m_{\text{eff}}$ and $E_{\text{spin}} = g\mu B$. Thus, InAs is a good choice, since it exhibits a low effective mass $m_{\text{eff}}/m_e = 0.023$ and a high g-factor of 14 in the bulk conduction band. The values in metals are $m_{\text{eff}}/m_e \approx 1$ and $g \approx 2$, resulting in energy splittings of only 1.25 and 1.20 meV at $B = 10$ T. This is obviously lower than the typical lifetime broadenings discussed in the previous section and also close to $\Delta E = 1.1$ meV achievable at $T = 4$ K.

Fortunately, the electron density in doped semiconductors is much lower, and thus the lifetime increases significantly. Figure 24.5a shows a set of spectroscopy curves obtained on InAs(110) in different magnetic fields [24.11]. Above E_F, oscillations with increasing intensity and energy distance are observed. They show the separation expected from Landau quantization. In turn, they can be used to deduce m_{eff} from the peak separation (Fig. 24.5b). An increase of m_{eff} with increasing E has been found, as expected from theory. Also, at high fields, spin quantization is observed (Fig. 24.5c). It is larger than expected from the bare g-factor due to contributions from exchange enhancement [24.72].

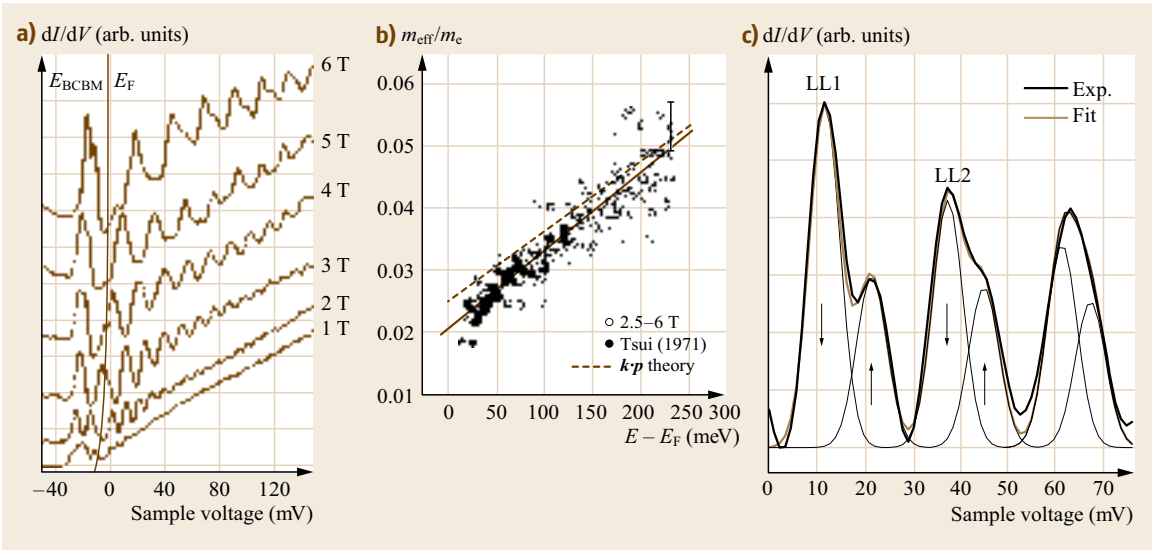

Fig. 24.5 **(a)** dI/dV curves of *n*-InAs(110) at different magnetic fields, as indicated; E_{BCBM} marks the bulk conduction band minimum; oscillations above E_{BCBM} are caused by Landau quantization; the *double peaks* at $B = 6\,T$ are caused by spin quantization. **(b)** Effective-mass data deduced from the distance of adjacent Landau peaks ΔE according to $\Delta E = heB/m_{eff}$ (*open symbols*); *filled symbols* are data from planar tunnel junctions (Tsui), the *solid line* is a mean-square fit of the data and the *dashed line* is the expected effective mass of InAs according to $\boldsymbol{k}\cdot\boldsymbol{p}$ theory. **(c)** Magnification of a dI/dV curve at $B = 6\,T$, exhibiting spin splitting; the Gaussian curves marked by *arrows* are the fitted spin levels

Atomic Energy Levels

Another opportunity at LT is to study electronic states and resonances of single adatoms. A complicated resonance is the Kondo resonance described below. A simpler resonance is a surface state bound at the adatom potential. It appears as a spatially localized peak below the onset of the extended surface state (Fig. 24.4a) [24.73, 74]. A similar resonance caused by a mixing of bulk states of the NiAl(110) substrate with atomic Au levels has been used to detect exchange splitting in Au dimers as a function of interatomic distance [24.75]. Single magnetic adatoms on the same surface also exhibit a double-peak resonance, but here due to the influence of spin-split d-levels of the adsorbate [24.76]. Atomic and molecular states decoupled from the substrate have finally been observed, when the atoms or molecules are deposited on an insulating thin film [24.22, 57].

Vibrational Levels

Inelastic tunneling processes contribute to the tunneling current. The coupling of electronic states to vibrational levels is one source of inelastic tunneling [24.33]. It provides additional channels contributing to $dI/dV(V)$ with final states at energies different from V. The final energy is simply shifted by the energy of the vibrational level. If only discrete vibrational energy levels couple to a smooth electronic DOS, one expects a peak in d^2I/dV^2 at the vibrational energy. This situation appears for molecules on noble-metal surfaces. As usual, the isotope effect can be used to verify the vibrational origin of the peak. First indications of vibrational levels have been found for H_2O and D_2O on TiO_2 [24.77], and completely convincing work has been performed for C_2H_2 and C_2D_2 on Cu(001) [24.33] (Fig. 24.6a). The technique has been used to identify individual molecules on the surface by their characteristic vibrational levels [24.60]. Moreover, the orientation of complexes with respect to the surface can be determined to a certain extent, since the vibrational excitation depends on the position of the tunneling current within the molecule. Finally, the excitation of certain molecular levels can induce such corresponding motions as hopping [24.50], rotation [24.52] (Fig. 24.6b–e), or desorption [24.49] leading to additional possibilities for manipulation on the atomic scale.

In turn, the manipulation efficiency as a function of applied voltage can be used to identify vibrational energies within the molecule, even if they are not detectable directly by d^2I/dV^2 spectroscopy [24.78]. Multiple vibronic excitations are found by positioning the molecule on an insulating film, leading to the observation of equidistant peaks in $d^2I/dV^2(V)$ [24.79].

Kondo Resonance

A rather intricate interaction effect is the Kondo effect. It results from a second-order scattering process be-

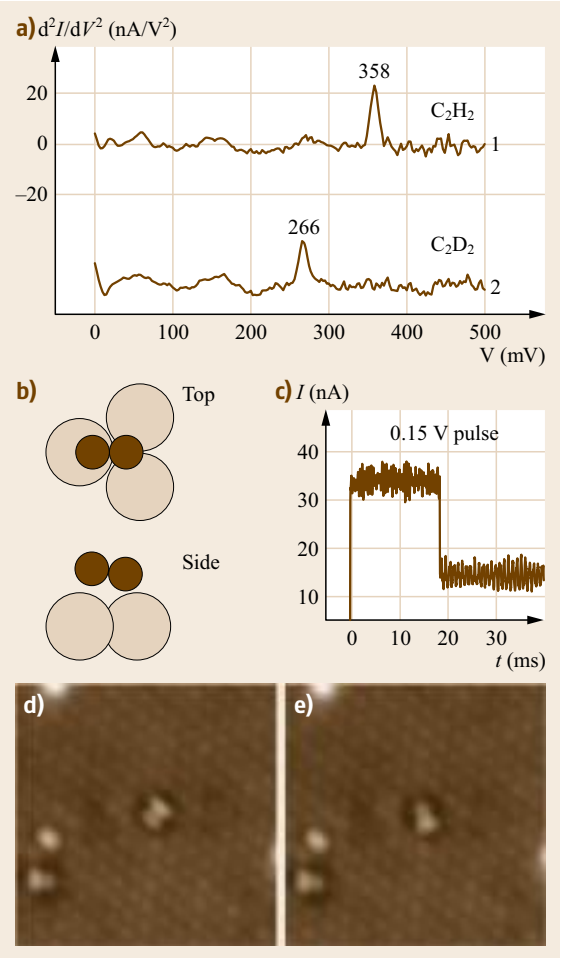

Fig. 24.6 **(a)** d^2I/dV^2 curves taken above a C_2H_2 and a C_2D_2 molecule on Cu(100); the *peaks* correspond to the C−H or C−D stretch-mode energy of the molecule, respectively. **(b)** Sketch of O_2 molecule on Pt(111). **(c)** Tunneling current above an O_2 molecule on Pt(111) during a voltage pulse of 0.15 V; the jump in current indicates rotation of the molecule. **(d,e)** STM images of an O_2 molecule on Pt(111) ($V = 0.05$ V), prior to and after rotation induced by a voltage pulse to 0.15 V (**(a–e)** © W. Ho, Irvine)

tween itinerate states and a localized state [24.80]. The two states exchange some degree of freedom back and forth, leading to a divergence of the scattering probability at the Fermi level of the itinerate state. Because of the divergence, the effect strongly modifies sample properties. For example, it leads to an unexpected increase in resistance with decreasing temperature for metals containing magnetic impurities [24.5]. Here, the exchanged degree of freedom is the spin. A spectroscopic signature of the Kondo effect is a narrow peak in the DOS at the Fermi level, continuously disappearing above a characteristic temperature (the Kondo temperature). STS provides the opportunity to study this effect on the local scale [24.81, 82].

Figure 24.7a–d shows an example of Co clusters deposited on a carbon nanotube [24.83]. While only a small dip at the Fermi level, probably caused by curvature influences on the π-orbitals, is observed without Co (Fig. 24.7b) [24.84], a strong peak is found around a Co cluster deposited on top of the tube (Co cluster is marked in Fig. 24.7a). The peak is slightly shifted with respect to $V = 0$ mV due to the so-called Fano resonance [24.85] which results from interference of the tunneling processes into the localized Co level and the itinerant nanotube levels. The resonance disappears within several nanometers of the cluster, as shown in Fig. 24.7d.

The Kondo effect has also been detected for different magnetic atoms deposited on noble-metal surfaces [24.81, 82]. There, it disappears at about 1 nm from the magnetic impurity, and the effect of the Fano resonance is more pronounced, contributing to dips in $dI/dV(V)$ curves instead of peaks. Detailed investigations show that the d-level occupation of the adsorbate [24.86] as well as the surface charge density [24.87, 88] matter for the Kondo temperature. Exchange interaction between adsorbates tunable by their mutual distance can be used to tune the Kondo temperature [24.89] or even to destroy the Kondo resonance completely [24.90]. Meanwhile, magnetic molecules have also been shown to exhibit Kondo resonances. This increases the tunability of the Kondo effect, e.g., by the selection of adequate ligands surrounding the localized spins [24.91, 92], by distant association of other molecules [24.93], or by conformational changes within the molecule [24.94].

A fascinating experiment has been performed by *Manoharan* et al. [24.95], who used manipulation to form an elliptic cage for the surface states of Cu(111) (Fig. 24.7e, *bottom part*). This cage was constructed to have a quantized level at E_F. Then, a Co atom was placed in one focus of the elliptic cage, producing a Kondo resonance. Surprisingly, the same resonance reappeared in the opposite focus, but not away from the focus (Fig. 24.7e, *top part*). This shows amazingly that complex local effects such as the Kondo resonance can be wave-guided to remote points.

24.3.3 Imaging Electronic Wave Functions

Bloch Waves

Since STS measures the sum of squared wavefunctions (24.1), it is an obvious task to measure the local appearance of the simplest wavefunctions in solids,

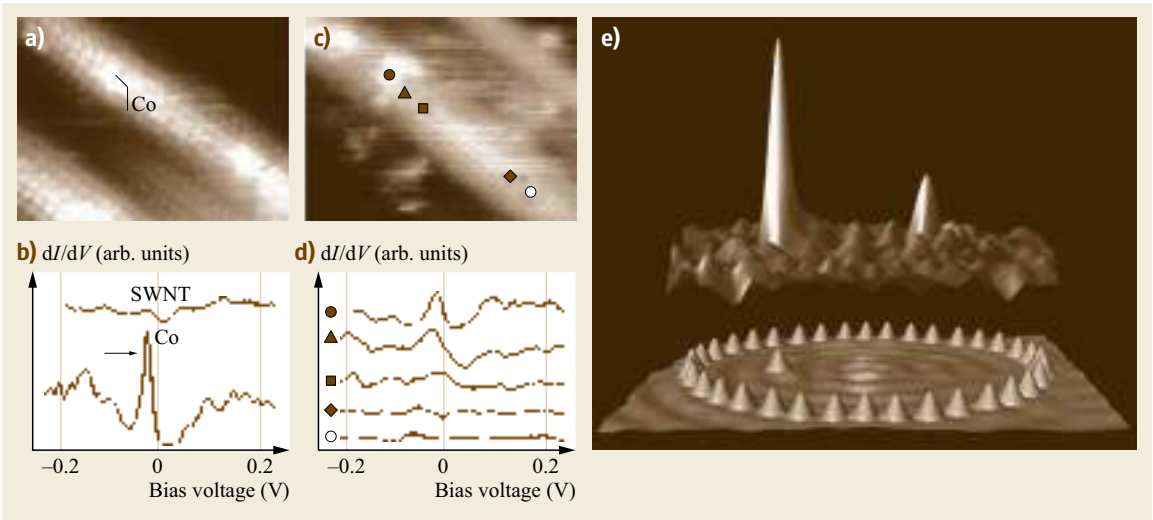

Fig. 24.7 **(a)** STM image of a Co cluster on a single-wall carbon nanotube (SWNT). **(b)** dI/dV curves taken directly above the Co cluster (Co) and far away from the Co cluster (SWNT); the *arrow* marks the Kondo peak. **(c)** STM image of another Co cluster on a SWNT with *symbols* marking the positions where the dI/dV curves displayed in **(d)** are taken. **(d)** dI/dV curves taken at the positions marked in **(c)** (**(a–d)** © C. Lieber, Cambridge). **(e)** *Lower part*: STM image of a quantum corral of elliptic shape made from Co atoms on Cu(111); one Co atom is placed at one of the foci of the ellipse. *Upper part*: map of the strength of the Kondo signal in the corral; note that there is also a Kondo signal at the focus that is not covered by a Co atom (**(e)** © D. Eigler, Almaden)

namely Bloch waves. The atomically periodic part of the Bloch wave is always measured if atomic resolution is achieved (*inset* of Fig. 24.9a). However, the long-range wavy part requires the presence of scatterers. The electron wave impinges on the scatterer and is reflected, leading to self-interference. In other words, the phase of the Bloch wave becomes fixed by the scatterer.

Such self-interference patterns were first found on graphite (0001) [24.96] and later on noble-metal surfaces, where adsorbates or step edges scatter the surface states (Fig. 24.8a) [24.30]. Fourier transforms of the real-space images reveal the k-space distribution of the corresponding states [24.97], which may include additional contributions besides the surface state [24.98]. Using particular geometries such as so-called quantum corrals, the Bloch waves can be confined (Fig. 24.8b). Depending on the geometry of the corral, the resulting state looks rather complex, but it can usually be reproduced by simple calculations involving single-particle states only [24.99].

Meanwhile, Bloch waves in semiconductors scattered at charged dopants (Fig. 24.8c,d) [24.100], Bloch states confined in semiconducting or organic quantum dots (Fig. 24.8e–g) [24.101–103] and quantum wells [24.104], as well as Bloch waves confined in short-cut carbon nanotubes (Fig. 24.8h,i) [24.105, 106] have been visualized. In special nanostructures, it was even possible to extract the phase of the wavefunction by using the mathematically known transformation matrices of so-called isospectral structures, i. e., geometrically different structures exhibiting exactly the same spatially averaged density of states. The resulting wavefunctions $\Psi(x)$ are shown in Fig. 24.8j [24.107].

More localized structures, where a Bloch wave description is not appropriate, have been imaged, too. Examples are the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of pentacene molecules deposited on NaCl/Cu(100) (Fig. 24.8k,l) [24.57], the different molecular states of C_{60} on Ag(110) (Fig. 24.8m–o) [24.108], the anisotropic states of Mn acceptors in a semiconducting host [24.109, 110], and the hybridized states developing within short monoatomic Au chains, which result in particular states at the end of the chains [24.111, 112]. Using pairs of remote Mn acceptors, even symmetric and antisymmetric pair wavefunctions have been imaged in real space [24.113].

The central requirements for a detailed imaging of wavefunctions are LT for an appropriate energetic distinction of an individual state, adequate decoupling of the state from the substrate in order to decrease lifetime-induced broadening effects, and, partly, the selection of a system with an increased Bohr radius in order to increase the spatial extension of details above the lat-

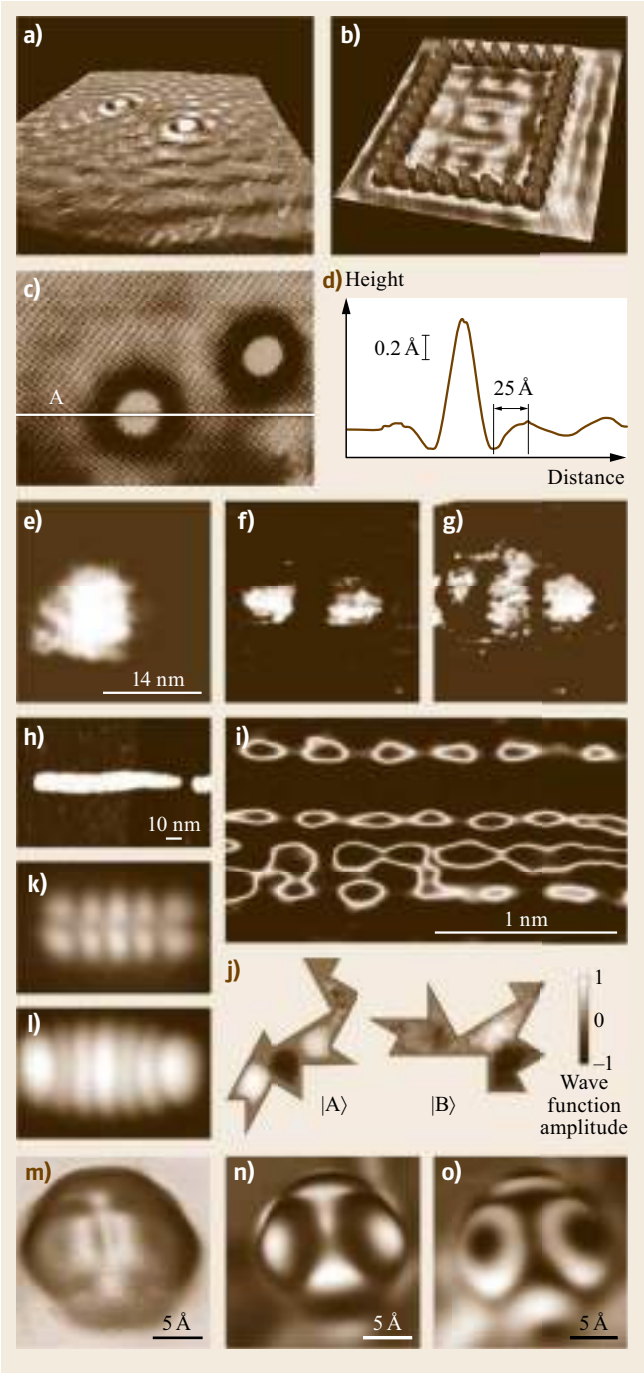

Fig. 24.8a–d **(a)** Low-voltage STM image of Cu(111) including two defect atoms; the waves are electronic Bloch waves scattered at the defects; **(b)** low-voltage STM image of a rectangular quantum corral made from single atoms on Cu(111); the pattern inside the corral is the confined state of the corral close to E_F; (© D. Eigler, Almaden **(a,b)**); **(c)** STM image of GaAs(110) around a Si donor, $V = -2.5$ V; the line scan along A, shown in **(d)**, exhibits an additional oscillation around the donor caused by a standing Bloch wave; the grid-like pattern corresponds to the atomic corrugation of the Bloch wave (© H. van Kempen, Nijmegen **(c,d)**); **(e–g)** dI/dV images of a self-assembled InAs quantum dot deposited on GaAs(100) and measured at different V (**(e)** 1.05 V, **(f)** 1.39 V, **(g)** 1.60 V). The *images* show the squared wavefunctions confined within the quantum dot, which exhibit zero, one, and two nodal lines with increasing energy. **(h)** STM image of a short-cut carbon nanotube; **(i)** greyscale plot of the dI/dV intensity inside the short-cut nanotube as a function of position (x-axis) and tunneling voltage (y-axis); four wavy patterns of different wavelength are visible in the voltage range from −0.1 to 0.15 V (© C. Dekker, Delft **(h,i)**); **(j)** two reconstructed wavefunctions confined in so-called isospectral corrals made of CO molecules on Cu(111). Note that $\Psi(x)$ instead of $|\Psi(x)|^2$ is displayed, exhibiting positive and negative values. Manoharan, Stanford **(j)**); **(k,l)** STM images of a pentacene molecule deposited on NaCl/Cu(100) and measured with a pentacene molecule at the apex of the tip at $V = -2.5$ V (**(k)** HOMO = highest occupied molecular orbital) and $V = 2.5$ V (**(l)** LUMO = lowest unoccupied molecular orbital) (© J. Repp, Regensburg **(k,l)**); **(m)** STM image of a C_{60} molecule deposited on Ag(100), $V = 2.0$ V; **(n,o)** dI/dV images of the same molecule at $V = 0.4$ V **(n)**, 1.6 V **(n)** (**(m–o)** © M. Crommie, Berkeley) ►

eral resolution of STM, thereby improving, e.g., the visibility of bonding and antibonding pair states within a dimer [24.113].

Wavefunctions in Disordered Systems

More complex wavefunctions result from interactions. A nice playground to study such interactions is doped semiconductors. The reduced electron density with respect to metals increases the importance of electron interactions with potential disorder and other electrons. Applying a magnetic field quenches the kinetic energy, thus enhancing the importance of interactions. A dramatic effect can be observed on InAs(110), where three-dimensional (3-D) bulk states are measured. While the usual scattering states around individual dopants are observed at $B = 0$ T (Fig. 24.9a) [24.114], stripe structures are found at high magnetic field (Fig. 24.9b) [24.115]. They run along equipotential lines of the disorder potential. This can be understood by recalling that the electron tries to move in a cyclotron circle, which becomes a cycloid path along an equipotential line within an inhomogeneous electrostatic potential [24.116].

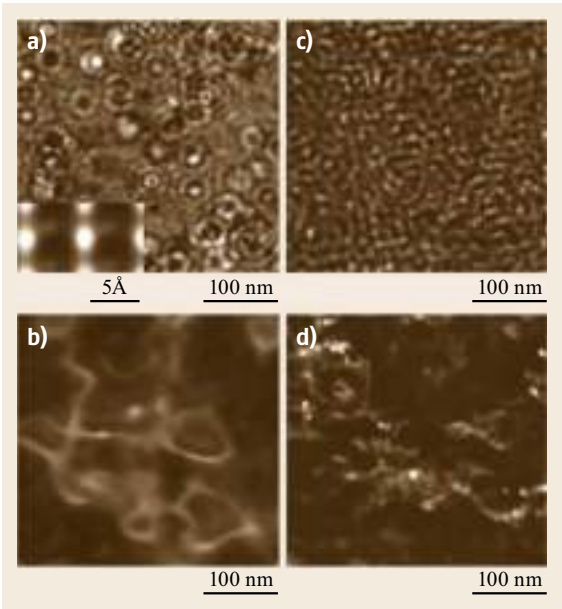

Fig. 24.9 **(a)** dI/dV image of InAs(110) at $V = 50\,\mathrm{mV}$, $B = 0\,\mathrm{T}$; circular wave patterns corresponding to standing Bloch waves around each sulphur donor are visible; *inset* shows a magnification revealing the atomically periodic part of the Bloch wave. **(b)** Same as **(a)**, but at $B = 6\,\mathrm{T}$; the stripe structures are drift states. **(c)** dI/dV image of a 2-D electron system on InAs(110) induced by the deposition of Fe, $B = 0\,\mathrm{T}$. **(d)** Same as **(c)** but at $B = 6\,\mathrm{T}$; note that the contrast in **(a)** is increased by a factor of ten with respect to **(b–d)**

The same effect has been found in two-dimensional (2-D) electron systems (2-DES) of InAs at the same large B-field (Fig. 24.9d) [24.117]. However, the scattering states at $B = 0\,\mathrm{T}$ are much more complex in 2-D (Fig. 24.9c) [24.118]. The reason is the tendency of a 2-DES to exhibit closed scattering paths [24.119]. Consequently, the self-interference does not result from scattering at individual scatterers, but from complicated self-interference paths involving many scatterers. Nevertheless, the wavefunction pattern can be reproduced by including these effects within the calculations.

Reducing the dimensionality to one dimension (1-D) leads again to complicated self-interference patterns due to the interaction of the electrons with several impurities [24.120, 121]. For InAs, they can be reproduced by single-particle calculations. However, experiments imaging self-interference patterns close to the end of a C-nanotube are interpreted as indications of spin charge separation, a genuine property of 1-D electrons not feasible within the single-particle description [24.122].

Charge Density Waves, Jahn–Teller Distortion

Another interaction modifying the LDOS is the electron–phonon interaction. Phonons scatter electrons between different Fermi points. If the wavevectors connecting Fermi points exhibit a preferential orientation, a so-called Peierls instability occurs [24.123]. The corresponding phonon energy goes to zero, the atoms are slightly displaced with the periodicity of the corresponding wavevector, and a charge density wave (CDW) with the same periodicity appears. Essentially, the CDW increases the overlap of the electronic states with the phonon by phase fixing with respect to the atomic lattice. The Peierls transition naturally occurs in one-dimensional (1-D) systems, where only two Fermi points are present and hence preferential orientation is excessive. It can also occur in 2-D systems if large parts of the Fermi line run in parallel.

STS studies of CDWs are numerous [24.124, 125]. Examples of a 1-D CDW on a quasi-1-D bulk material and of a 2-D CDW are shown in Fig. 24.10a–d and Fig. 24.10e–h, respectively [24.126, 127]. In contrast to usual scattering states, where LDOS corrugations are only found close to the scatterer, the corrugations of CDWs are continuous across the surface. Heating the substrate toward the transition temperature leads to a melting of the CDW lattice, as shown in Fig. 24.10f–h.

CDWs have also been found on monolayers of adsorbates such as a monolayer of Pb on Ge(111) [24.128]. These authors performed a nice temperature-dependent study revealing that the CDW is nucleated by scattering states around defects, as one might expect [24.129]. Some of the transitions have been interpreted as more complex Mott–Hubbard transitions caused primarily by electron–electron interactions [24.130]. One-dimensional systems have also been prepared on surfaces showing Peierls transitions [24.131, 132]. Finally, the energy gap occurring at the transition has been studied by measuring $dI/dV(V)$ curves [24.133].

A more local crystallographic distortion due to electron–lattice interactions is the Jahn–Teller effect. Here, symmetry breaking by elastic deformation can lead to the lifting of degeneracies close to the Fermi level. This results in an energy gain due to the lowering of the energy of the occupied levels. By tuning the Fermi level of an adsorbate layer to a degeneracy via doping, such a Jahn–Teller deformation has been induced on a surface and visualized by STM [24.134].

Superconductors

An intriguing effect resulting from electron–phonon interaction is superconductivity. Here, the attractive part of the electron–phonon interaction leads to the coupling of electronic states with opposite wave vector

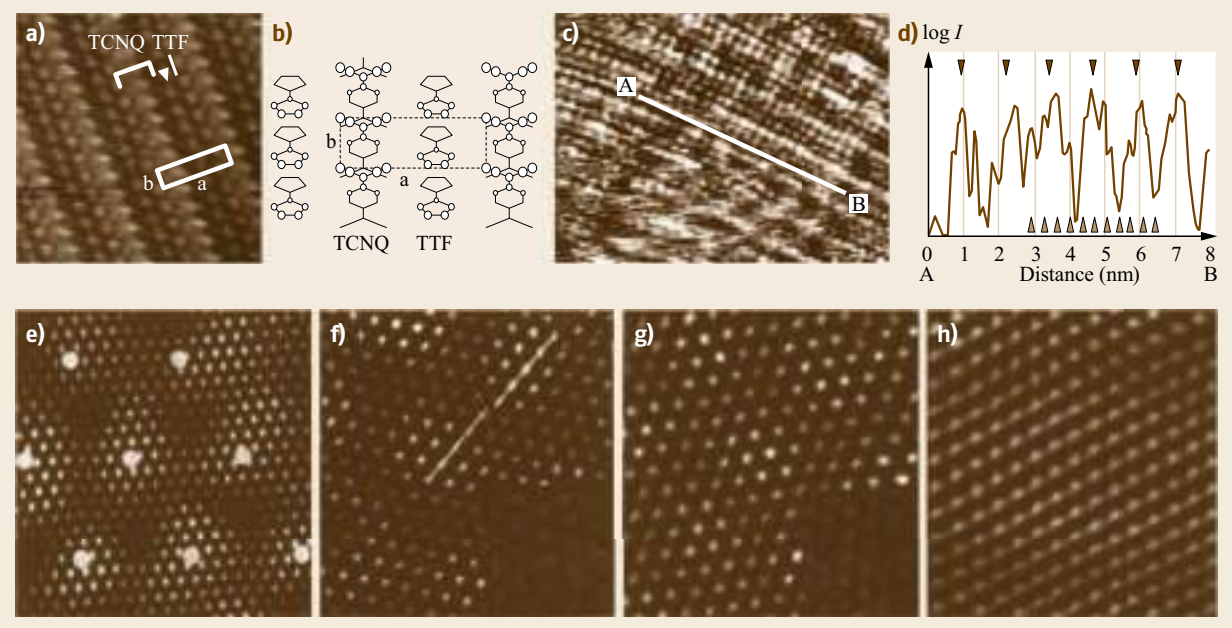

Fig. 24.10 **(a)** STM image of the *ab*-plane of the organic quasi-1-D conductor tetrathiafulvalene tetracyanoquinodimethane (TTF-TCNQ), $T = 300\,\mathrm{K}$; while the TCNQ chains are conducting, the TTF chains are insulating. **(b)** Stick-and-ball model of the *ab*-plane of TTF-TCNQ. **(c)** STM image taken at $T = 61\,\mathrm{K}$; the additional modulation due to the Peierls transition is visible in the profile along line AB shown in **(d)**; the *brown triangles* mark the atomic periodicity and the *black triangles* the expected CDW periodicity (**(a–d)** © M. Kageshima, Kanagawa). **(e–h)** Low-voltage STM images of the two-dimensional CDW system 1 T-TaS_2 at $T = 242\,\mathrm{K}$ **(e)**, 298 K **(f)**, 349 K **(g)**, and 357 K **(h)**. A long-range, hexagonal modulation is visible besides the atomic spots; its periodicity is highlighted by *large white dots* in **(e)**; the additional modulation obviously weakens with increasing T, but is still apparent in **(f)** and **(g)**, as evidenced in the lower-magnification images in the *insets* (**(e–h)** © C. Lieber, Cambridge)

and mostly opposite spin [24.135]. Since the resulting Cooper pairs are bosons, they can condense at LT, forming a coherent many-particle phase, which can carry current without resistance. Interestingly, defect scattering does not influence the condensate if the coupling along the Fermi surface is homogeneous (s-wave superconductor). The reason is that the symmetry of the scattering of the two components of a Cooper pair effectively leads to a scattering from one Cooper pair state to another without affecting the condensate. This is different if the scatterer is magnetic, since the different spin components of the pair are scattered differently, leading to an effective pair breaking, which is visible as a single-particle excitation within the superconducting gap. On a local scale, this effect was first demonstrated by putting Mn, Gd, and Ag atoms on a Nb(110) surface [24.136]. While the nonmagnetic Ag does not modify the gap shown in Fig. 24.11a, it is modified in an asymmetric fashion close to Mn or Gd adsorbates, as shown in Fig. 24.11b. The asymmetry of the additional intensity is caused by the breaking of the particle–hole symmetry due to the exchange interaction between the localized Mn state and the itinerate Nb states.

Another important local effect is caused by the relatively large coherence length of the condensate. At a material interface, the condensate wavefunction cannot stop abruptly, but overlaps into the surrounding material (proximity effect). Consequently, a superconducting gap can be measured in areas of nonsuperconducting material. Several studies have shown this effect on the local scale using metals and doped semiconductors as surrounding materials [24.137, 138].

While the classical type I superconductors are ideal diamagnets, the so-called type II superconductors can contain magnetic flux. The flux forms vortices, each containing one flux quantum. These vortices are accompanied by the disappearance of the superconducting gap and, therefore, can be probed by STS [24.139]. LDOS maps measured inside the gap lead to bright features in the area of the vortex core. Importantly, the length scale of these features is different from the length scale of the magnetic flux due to the difference between the London penetration depth and the electronic coherence length. Thus, STS probes a different property of the vortex than the usual magnetic imaging techniques (Sect. 24.4.5). Surprisingly, first measurements of the

The STM image shows the atomic structure of the cleavage plane, while the dI/dV image shows a bound state within the superconducting gap, which is located around a single Zn impurity. The fourfold symmetry of the bound state reflects the d-like symmetry of the superconducting pairing function; **(j)** dI/dV spectra of $Bi_2Sr_2CaCu_2O_{8+\delta}$ measured at different positions of the surface at $T = 4.2\,K$; the phonon peaks are marked by *arrows*, and the determined local gap size Δ is indicated; note that the strength of the phonon peak increases with the strength of the coherence peaks surrounding the gap; **(k)** LDOS in the vortex core of slightly overdoped $Bi_2Sr_2CaCu_2O_{8+\delta}$, $B = 5\,T$; the dI/dV image taken at $B = 5\,T$ is integrated over $V = 1-12\,mV$, and the corresponding dI/dV image at $B = 0\,T$ is subtracted to highlight the LDOS induced by the magnetic field. The checkerboard pattern within the seven vortex cores exhibits a periodicity, which is fourfold with respect to the atomic lattice shown in **(i)** and is thus assumed to be a CDW; **(l)** STM image of cleaved $Ca_{1.9}Na_{0.1}CuO_2Cl_2$ at $T = 0.1\,K$, i. e., within the superconducting phase of the material; a checkerboard pattern with fourfold periodicity is visible on top of the atomic resolution (© S. Davis, Cornell and S. Uchida, Tokyo **(i–l)**) ◄

vortices on $NbSe_2$ revealed vortices shaped as a sixfold star [24.140] (Fig. 24.11c). With increasing voltage inside the gap, the orientation of the star rotates by 30° (Fig. 24.11d,e). The shape of these stars could finally be reproduced by theory, assuming an anisotropic pairing of electrons in the superconductor (Fig. 24.11f–h) [24.141]. Additionally, bound states inside the vortex core, which result from confinement by the surrounding superconducting material, are found [24.140]. Further experiments investigated the arrangement of the vortex lattice, including transitions between hexagonal and quadratic lattices [24.142], the influence of pinning centers [24.143], and the vortex motion induced by current [24.144].

A central topic is still the understanding of high-temperature superconductors (HTSC). An almost accepted property of HTSC is their d-wave pairing symmetry, which is partly combined with other contributions [24.145]. The corresponding $\boldsymbol{k}$-dependent gap (where $\boldsymbol{k}$ is the reciprocal lattice vector) can be measured indirectly by STS using a Fourier transformation of the LDOS(x, y) determined at different energies [24.146]. This shows that LDOS modulations in HTSC are dominated by simple self-interference patterns of the Bloch-like quasiparticles [24.147]. However, scattering can also lead to pair breaking (in contrast to s-wave superconductors), since the Cooper-pair density vanishes in certain directions. Indeed, scattering states (bound states in the gap) around nonmagnetic Zn impurities have been observed in $Bi_2Sr_2CaCu_2O_{8+\delta}$ (BSCCO) (Fig. 24.11i,j) [24.148]. They reveal a d-like symmetry, but not the one expected from simple Cooper-pair scattering. Other effects such as magnetic polarization in the environment probably have to be taken into account [24.149]. An interesting topic is the importance of inhomogeneities in HTSC materials. Evidence for inhomogeneities has indeed been found in underdoped materials, where puddles of the superconducting phase identified by the coherence peaks around the gap are shown to be embedded in nonsuperconducting areas [24.36].

In addition, temperature-dependent measurements of the gap size development at each spatial position exhibit a percolation-type behavior above T_c [24.35]. This stresses the importance of inhomogeneities, but the observed percolation temperature being higher than T_c shows that T_c is not caused by percolation of superconducting puddles only. Conversely, it was found that for overdoped and optimally doped samples the gap develops continuously across T_c, showing a universal relation between the local gap size $\Delta(T = 0)$ (measured at low temperature) and the local critical temperature T_p (at which the gap completely disappears): $2\Delta(T = 0)/(k_B T_p) \approx 8$. The latter result is evidence that the so-called pseudogap phase is a phase with incoherent Cooper pairs. The results are less clear in the underdoped region, where probably two gaps complicate the analysis. Below T_c, it turns out that the strength of the coherence peak is anticorrelated to the local oxygen acceptor density [24.147] and, in addition, correlated to the energy of an inelastic phonon excitation peak in dI/dV spectra [24.37]. Figure 24.11j shows corresponding spectra taken at different positions, where the coherence peaks and the nearby phonon peaks marked by arrows are clearly visible. The phonon origin of the peak has been proven by the isotope effect, similar to Fig. 24.6a. The strong intensity of the phonon

side-peak as well as the correlation of its strength with the coherence peak intensity points towards an important role of electron–phonon coupling for the pairing mechanism. However, since the gap size does not scale with the strength of the phonon peak [24.150], other contributions must be involved too.

Of course, vortices have also been investigated for HTSC [24.151]. Bound states are found, but at energies that are in disagreement with simple models, assuming a Bardeen–Cooper–Schrieffer (BCS)-like d-wave superconductor [24.152, 153]. Theory predicts, instead, that the bound states are magnetic-field-induced spin density waves, stressing the competition between antiferromagnetic order and superconductivity in HTSC materials [24.154]. Since the spin density wave is accompanied by a charge density wave of half wavelength, it can be probed by STS [24.155]. Indeed, a checkerboard pattern of the right periodicity has been found in and around vortex cores in BSCCO (Fig. 24.11k). Similar checkerboards, which do not show any $E(k)$ dispersion, have also been found in the underdoped pseudogap phase at temperatures higher than the superconducting transition temperature [24.156] or at dopant densities lower than the critical doping [24.157]. Depending on the sample, the patterns can be either homogeneous or inhomogeneous and exhibit slightly different periodicities. However, the fact that the pattern persists within the superconducting phase as shown in Fig. 24.11l, at least for Na-CCOC, indicates that the corresponding phase can coexist with superconductivity. This raises the question of whether spin density waves are the central opponent to HTSC. Interestingly, a checkerboard pattern of similar periodicity, but without long-range order, is also found, if one displays the particle–hole asymmetry of $\mathrm{d}I/\mathrm{d}V(V)$ intensity in underdoped samples at low temperature [24.158]. Since the observed asymmetry is known to be caused by the lifting of the correlation gap with doping, the checkerboard pattern might be directly linked to the corresponding localized holes in the CuO planes appearing at low doping. Although a comprehensive model for HTSC materials is still lacking, STS contributes significantly to disentangling this puzzle.

Notice that all the measurements described above have probed the superconducting phase only indirectly by measuring the quasiparticle LDOS. The superconducting condensate itself could principally also be probed directly using Cooper-pair tunneling between a superconducting tip and a superconducting sample. A proof of principle of this detection scheme has indeed been given at low tunneling resistance ($R \approx 50\,\mathrm{k}\Omega$) [24.159], but meaningful spatially resolved data are still lacking.

24.3.4 Imaging Spin Polarization: Nanomagnetism

Conventional STS couples to the LDOS, i. e., the charge distribution of the electronic states. Since electrons also have spin, it is desirable to also probe the spin distribution of the states. This can be achieved by spin-polarized STM (SP-STM) using a tunneling tip covered by a ferromagnetic material [24.160]. The coating acts as a spin filter or, more precisely, the tunneling current depends on the relative angle α_{ij} between the spins of the tip and the sample according to $\cos(\alpha_{ij})$. Consequently, a particular tip is not sensitive to spin orientations of the sample perpendicular to the spin orientation of the tip. Different tips have to be prepared to detect different spin orientations. Moreover, the stray magnetic field of the tip can perturb the spin orientation of the sample. To avoid this, a technique using antiferromagnetic Cr as a tip coating material has been developed [24.161]. This avoids stray fields, but still provides a preferential spin orientation of the few atoms at the tip apex that dominate the tunneling current. Depending on the thickness of the Cr coating, spin orientations perpendicular or parallel to the sample surface, implying corresponding sensitivities to the spin directions of the sample, are achieved.

SP-STM has been used to image the evolution of magnetic domains with increasing B field (Fig. 24.12a–d) [24.162], the antiferromagnetic order of a Mn monolayer on W(110) [24.163] as well as of a Fe monolayer on W(100) (Fig. 24.12e) [24.164], and the out-of-plane orientation of a magnetic vortex core in the center of a nanomagnet exhibiting the flux closure configuration [24.165].

In addition, more complex atomic spin structures showing chiral or noncollinear arrangements have been identified [24.166–168]. Even the spin orientation of a single adatom could be detected, if the adatom is placed either directly on a ferromagnetic island [24.169] or close to a ferromagnetic stripe [24.26]. In the latter case, hysteresis curves of the ferromagnetic adatoms could be measured, as shown in Fig. 24.12f–h. It was found that the adatoms couple either ferromagnetically (Fig. 24.12g) or antiferromagnetically (Fig. 24.12h) to the close-by magnetic stripe; i. e., the hysteresis is either in-phase or out-of-phase with the hysteresis of the stripe. This behavior, depending on adatom–stripe distance in an oscillating fashion, directly visualizes the famous Ruderman–Kittel–Kasuya–Yoshida (RKKY) interaction [24.26].

An interesting possibility of SP-STM is the observation of magnetodynamics on the nanoscale. Nanoscale ferromagnetic islands become unstable at a certain temperature, the so-called superparamagnetic tran-

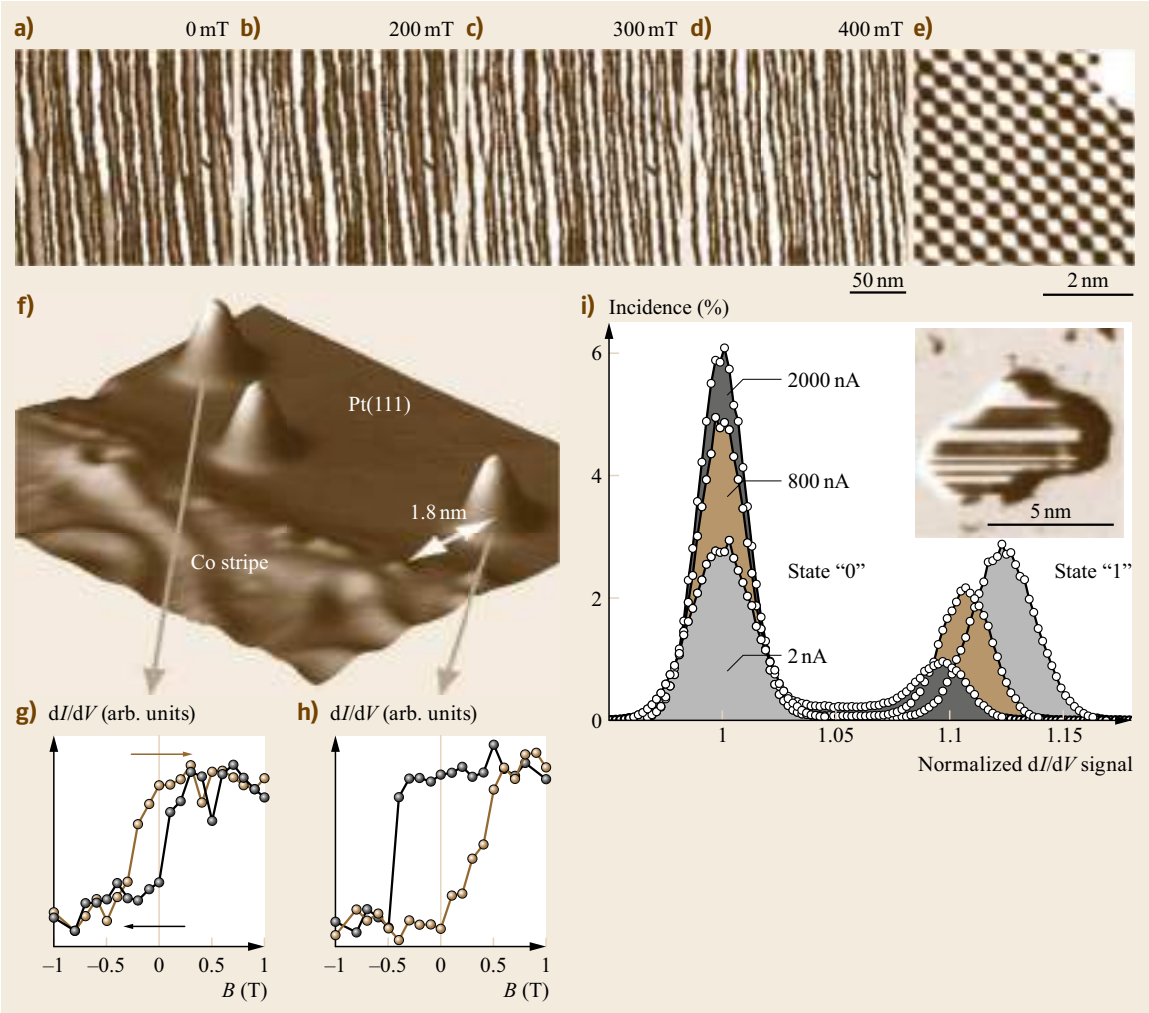

Fig. 24.12 **(a–d)** Spin-polarized STM images of 1.65 monolayers of Fe deposited on a stepped W(110) surface measured at different B fields, as indicated. Double-layer and monolayer Fe stripes are formed on the W substrate; only the double-layer stripes exhibit magnetic contrast with an out-of-plane sensitive tip, as used here. *White* and *grey areas* correspond to different domains. Note that more white areas appear with increasing field (© M. Bode, Argonne **(a–d)**). **(e)** STM image of an antiferromagnetic Fe monolayer on W(001) exhibiting a checkerboard pattern of spin-down (*dark*) and spin-up (*bright*) atoms (© A. Kubetzka, Hamburg); **(f)** STM image of a Pt(111) surface with a Co stripe deposited at the Pt edge as marked. Single Co atoms, visible as *three hills*, are deposited subsequently on the surface at $T = 25\,\mathrm{K}$; **(g,h)** $\mathrm{d}I/\mathrm{d}V(B)$ curves obtained above the Co atoms marked in **(f)** using a spin-polarized tip at $V = 0.3\,\mathrm{V}$. The *colors* mark the sweeping direction of the B field. Obviously the resulting contrast is hysteretic with B and opposite for the two Co atoms. This indicates a different sign of ferromagnetic coupling to the Co stripe. (© J. Wiebe, Hamburg **(f–h)**); **(i)** observed incidences of differential conductivities above a single monolayer Fe island on W(110) with a spin-polarized tip. The *three curves* are recorded at different tunneling currents and the increasing asymmetry shows a preferential spin direction with increasing spin-polarized current. *Inset*: $\mathrm{d}I/\mathrm{d}V$ image of the Fe island at $T = 56\,\mathrm{K}$ showing the irregular change of $\mathrm{d}I/\mathrm{d}V$ intensity (© S. Krause, Hamburg)

sition temperature. Above this temperature, the direction of magnetization switches back and forth due to thermal excitations. This switching results in a stripe-like contrast in SP-STM images, as visible in the *inset* of Fig. 24.12i. The island appears dark during the time when the orientation of the island spin is opposite to the orientation of the tip spin, and switches to bright when the island spin orientation changes. By observing

the switching as a function of time on different islands at different temperatures, the energy barriers of individual islands can be determined [24.170]. Even more importantly, the preferential orientation during switching can be tuned by the tunneling current. This is visible in Fig. 24.12i, which shows the measured orientational probability at different tunneling currents [24.171]. The observed asymmetry in the peak intensity increases with current, providing evidence that current-induced magnetization switching is possible even on the atomic scale.

24.4 Scanning Force Microscopy and Spectroscopy

The examples discussed in the previous section show the wide variety of physical questions that have been tackled with the help of LT-STM. Here, we turn to the other prominent scanning probe method that is applied at low temperatures, namely SFM, which gives complementary information on sample properties on the atomic scale.

The ability to detect *forces* sensitively with spatial resolution down to the atomic scale is of great interest, since force is one of the most fundamental quantities in physics. Mechanical force probes usually consist of a micromachined cantilever with a tip at its free end that is brought close to the sample surface. Basically, two methods exist to detect forces with cantilever-based probes: the *static* and the *dynamic* mode [24.172, 173]. They can be used to generate a laterally resolved image (*microscopy* mode) or to determine the distance dependence of force or a related quantity (*spectroscopy* mode).

In the static mode, a force that acts on the tip bends the cantilever. By measuring its deflection Δz, the tip–sample force F_{ts} can be directly calculated from Hooke's law: $F_{\mathrm{ts}} = c_{\mathrm{z}} \Delta z$, where c_{z} denotes the spring constant of the cantilever. In the various dynamic modes, the cantilever is oscillated with amplitude A, typically at or near its eigenfrequency f_0. Under ambient conditions or in liquids, amplitude modulation (AM-SFM) is typically used to detect amplitude changes or the phase shift between the driving excitation and cantilever oscillation. In vacuum, the frequency shift Δf of the cantilever due to tip–sample interaction is measured by the frequency modulation technique (FM-SFM). Converting the measured quantity (amplitude, phase or frequency shift) into a physically meaningful quantity, e.g., the tip–sample interaction force F_{ts} or potential V_{ts}, is not always straightforward and requires an analysis of the equation of motion of the oscillating tip [24.174–177]. Whatever method is used, the resolution of a cantilever-based force detection method is fundamentally limited by its intrinsic *thermomechanical* noise. If the cantilever is in thermal equilibrium at a temperature T, the equipartition theorem predicts a thermally induced *root-mean-square* (rms) motion of the cantilever in the z-direction of $z_{\mathrm{rms}} = (k_{\mathrm{B}} T / c_{\mathrm{eff}})^{1/2}$, where k_{B} is the Boltzmann constant and $c_{\mathrm{eff}} = c_{\mathrm{z}} + \partial F_{\mathrm{ts}} / \partial z$. Note that usually $\partial F_{\mathrm{ts}} / \partial z \gg c_{\mathrm{z}}$ in the contact regime and $\partial F_{\mathrm{ts}} / \partial z < c_{\mathrm{z}}$ in the noncontact regime. Evidently, this fundamentally limits the force resolution in the static mode. Of course, the same is true for the different dynamic modes, because the thermal energy $k_{\mathrm{B}} T$ excites the eigenfrequency f_0 of the cantilever. Thermal noise is *white* noise, i. e., its spectral density is flat. However, if the cantilever transfer function is taken into account, one can see that the thermal energy mainly excites f_0. This explains the term *thermo* in thermomechanical noise, but what is the *mechanical* part?

A more detailed analysis reveals that the thermally induced cantilever motion is given by

$$z_{\mathrm{rms}} = \sqrt{\frac{2 k_{\mathrm{B}} T B}{\pi c_{\mathrm{z}} f_0 Q}} \,, \tag{24.2}$$

where B is the measurement bandwidth and Q is the quality factor of the cantilever. Analogous expressions can be obtained for all quantities measured in dynamic modes, because the deflection noise translates, e.g., into frequency noise [24.8]. Note that f_0 and c_{z} are correlated with each other via $2\pi f_0 = (c_{\mathrm{z}} / m_{\mathrm{eff}})^{1/2}$, where the effective mass m_{eff} depends on the geometry, the density, and the elasticity of the material. The Q-factor of the cantilever is related to the external damping of the cantilever motion in a medium and on the intrinsic damping within the material. This is the *mechanical* part of the fundamental cantilever noise. Thus, it becomes evident from (24.2) that the smallest fundamental noise is achievable in vacuum, where the Q-factors are more than 100 times larger than in air, and at low temperatures.

Besides the reduced noise, the application of force detection at low temperatures is motivated by increased stability and the possibility to observe phenomena that appear below a certain critical temperature T_{c}, as outlined before. SFM experiments which have been performed at low temperatures until now were motivated by at least one of these reasons and have focused on atomic-scale and intramolecular imaging, force spectroscopy, atomic and molecular manipulation as well as the investigation of electrostatic and magnetic properties at increasingly small length scales. In the following, we briefly describe some exemplary results from each area.

24.4.1 Atomic-Scale and Intramolecular Imaging

In a simplified picture, the dimensions of the tip end and its distance to the surface limit the lateral resolution of force microscopy, since it is a near-field technique. Consequently, atomic resolution requires a stable single atom at the tip apex that has to be brought to a distance of some tenths of nanometers over an atomically flat surface. The latter condition can only be fulfilled in the dynamic mode, where the additional restoring force $c_z A$ at the lower turnaround point prevents the *jump-to-contact* phenomenon [24.19]. By preventing jump-to-contact, true atomic resolution is nowadays routinely obtained in vacuum (and increasingly, in liquids and air) by FM-SFM.

Si(111)-(7 × 7) was the first surface on which true atomic resolution was achieved [24.178] and several studies have been performed at low temperatures on this well-known material [24.179–181]. Because of its importance to the microelectronics industry, the Si(100) surface has also been targeted by low-temperature FM-SFM measurements. In particular, measurements performed at low temperatures have shown that the structure of the surface is defined by buckled Si dimers with tilted bonds leading to a $c(4 \times 2)$ reconstruction [24.182]. Additionally, it has been determined that tip-induced interactions at small tip–sample distances lead to dimer *flipping*, resulting in the occasional observation of a $p(2 \times 1)$ reconstruction during low temperature experiments [24.183]. Moreover, experiments by *Sweetman* et al. have demonstrated deliberate flipping of single dimers on the Si(100) surface at low temperatures via controlled tip–sample interactions, corresponding to pure mechanical toggling of an atomic-scale switch (Fig. 24.13) [24.184, 185]. Other low-temperature SFM experiments performed on semiconducting surfaces include those on indium arsenide, where noticeable displacements of tip and sample atoms due to interaction forces have been observed [24.186, 187]. Additionally, the combination of SFM and STM methods thanks to the utilization of tuning forks have allowed the precise determination of the surface structure of metal-semiconductor systems such as Ag:Si(111)-$(\sqrt{3} \times \sqrt{3})R30^\circ$ at low temperatures [24.188].

As discussed before, a particular advantage associated with low-temperature SFM operation is reduced noise and increased thermal as well as mechanical stability, which allow atomic-resolution imaging of, e.g., *weakly interacting* van der Waals surfaces. For such surfaces, much smaller atomic corrugation amplitudes are expected compared with strongly interacting surfaces of, e.g., semiconductors. A typical example is graphite, a layered material, where the carbon atoms are covalently bonded and arranged in a honeycomb structure within the (0001) plane. Individual graphene layers stick together by van der Waals forces. Because of the *ABA* stacking, three distinctive sites exist on the (0001) surface: carbon atoms with (*A*-type) and without (*B*-type) a neighbor in the next graphite layer and the *hollow site* (*H*-site) in the hexagon center. In static force microscopy operated in the contact regime as well as in STM, the contrast usually exhibits a trigonal symmetry with a periodicity of 246 pm, where *A*- and *B*-site carbon atoms could not be distinguished. However, in high-resolution SFM images acquired at low temperatures, a large maximum and two different minima can be resolved [24.10, 189]. By comparison with other experimental and simulation results in the literature [24.190–192], the large maximum can be assigned to the *H*-site, while the two different minima represent A- and B-type carbon atoms. In addition to graphite, the atomic-scale structure of a pure van der Waals crystal consisting of individual xenon atoms could also be resolved by SFM performed at low temperatures, demonstrating the outstanding resolution and stability of the approach [24.193].

Of course, low-temperature SFM imaging experiments are not limited to semiconductor and van der Waals surfaces only. In particular, metal oxide surfaces such as TiO_2(110) [24.194, 195] and ionic crystal surfaces such as KBr(001) [24.196] have also been imaged with atomic resolution at low temperatures, among others.

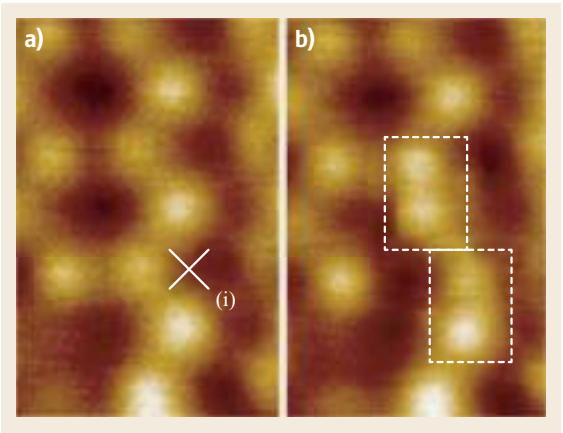

Fig. 24.13 LT-SFM images of the Si(100) surface that **(a)** demonstrate the atomic arrangement of the surface featuring the $c(4 \times 2)$ reconstruction and **(b)** *dimer flipping* (highlighted by *dashed rectangles*) induced by controlled force spectroscopy performed at location (i) in part **(a)**. Adapted from [24.185]

Performing SFM experiments at low temperatures not only allows atomic-scale imaging of clean, atomically flat surfaces but may also remarkably lead to the detailed visualization of *intramolecular* structure of individual molecules adsorbed on surfaces [24.197–202] and even bonds *between* individual molecules [24.203]. The key factor enabling the associated high resolution is the selective and deliberate *functionalization* of the SFM probe tip by, typically, an individual CO molecule. While the exact physical mechanism that gives rise to the submolecular imaging capability (Pauli repulsion versus force-interaction-induced relaxations of the CO molecule *dangling* at the tip end) is still under debate [24.204, 205], high-resolution imaging with functionalized probes certainly represents the state-of-the-art in low-temperature SFM experiments. In particular, while the visualization of the structural backbone of a single pentacene molecule [24.199] was covered worldwide by major media outlets (Fig. 24.14), the applications of the method rather quickly expanded and it recently became possible to precisely identify the structures of certain organic molecules [24.197, 200, 202], discriminate bond order [24.201], and perform KPFM with submolecular resolution [24.206, 207].

24.4.2 Force Spectroscopy

A wealth of information about the nature of the tip–sample interaction can be obtained by measuring its distance dependence. This is usually done by recording the measured quantity (deflection, frequency shift, amplitude change, phase shift) while changing the tip–sample distance by applying an appropriate voltage ramp to the z-electrode of the scan piezo. According to (24.2), low temperatures and high Q-factors (vacuum) considerably increase the force resolution. In the static mode, long-range forces and contact forces can be examined. Force measurements at small tip–sample distances are inhibited by the jump-to-contact phenomenon: If the force gradient $\partial F_{\mathrm{ts}}/\partial z$ becomes larger than the spring constant c_{z}, the cantilever cannot resist the attractive tip–sample forces and the tip snaps into the surface. Sufficiently large spring constants prevent this effect, but reduce the force resolution. In the dynamic modes, as explained before, jump-to-contact can be avoided due to the additional restoring force $c_{\mathrm{z}}A$. The highest sensitivity can be achieved in vacuum by using the FM technique, i. e., by recording $\Delta f(z)$-curves. An alternative FM spectroscopy method, the recording of $\Delta f(A)$-curves, has been suggested in [24.208]. Note that if the amplitude is much larger than the characteristic decay length of the tip–sample force, the frequency shift cannot simply be converted into force gradients by using $\partial F_{\mathrm{ts}}/\partial z = 2c_{\mathrm{z}}\Delta f/f_0$ [24.209]. Several methods have been published to convert $\Delta f(z)$ data into the tip–sample force $F_{\mathrm{ts}}(z)$ and the tip–sample potential $V_{\mathrm{ts}}(z)$ [24.174–177]. In addition to reducing noise and increasing force resolution, a major benefit of perform-

ing force spectroscopy at low temperatures is drastically reduced thermal drift, which allows recording spectroscopy data on the same atomically defined surface site for extended periods of time.

Several research groups around the world have reported atomically resolved force spectroscopy results acquired at low temperatures not long after the first demonstration of atomic-resolution imaging via FM-SFM [24.191, 210–213]. In particular, force spectroscopy data obtained on graphite has been found to be in good agreement with well-known interaction laws (Fig. 24.15a) [24.211]. Additionally, small differences in interaction forces exhibited by different surface atoms on Si(111)-(7 × 7) have also been detected via low-temperature force spectroscopy [24.213]. Moreover, low-temperature force spectroscopy has been utilized on ionic crystal surfaces to, e.g., chemically identify tip and surface atoms as well as characterize elastic deformations and asymmetry artifacts [24.210, 212]. It was even shown that CO-terminated probes can be used to acquire several $\Delta f(z)$-curves above another CO molecule adsorbed on a Cu(111) surface at low temperatures, to obtain a two-dimensional, vertical map of interaction energy between the two molecules with high resolution (Fig. 24.15b) [24.214]. It should be mentioned that while spectacular results regarding chemical identification of individual atoms via force spectroscopy have been previously reported based on experiments performed at *room temperature* [24.215], the signal-to-noise-ratio had to be drastically increased by averaging about 100 curves at every atom species, which required an appropriate atom tracking scheme [24.6, 216].

While the pioneering experiments described above are all based on the careful acquisition of individual $\Delta f(z)$ curves at well-defined surface sites (or several such curves to form two-dimensional, vertical maps as in [24.214] and [24.218]) and eventual conversion to $F_{ts}(z)$ or $V_{ts}(z)$ data, it has recently been shown that it is possible to reliably combine *thousands* of such curves via the method of *three-dimensional atomic force microscopy* (3-D-AFM) to construct volumetric maps of interaction force/energy with pm spatial and pN (meV) force (energy) resolution [24.10, 194, 217, 219, 220], mainly thanks to the development of specialized data acquisition/processing procedures and operation at low temperatures which severely reduces thermal drift [24.221, 222]. Following the first *proof-of-concept* demonstration of 3-D-AFM on graphite [24.10], the method has been expanded to cover simultaneous acquisition of tunneling currents together with interaction forces. The corresponding technique of 3-D-AFM/STM (or alternatively, 3-D-SPM) has been recently shown to deliver complementary 3-D maps of interaction force

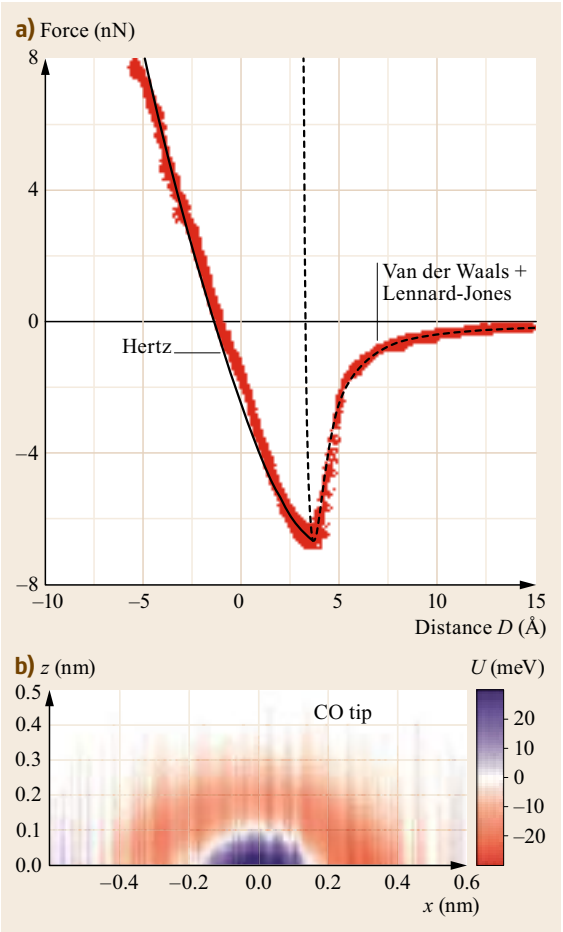

Fig. 24.15 **(a)** A force spectroscopy curve acquired on graphite with a silicon tip at low temperature. The interaction at first closely follows a combination of van der Waals and Lennard-Jones laws. At closer tip–sample distances, Hertzian contact mechanics approximates the force interaction reasonably well. **(b)** A two-dimensional map of interaction energy acquired with a CO-terminated tip on a CO molecule adsorbed on Cu(111). *Red* (*blue*) corresponds to attractive (repulsive) interactions. and tunneling current on sample surfaces of surface-oxidized copper (Cu(100)–O) [24.217] and most recently, TiO_2(110) [24.194], with atomic resolution. Specifically, Fig. 24.16 shows the atomic structure associated with the Cu(100)–O surface and the corresponding three-dimensional map of interaction forces spanning a lateral extent of 2.89 nm × 2.89 nm. The magnitude of the maximum interaction force measured in the bottom plane is ≈ 1.34 nN whereas the contrast between atomically defined lattice sites is ≈ 23 pN. Moreover, a *horizontal* cut of interaction forces ex-

tracted from the 3-D force map of Fig. 24.16b at the tip–sample distance of closest approach is shown in Fig. 24.17a, together with the simultaneously recorded map of tunneling currents at the same tip–sample distance (Fig. 24.17b). While symmetry arguments allow assigning the bright spots in the force image to individual oxygen atoms, the tunneling current map exposes a completely different structural arrangement that corresponds to the copper atoms of the surface. In addition to the simultaneous imaging of multiple atomic species on the sample surface, other exciting features of the discussed data set involve (i) the detection of minute differences in force interaction on individual oxygen atoms and (ii) the visualization and structural/chemical identification of surface defects, with support from ab initio calculations [24.217]. To further illustrate the scientific insight that 3-D-AFM/STM measurements can provide, simultaneously acquired maps of interaction force and tunneling current on the prototypical metal oxide surface of TiO_2(110) are shown in Fig. 24.17c,d. In particular, it is observed that a peculiar defect in the form of a subsurface hydrogen atom modulates the surface density of electronic states, without a detectable influence on interaction force [24.194]. Thus, it is seen that the detailed information on tip–sample interactions that is obtained by 3-D-AFM/STM definitely has the potential to provide much needed experimental input into research fields as diverse as catalysis and friction, among others.

It must be mentioned that the application of the method of 3-D-AFM is not restricted to low temperatures and it has indeed been applied multiple times at room temperature thanks to the development of software-based drift correction methods [24.223, 224].

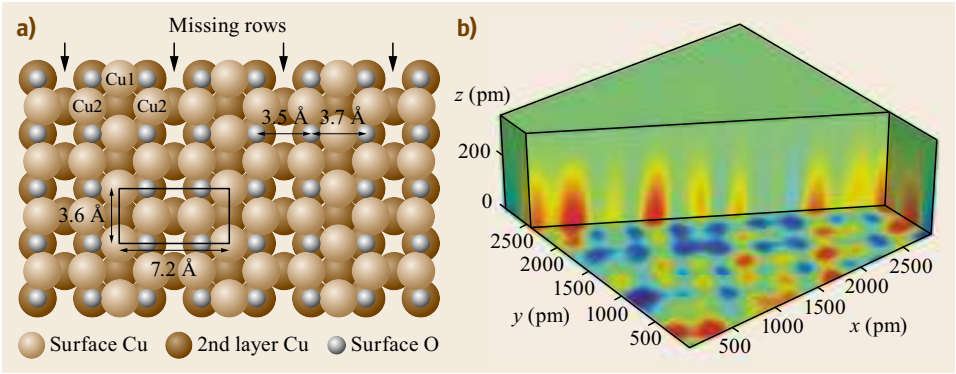

Fig. 24.16 **(a)** Structural model of the surface-oxidized Cu(100) surface (Cu(100)–O). **(b)** Atomically resolved, 3-D map of interaction forces acquired on Cu(100)–O via 3-D-AFM at low temperature. Adapted from [24.217]

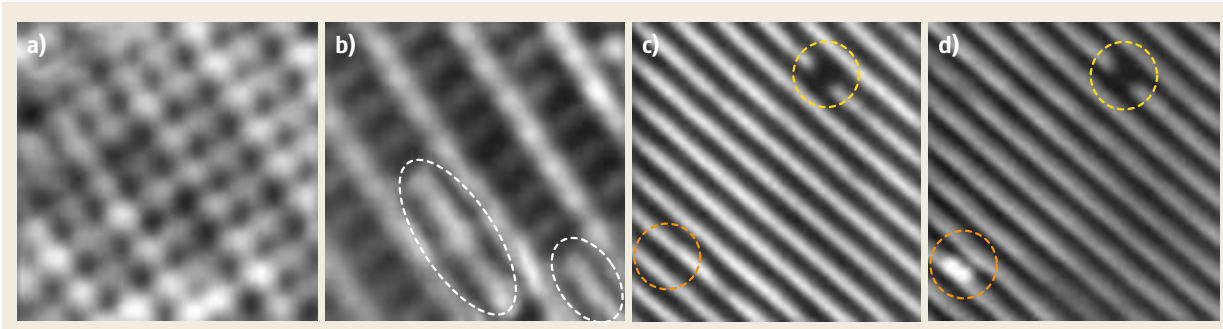

Fig. 24.17 **(a,b)** Simultaneously acquired, atomic-scale maps (2.89 nm × 2.89 nm) of interaction force **(a)** and tunneling current **(b)** on the Cu(100)–O surface at low temperature. Circular maxima in **(a)** correspond to oxygen atoms while the tunneling current channel **(b)** resolves copper atoms. Linear surface defects are highlighted by *dashed white ellipses*. **(c,d)** Simultaneously acquired, atomic-scale maps (6.55 nm × 6.55 nm) of interaction force **(c)** and tunneling current **(d)** on the TiO_2(110) surface at low temperature. *Bright rows* correspond to the arrangement of bridging oxygen ions on the surface. While a point defect in the form of an oxygen vacancy (*dashed yellow circle*) is visible in both data channels, a subsurface hydrogen interstitial (*dashed orange circle*) is found to modulate only the tunneling current data, without a detectable influence on interaction force. Adapted from [24.217] and [24.194], respectively

On the other hand, low-temperature operation results in certain significant advantages that have been discussed in detail in the literature [24.222, 225]. Finally, the application of 3-D-AFM has recently expanded from atomically flat substrate surfaces to individual molecules [24.199, 226].

24.4.3 Atomic and Molecular Manipulation

Atomic-scale manipulation has first been demonstrated via the application of LT-STM and the method is still used successfully to manipulate individual adsorbates (atoms or molecules) on conducting surfaces (Sect. 24.3.1). In most of these experiments the adsorbate is dragged with the tip by the attractive force acting between the foremost tip apex atoms and the adsorbate. By adjusting a large or a small tip–sample distance via the tunneling resistance, it is possible to switch between imaging and manipulation. In the past decade, it has been shown that controlled manipulation of individual atoms and molecules is also possible by using dynamic SFM. Vertical manipulation was performed by pressing the tip in a controlled manner into a Si(111)-(7×7) surface [24.227] at low temperatures. The strong repulsion leads to the removal of the selected silicon atom. The process could be traced by recording the frequency shift and the damping signal during the approach. For lateral manipulation, a *rubbing* technique has been utilized [24.228] – again at low temperature – where the slow scan axis is halted above a selected atom, while the tip–surface distance is gradually reduced until the selected atom hops to a new stable position. Figure 24.18 shows a Ge adatom on Ge(111)-$c(2\times8)$ that was moved during scanning in two steps from its original position (Fig. 24.18a) to its final position (Fig. 24.18c). More recently, vertical manipulation of individual Cu atoms on a reconstructed Cu(110): O $-$ $p(2\times1)$ surface has been demonstrated at low temperature and the associated mechanism elucidated via a combined density functional theory and kinetic Monte Carlo simulation approach [24.229].

While it is not unreasonable to think that operation at low temperature would be a prerequisite for atomic-scale manipulation due to the fact that the diffusion and desorption processes associated with the adsorbates would be severely suppressed, it has been shown that it is in fact possible to perform atomic-scale manipulation successfully at room temperature using dynamic SFM on semiconducting [24.230, 231] and even insulating surfaces [24.232], leading to the ability to construct complex atomic-scale patterns on surfaces via a bottom-up and deterministic approach (Fig. 24.19), with serious implications for *atomic-scale* device designs.

Atoms have not been the only species that have been controllably manipulated via SFM. In particular, it was shown a decade ago that individual, water-related defects can be manipulated on the insulating CaF_2(111) surface [24.233]. Additionally, individual molecules have also been laterally manipulated on various substrates by SFM [24.47, 234–236] and even directed rotations of individual porphyrin molecules could be induced by precisely controlled force spectroscopy [24.237].

A major advantage of SFM compared to STM within the framework of atomic-scale manipulation is the fact that SFM allows researchers to measure vertical and lateral forces involved in the manipulation process. In a seminal paper published in 2008, *Ternes* et al. have manipulated individual Co atoms and CO molecules on Pt(111) and Cu(111) surfaces, and precisely measured the lateral forces required for manip-

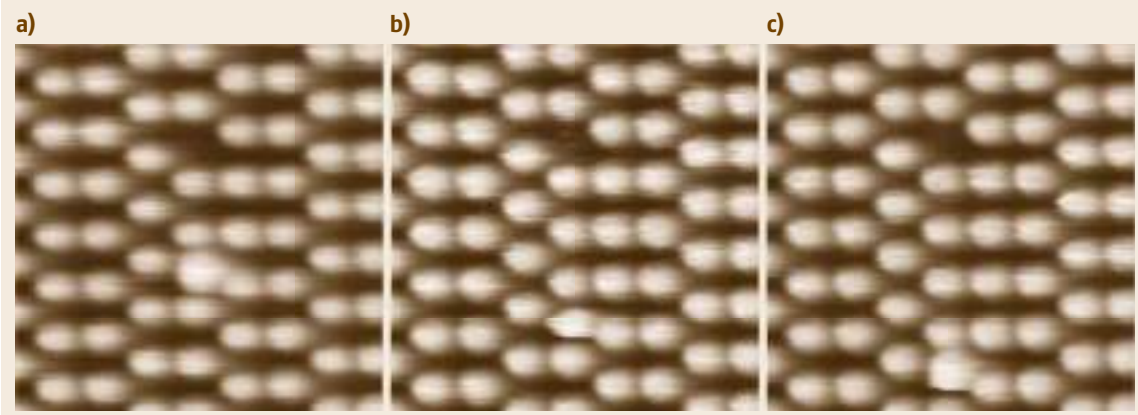

Fig. 24.18a–c Consecutively recorded FM-AFM images showing the tip-induced manipulation of a Ge adatom on Ge(111)-c(2×8) at 80 K. Scanning was performed from bottom to top (© N. Oyabu [24.228])

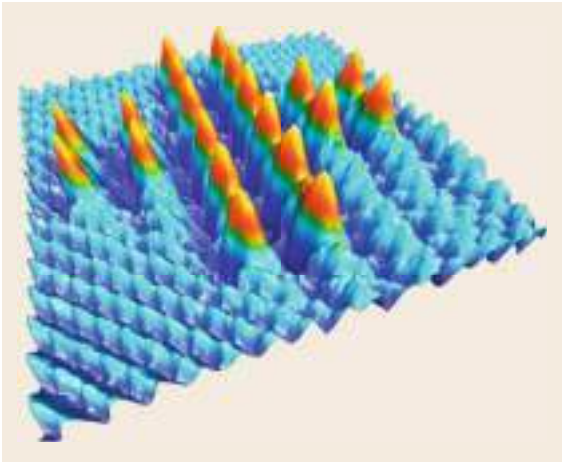

Fig. 24.19 Three-dimensional representation of a *Swiss cross* made of substitutional bromine ions that are assembled atom-by-atom on a sodium chloride surface via SFM. This result represents the first time that controllable atomic-scale manipulation on an insulator surface has been accomplished at room temperature. Adapted from [24.232]

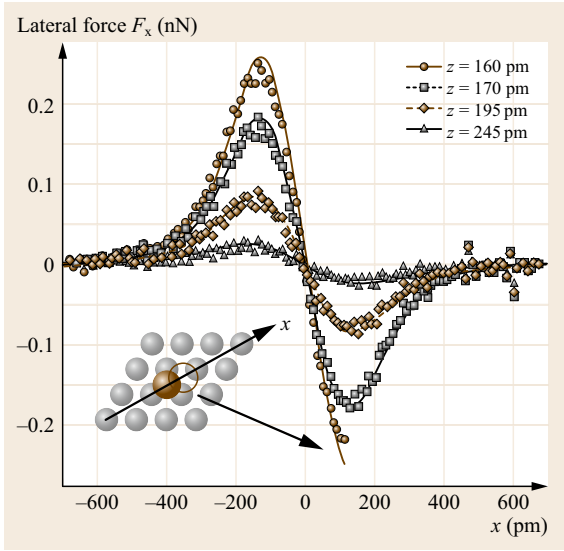

Fig. 24.20 Lateral force curves recorded at constant tip–sample separation z. At the lowest separation a discontinuity appears, which marks the jump of the Co atom form one site to the next as indicated in the *inset* (©. M. Ternes [24.47])

ulation [24.47]. This goal was achieved by recording constant-height data at different tip–sample distances to obtain first $V_{ts}(x, z)$ and then the lateral force $F_x(x, z) = \partial V_{ts}(x, z)/\partial x$. Four curves of the whole data set are displayed in Fig. 24.20. The discontinuity of the lateral force at the lowest adjusted tip–sample distance ($z = 160\,\text{pm}$) indicates the jump of a Co atom from one hollow site to the next on Pt(111) (see *inset* of Fig. 24.20). The jump takes place at about 210 pN, corresponding to the lateral force required for manipulation. More recently, *Kawai* et al. have performed a remarkable experiment where individual nanoribbons of graphene have been picked up from one side and controllably slid on a clean Au(111) surface via dynamic SFM at low temperature, whereby *superlubric* sliding was encountered [24.238].

24.4.4 Kelvin Probe Force Microscopy

The use of Kelvin probe force microscopy (KPFM) [24.239] in nanoscience and nanotechnology research has accelerated rapidly in recent years, thanks to the capability of the method to readily visualize local contact potential differences (LCPDs) over sample surfaces and even individual molecules with very high (down to atomic-scale and even intramolecular) resolution. The operational details of the method are explained elsewhere [24.240] and it should be sufficient here to state that KPFM is applied in conjunction with dynamic SFM, and the imaging typically involves a new feedback loop that is employed to determine the LCPD at each lateral position on a given sample surface by precisely measuring the bias voltage that needs to be applied for a minimization of the electrostatic tip–sample interaction. This leads to the simultaneous acquisition of a *KPFM map* together with the conventional topography map on the sample surface, whereby the KPFM map now reflects local LCPD variations on the surface.

While the mentioned variations in LCPD can be directly correlated to work function differences for conducting surfaces, in the case of insulating surfaces, KPFM contrast was shown to be determined by fixed charges and/or dipoles [24.240]. Even though the application of the KPFM method is not restricted to low temperatures, certain exciting results have been reported under such conditions. In particular, *König* et al. have determined the charge state of individual defects [24.241] and it was even possible to achieve submolecular resolution with KPFM and thus probe the charge distribution inside individual molecules at low temperatures [24.206, 207]. Specifically, a CO-functionalized tip has been utilized by *Mohn* et al. to perform combined NC-AFM/KPFM (NC: non-contact) experiments on a single naphthalocyanine molecule, revealing an asymmetric charge distribution inside the molecule (Fig. 24.21) [24.206]. Thus, the capability of KPFM at low temperatures to provide essential quantitative information about the physical and chemical properties of individual adsorbates is demonstrated.

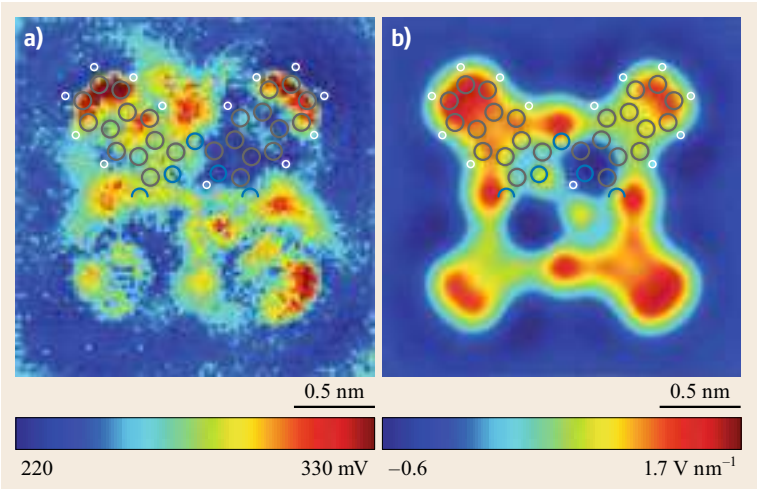

Fig. 24.21 **(a)** KPFM map of an individual naphthalocyanine molecule acquired at low temperature that highlights an asymmetric intramolecular charge distribution and **(b)** the corresponding calculation of electric field magnitude at a distance of 0.3 nm above the molecule. Adapted from [24.206]

24.4.5 Magnetic Force Microscopy

To detect magnetostatic tip–sample interactions with magnetic force microscopy (MFM), a ferromagnetic probe has to be used. Such probes are readily prepared by evaporating a thin magnetic layer, e.g., 10 nm iron, onto the tip. Because of the in-plane shape anisotropy of thin films, the magnetization of such tips lies predominantly along the tip axis, i. e., perpendicular to the surface. Since magnetostatic interactions are long-range, they can be separated from the topography by scanning at a certain constant height (typically around 20 nm) above the surface, where the z-component of the sample stray field is probed (Fig. 24.22a). Therefore, MFM is always operated in the noncontact regime. The signal from the cantilever is directly recorded while the z-feedback is switched off. MFM can be operated in the static mode or in the dynamic modes (AM-MFM at ambient pressures and FM-MFM in vacuum; AM – amplitude-modulation; FM – frequency-modulation). A lateral resolution below 50 nm can be routinely obtained.

Observation of Domain Patterns

MFM is widely used to visualize domain patterns of ferromagnetic materials. At low temperatures, *Moloni* et al. observed the domain structure of magnetite below its Verwey transition temperature (T_V = 122 K) [24.242], but most of the work concentrated on thin films of $La_{1-x}Ca_xMnO_3$ [24.243–245]. Below T_V, the conductivity decreases by two orders of magnitude and a small structural distortion is observed. The domain structure of this mixed valence manganite is of great interest, because its resistivity strongly depends on the external magnetic field, i. e., it exhibits a large colossal magnetoresistive effect. To investigate the field dependence of domain patterns under ambient conditions, electromagnets have to be used. They can cause severe thermal drift problems due to Joule heating of the coils by large currents. Flux densities on the order of 100 mT can be achieved. In contrast, much larger flux densities (more than 10 T) can be rather easily produced by implementing a superconducting magnet in low-temperature setups. With such a design, *Liebmann* et al. recorded the domain structure along the major hysteresis loop of $La_{0.7}Ca_{0.3}MnO_3$ epitaxially grown on $LaAlO_3$ (Fig. 24.22b–f) [24.243]. The film geometry (with thickness of 100 nm) favors an in-plane magnetization, but the lattice mismatch with the substrate induces an out-of-plane anisotropy. Thereby, an irregular pattern of strip domains appears at zero field. If the external magnetic field is increased, the domains with antiparallel orientation shrink and finally disappear in saturation (Fig. 24.22b,c). The residual contrast in saturation (Fig. 24.22d) reflects topographic features. If the field is decreased after saturation (Fig. 24.22e,f), cylindrical domains first nucleate and then start to grow. At zero field, the maze-type domain pattern evolves again. Such data sets can be used to analyze domain nucleation and the domain growth mode. Moreover, because of negligible drift at low temperatures, domain structure and surface morphology can be directly compared, because every MFM can be used as a regular topography-imaging force microscope.

Detection of Individual Vortices in Superconductors

Numerous low-temperature MFM experiments have been performed on superconductors [24.246–252]. Some basic features of superconductors have been mentioned already in Sect. 24.3.3, *Superconductors*. The main difference of STM/STS compared to MFM is its

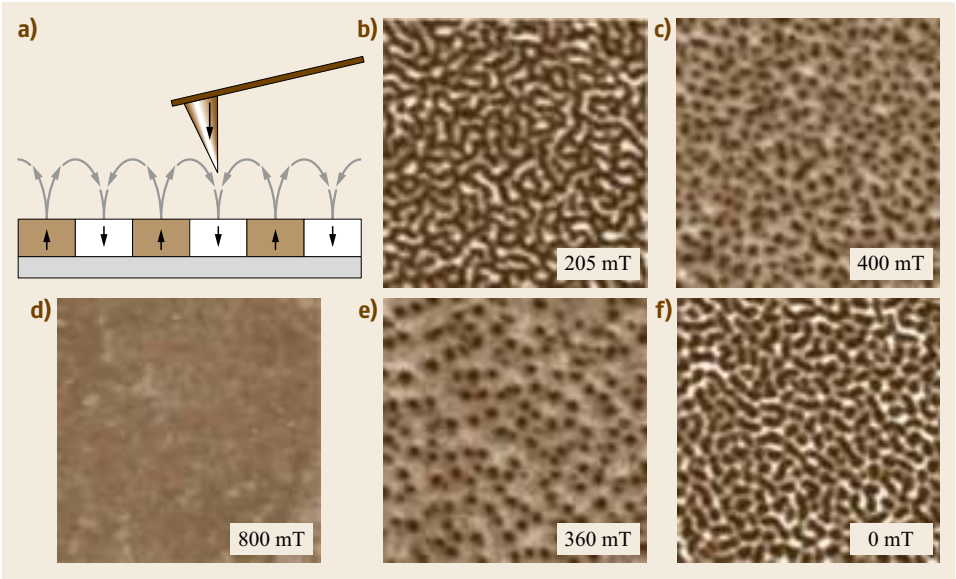

Fig. 24.22 Principle of MFM operation **(a)** and field-dependent domain structure of a ferromagnetic thin film **(b–f)** recorded at 5.2 K with FM-MFM. All images were recorded on the same $4\,\mu m \times 4\,\mu m$ scan area. The $La_{0.7}Ca_{0.3}MnO_3/LaAlO_3$ system exhibits a substrate-induced out-of-plane anisotropy. *Bright* and *dark areas* are visible and correspond to attractive and repulsive magnetostatic interactions, respectively. The series shows how the domain pattern evolves along the major hysteresis loop, i. e., from zero field to saturation at 600 mT and back to zero field. **(b–f)** adapted from [24.243]

high sensitivity to the electronic properties of the surface. Therefore, careful sample preparation is a prerequisite. This is not so important for MFM experiments, since the tip is scanned at a certain distance above the surface.

Superconductors can be divided into two classes with respect to their behavior in an external magnetic field. For type-I superconductors, all magnetic flux is entirely excluded below their critical temperature T_c (Meissner effect), while for type-II superconductors, cylindrical inclusions (*vortices*) of normal material exist in a superconducting matrix (*vortex* state). The radius of the vortex *core*, where the Cooper pair density decreases to zero, is on the order of the coherence length ξ. Since the superconducting gap vanishes in the core, they can be detected by STS. Additionally, each vortex contains one magnetic quantum flux $\Phi = h/2e$ (where h represents Planck's constant and e the electron charge). Circular supercurrents around the core screen the magnetic field associated with a vortex; their radius is given by the London penetration depth λ of the material. This magnetic field of the vortices can be detected by MFM. Investigations have been performed on the two most popular copper oxide high-T_c superconductors $YBa_2Cu_3O_7$ [24.246, 252, 253] and $Bi_2Sr_2CaCu_2O_8$ [24.247, 252], on the only elemental conventional type-II superconductor Nb [24.249, 250], and on the layered compound crystal $NbSe_2$ [24.250, 254].

Most often, vortices have been generated by cooling the sample from the normal state to below T_c in an external magnetic field. After such a *field cooling* procedure, the energetically most favorable vortex arrangement is a regular triangular Abrikosov lattice. *Volodin* et al. were able to observe such an Abrikosov lattice on $NbSe_2$ [24.254]. The intervortex distance d is related to the external field B during cool-down via $d = (4/3)^{1/4}(\Phi/B)^{1/2}$. Another way to introduce vortices into a type-II superconductor is vortex penetration from the edge by applying a magnetic field at temperatures below T_c. According to the Bean model, a vortex density gradient exists under such conditions within the superconducting material. *Pi* et al. slowly increased the external magnetic field until the vortex front approaching from the edge reached the scanning area [24.247].

If the vortex configuration is dominated by the *pinning* of vortices at randomly distributed structural defects, no Abrikosov lattice emerges. The influence of pinning centers can be studied easily by MFM, because every MFM can be used to scan the topography in its AFM mode. This has been done for natural growth defects by *Moser* et al. on $YBa_2Cu_3O_7$ [24.253] and for $YBa_2Cu_3O_7$ and niobium thin films, respectively, by *Volodin* et al. [24.251]. *Roseman* et al. investigated

the formation of vortices in the presence of an artificial structure on niobium films [24.249], while *Pi* et al. produced columnar defects by heavy-ion bombardment in a $Bi_2Sr_2CaCu_2O_8$ single crystal to study the strong pinning at these defects [24.247].

Figure 24.23 demonstrates that MFM is sensitive to the polarity of vortices. In Fig. 24.23a, six vortices have been produced in a niobium film by field cooling in $+0.5$ mT. The external magnetic field and tip magnetization are parallel, therefore, the tip–vortex interaction is attractive (bright contrast). To remove the vortices, the niobium was heated above T_c (≈ 9 K). Thereafter, vortices of opposite polarity have been produced by field cooling in -0.5 mT, which appear dark in Fig. 24.23b. The vortices are probably bound to strong pinning sites, because the vortex positions are identical in both images of Fig. 24.23. By imaging the vortices at different scanning heights, *Roseman* et al. tried to extract values for the London penetration depth from the scan-height dependence of their profiles [24.248]. While good qualitative agreement with theoretical predictions has been found, the absolute values do not agree with published literature values. The disagreement was attributed to the convolution between the tip and vortex stray fields. Better values might be obtained with calibrated tips.

24.4.6 Magnetic Exchange Force Microscopy and Spectroscopy

The resolution of MFM is limited to the nanometer range, because the long-range magnetostatic tip–sample interaction is not localized between individual surface atoms and the foremost tip apex atom [24.255].

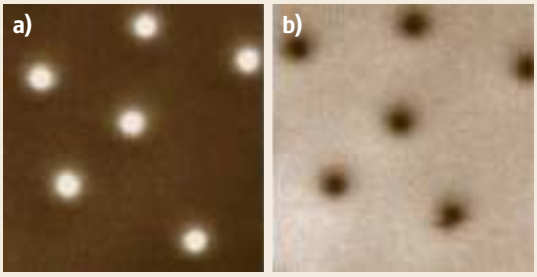

Fig. 24.23 Two $5\,\mu m \times 5\,\mu m$ FM-MFM images of vortices in a niobium thin film after field-cooling at 0.5 mT **(a)** and -0.5 mT **(b)**, respectively. Since the external magnetic field was parallel in **(a)** and antiparallel in **(b)** with respect to the tip magnetization, the vortices exhibit opposite contrast. Strong pinning dominates the position of the vortices, since they appear at identical locations in **(a)** and **(b)** and are not arranged in a regular Abrikosov lattice (© P. Grütter [24.248])

As early as 1991 *Wiesendanger* et al. [24.256] proposed that the short-range magnetic exchange interaction can be utilized to image the configuration of magnetic moments with atomic resolution. For the suggested test system – NiO(001), an antiferromagnetic insulator – *Momida* and *Oguchi* provided density functional calculations [24.257]. They found a magnetic exchange force between the magnetic moments of a single iron atom (the tip) and nickel surface atoms of more than 0.1 nN at tip–sample distances below 0.5 nm. Eventually, *Kaiser* et al. were able to prove the feasibility of magnetic exchange force microscopy (MExFM) on NiO(001) [24.258]. The super-exchange between neighboring (111) planes via bridging oxygen atoms results in a row-wise antiferromagnetic configuration of magnetic moments on the (001) surface. Hence the magnetic surface unit cell is twice as large as the chemical surface unit cell. Figure 24.24a shows the atomic-scale contrast due to a pure chemical interaction. Maxima and minima correspond to the oxygen and nickel atoms, respectively. Their arrangement represents the (1×1) surface unit cell. Figure 24.24b exhibits an additional modulation on chemically and structurally equivalent rows of nickel atoms (the minima). The structure corresponds to the (2×1) magnetic surface unit cell. Since the spin-carrying nickel 3d states are highly localized, the magnetic contrast only becomes significant at very small tip–sample distances. Subsequently, *Schmidt*

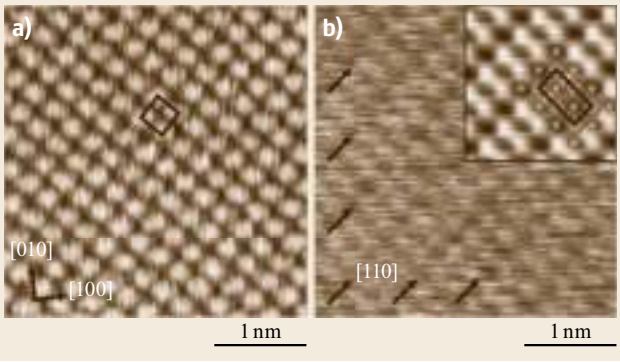

Fig. 24.24 **(a)** Pure chemical contrast on NiO(001) obtained with AFM using a nonmagnetic tip. Oxygen and nickel atoms are represented as maxima and minima, respectively, forming the (1×1) surface unit cell (*black square*). *Arrows* indicate the main crystallographic directions. **(b)** Additional modulation on neighboring nickel rows along the [110] direction (see *arrows*) due to the magnetic exchange interaction obtained with MExFM using a magnetic tip. The (2×1) structure (*black rectangle in the inset*) represents the magnetic surface unit cell. The *inset* is tiled together from the averaged magnetic unit cell calculated from the raw data, whereby the signal-to-noise ratio is significantly increased. Adapted from [24.258]

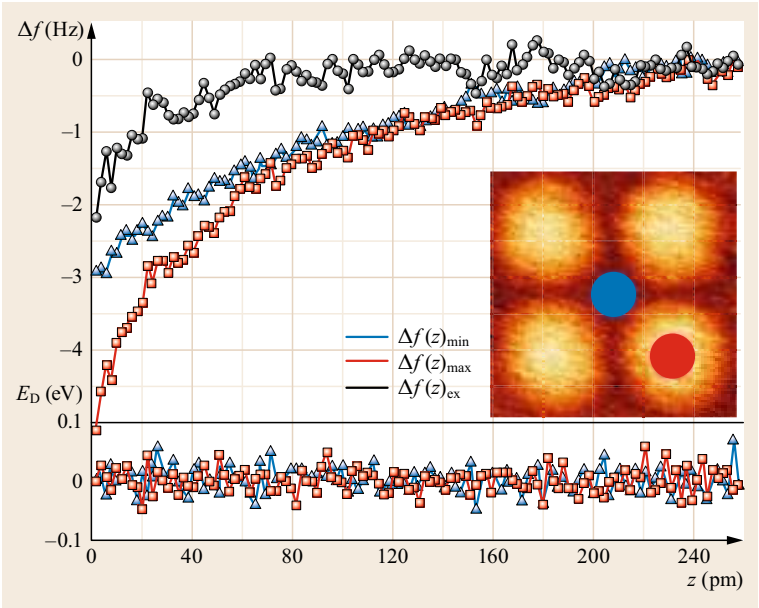

Fig. 24.25 Individual force spectroscopy curves acquired on two iron atoms with opposite spin (*blue* and *red*, respectively) and the corresponding difference (*black*) which is directly related to the magnetic exchange interaction. The curves in the bottom panel highlight the use of a *nondissipative* tip (energy dissipation $E_D \approx 0$). Adapted from [24.259]

et al. were able to perform MExFM with a much better signal-to-noise ratio on an itinerant metallic system: the antiferromagnetic iron monolayer on W(001) [24.260]. Density functional theory performed with a realistic tip model indicated significant relaxations of tip and sample atoms during imaging. Moreover, a comparison between simulation and experimental data revealed complex interplay between chemical and magnetic interaction, which results in the observed atomic-scale contrast. More recently, it became possible to quantify the distance dependence of the magnetic exchange interaction on metallic systems using magnetic exchange force spectroscopy (MExFS) [24.259] that relies on three-dimensional recording of interaction forces (Sect. 24.4.2). Specifically, force spectroscopy data obtained on atoms with opposite spin are subtracted from each other and the result corresponds to the magnetic exchange interaction (Fig. 24.25). Moreover, controllable magnetization switching via the utilization of the magnetic exchange interaction during MExFS experiments has been demonstrated [24.261].

24.4.7 Magnetic Resonance Force Microscopy

Another ambitious force-based approach utilizing magnetic tips is the proposed detection of individual spins by magnetic resonance force microscopy (MRFM) [24.262, 263]. Conventionally, nuclear spins are investigated by nuclear magnetic resonance (NMR), a spectroscopic technique to obtain microscopic chemical and physical information about molecules. An important application of NMR for medical diagnostics is magnetic resonance imaging (MRI). This tomographic imaging technique uses the NMR signal from thin slices through, e.g., the human body, to reconstruct its three-dimensional structure. Currently, at least 10^{12} nuclear spins must be present in a given volume to obtain a significant MRI signal. The ultimate goal of MRFM is to combine aspects of force microscopy with MRI to achieve true 3-D imaging with atomic resolution and elemental selectivity.

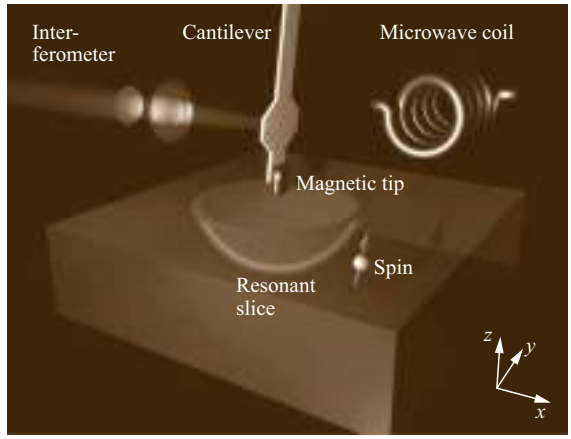

Fig. 24.26 MRFM setup. The cantilever with the magnetic tip oscillates parallel to the surface. Only electron spins within a hemispherical slice, where the stray field of the tip plus the external field matches the condition for magnetic resonance, can contribute to the MRFM signal due to cyclic spin inversion (© D. Rugar [24.264])

The experimental setup is sketched in Fig. 24.26. An oscillating cantilever with a magnetic tip at its end points toward the surface. The spherical resonant slice within the sample represents those points where the stray field from the tip and the external field match the condition for magnetic resonance. The cyclic spin flip causes a slight shift of the cantilever frequency due to the magnetic force exerted by the spin on the tip. Since the forces are extremely small, very low temperatures are required.

To date, no individual nuclear spins have been detected by MRFM. However, the design of ultrasensitive cantilevers made considerable progress, and the detection of forces below 1×10^{-18} N has been achieved [24.265]. Thereby, it became possible to perform nuclear magnetic resonance [24.266] and ferromagnetic resonance [24.267] experiments of spin ensembles with micrometer resolution. Moreover, in SiO_2 the magnetic moment of a single electron, which is three orders of magnitude larger than the nuclear magnetic moment, could be detected by *Rugar* et al. using the setup shown in Fig. 24.26 at 1.6 K [24.264]. This major breakthrough demonstrates the capability of force microscopy to detect single spins. More recently, *Degen* et al. have combined MRFM with 3-D image reconstruction to enable MRI on biological samples with a spatial resolution of $\approx$ 10 nm [24.268].

24.5 Summary

It was the intention of this chapter to give an introduction to the application of scanning probe microscopy at low temperatures. The first three sections were devoted to a general introduction, an analysis of the specialities of microscope operation at low temperatures, and an overview of related instrumentation. It was emphasized that low-temperature operation of SPMs can significantly increase both the achievable resolution and the overall stability of the instrument.

The goal of the subsequent sections was to illustrate some of the most active areas of application for LT-SPM. In particular, LT-STM allows the controlled manipulation of individual atoms and the characterization of electronic properties with atomic specificity. On essentially the same scale, LT-SFM allows the measurement of different types of force fields that provide complementary information. Nevertheless, the provided list of applications is certainly not complete, as this would go far beyond the scope of this handbook chapter.

In summary, the wide variety of associated techniques as well as the many physical questions which can be tackled by LT-SPM make it an unprecedented tool for nanotechnology. And despite the many investigations using LT-SPM that have already been performed, the authors believe that *there is still plenty of room at the bottom* [24.269].

25. Biomedical Sensing with the Atomic Force Microscope

Constanze Lamprecht, Jürgen Strasser, Melanie Koehler, Sandra Posch, Yoojin Oh, Rong Zhu, Lilia A. Chtcheglova, Andreas Ebner, Peter Hinterdorfer

In this chapter we highlight the use and advantages of the atomic force microscope (AFM) in life science. Our aim is to present the wealth of experimental possibilities provided by this powerful toolbox with special regard to biomedical sensing applications. Originally invented in the 1980s to visualize solid surfaces on the nanometer scale, today AFM imaging is routinely used to nondestructively map the surface-ultrastructure of soft biological samples under physiological conditions with unprecedented lateral resolution. Owing to its force detection sensitivity that ranges from nano-Newtons down to a few pico-Newtons, the AFM has become an established technique for exploring kinetic and structural details of inter- and intramolecular interactions and biomolecular recognition processes. The combination of such single-molecule force measurements with topographical imaging has led to the development of recognition imaging, which allows for identification and mapping of specific components in complex biological samples with high spatial accuracy. In the following, the basic principles of biologically relevant AFM imaging modes, as well as the methods of single-molecule force spectroscopy (SMFS) and simultaneous topography and recognition imaging (TREC) will be introduced and discussed. Selected experiments will be presented in more detail to illustrate the combined application of these techniques in the elucidation of questions in molecular biology, pharmaceutical science and the medical field.

25.1 **Topographical Imaging of Biological Samples** 810
25.1.1 Basic Imaging Modes for Biological Application 811
25.1.2 Sample Preparation and Imaging Conditions 812
25.1.3 Imaging Artifacts 812
25.2 **Single-Molecule Force Spectroscopy (SMFS)** 814
25.2.1 Basic Principle of SMFS 814
25.2.2 Theory of Single-Molecule Binding and Force Spectroscopy 816
25.2.3 Data Evaluation and Determination of Interaction Rate Constants 818
25.2.4 AFM Tip Chemistry 819
25.3 **Simultaneous Topography and Recognition Imaging (TREC)** 821
25.3.1 Principle of TREC 821
25.3.2 Parameter Optimization in TREC 821
25.3.3 Application of TREC 822
25.4 **AFM Biomedical Sensing – Examples** 827
25.4.1 Isolated Membranes 828
25.4.2 Mammalian Cells 830
25.4.3 Bacteria 832
25.5 **Perspectives and Concluding Remarks** 836
References 837

Invented in 1986 as a further development of the scanning tunneling microscope [25.1], the atomic force microscope (AFM) has successfully complemented scanning and transmission electron microscopy as an instrument to visualize cells, biological membranes and molecules from the micrometer scale down to the subnanometer range. Surface textures and shapes of biological specimens are visualized as three-dimensional maps with an exceptionally good vertical resolution by scanning the surface with a sharp tip attached to a sensitive cantilever. Where electron microscopy operates under vacuum and requires extensive sample preparation, including steps such as freeze drying, staining or metal coating, AFM measurements can be carried out in aqueous and physiological environments without laborious sample preparation, staining or labeling. Structures and physiological functions of biological samples like membrane proteins, native membranes [25.2–4] and live cells [25.5–7] are preserved over an extended period of time making it possible to

follow structural changes and other dynamic processes at the nanoscale [25.8–11]. Next to topographical imaging, the tip of the AFM cantilever can be used to probe physical properties of biomolecules, cells and tissues [25.12–15] and to measure inter- and intramolecular forces [25.12, 16, 17] on the single-molecule level with outstanding signal-to-noise ratio and pico-Newton resolution [25.18–20]. The use of biomolecule functionalized AFM tips for observation and quantification of single ligand-receptor interactions, their affinity, rate constants and conformation in comparison with results from ensemble-average techniques is also of particular interest in life sciences and biomedicine [25.20, 21].

In recognition of the rapidly growing literature on AFM life science applications [25.22–25] we will highlight the use and advantages of AFM for biomedical sensing ranging from the elucidation of basic biological processes to pharmaceutical research and diagnostics [25.26]. After a brief introduction to the most relevant modes for topographical imaging of biological samples, a special emphasis will be placed on the principles and theory of single-molecule force spectroscopy (SMFS), biochemical functionalization of the AFM tip, and simultaneous topographical and recognition imaging (TREC) [25.27, 28] as the combination of topographical imaging with biosensing AFM tips. Representative studies on isolated membrane preparations, mammalian cells and bacteria will be presented to emphasize the biomedical sensing capabilities of the AFM toolbox.

25.1 Topographical Imaging of Biological Samples

AFM imaging offers the possibility to nondestructively map the topography of soft biological samples under physiological conditions and yields three-dimensional images of the surface ultrastructure with a high lateral resolution of a few nm. In general, a cantilever carrying a sharp tip is scanned laterally over a specimen. Due to the interaction with features on the surface, the cantilever is bent. In most commercial setups a laser beam is focused on the back of the cantilever and reflected into a four-segment photodiode to monitor the bending and separate the movements of the laser beam in the horizontal and vertical direction. The up and down deflection leads to a voltage difference, which can be directly attributed to changes in the z direction. Lateral movement of the cantilever leads to a shift of the laser beam between the left and the right section of the photodiode. Tip scanning can be performed in numerous different modes; the most basic and biologically relevant ones will be discussed in this section. In addition the issue of imaging conditions and artifacts,

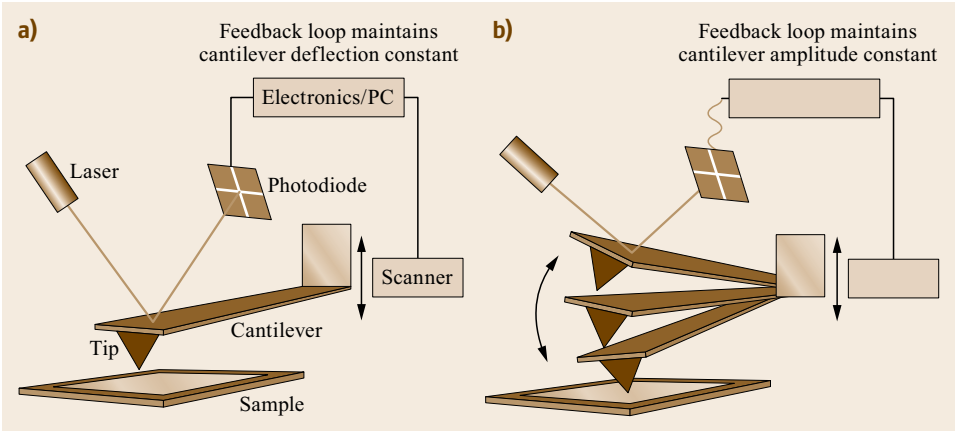

Fig. 25.1a,b Schematic illustration of the working principle of AFM. A sample is probed by an ultra-sharp tip mounted on a cantilever that scans laterally over the sample surface. Deflections of the cantilever are reported by a laser beam that is reflected from the back of the cantilever into a photodiode. The deflection signal is fed into a feedback loop that controls the movement of the piezoelectric scanner by which the tip is lifted from or lowered to the surface in order to keep the force of the tip-sample interaction constant. A topographic image of the sample is then reconstructed from the movement of the scanner in z-direction. **(a)** In contact mode the deflection is kept at a constant value. **(b)** In acoustic and magnetic AC mode the amplitude of the cantilever oscillation is maintained constant and the tip just briefly touches the sample surface

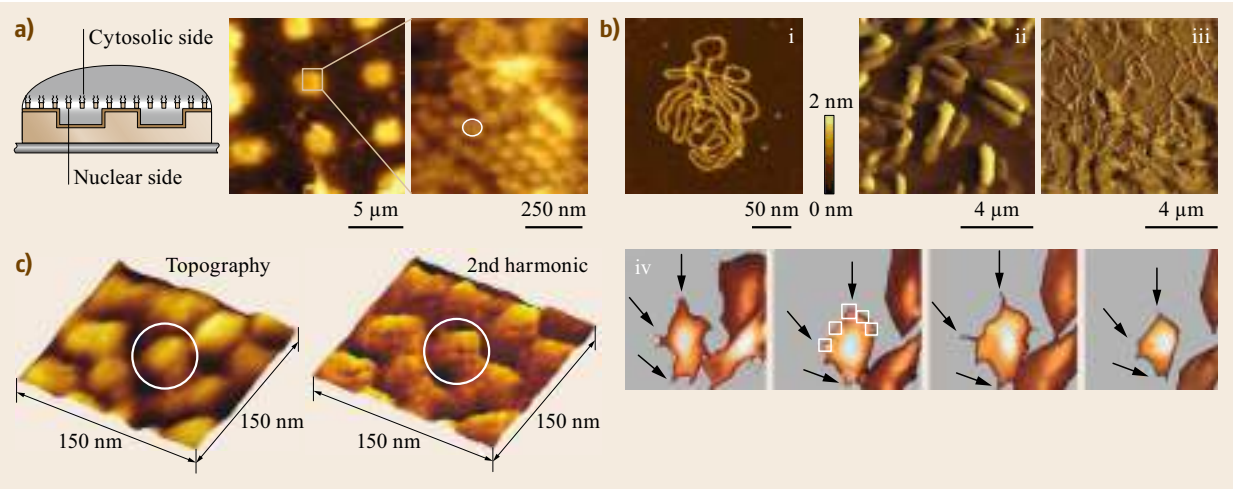

Fig. 25.2a–c Basic topographical imaging modes for biological application. **(a)** Contact mode imaging of nuclear envelope (NE) patches on microstructured PDMS (*left*, *yellow*). (Reprinted with permission from [25.29]). The thickness of the PDMS grid is about ≈ 1 mm with plateaus and wells of 3 µm in width and 0.7 µm in depth, which form microchambers into which the nuclear baskets of the nuclear pore can extend. An overview scan image of the membrane preparation performed in contact mode shows the elevated plateaus and lower regions where the membrane spans the microwells. A zoom-in on a plateau region reveals the donut-shaped nuclear pore complexes (*white circle*). **(b)** Tapping and MAC mode imaging examples of (i) a relaxed plasmid DNA cluster on 3-aminopropyl-modified mica (after [25.30]), (ii, iii) amplitude images of wild-type *E. coli* bacteria on a gelatin-coated mica surface (ii) and flagella-like nanowire structures of $CsgA^-$ mutant bacteria after removal of the cells with an AFM tip (Reprinted from [25.31] with permission from Elsevier) and (iv) visualization of shape changes of living blood platelets during activation where a series of filopodia extrusion and blebbing steps can be observed before the cells shrink and detach (Reprinted from [25.32] with permission from Elsevier). (Image size: 15 µm, color range: 0–800 nm). **(c)** Higher harmonics imaging of a dense layer of human rhinovirus serotype 2 (HRV2) on mica in buffer. The simultaneously recorded second harmonic amplitude image reveals substructures of the viral capsides (*circle*) that remain hidden in the topographical image. (Scan size: $350 \times 350\,nm^2$; color range: 0–13 nm, 0–0.35 V)

as well as some general sample preparation procedures will be addressed.

25.1.1 Basic Imaging Modes for Biological Application

AFM contact mode is the most basic imaging mode in biological applications. The tip is in permanent contact with the sample surface (Fig. 25.1a). Either the force (constant force mode) acting on the sample or the height (constant height mode) between substrate and cantilever is held constant. The latter mode is applied rather to flat samples and hard surfaces, as high shear forces might damage soft biological samples. The topography image results from the deflection of the cantilever as the tip scans over the surface. In constant force mode, the feedback loop keeps the deflection of the cantilever, i. e., the force between the tip and the sample constant. The topography image is then created from the traveling distance of the z-piezoelectric element in the scanner. The finite reaction rate of the feedback loop decreases the fastest possible scanning velocity as opposed to constant height scanning, but due to the control of forces, less sample damage can be expected. Using very soft cantilevers with a spring constant in the range of 0.1–0.301 N/m, constant force imaging can be well suited even for delicate biological applications. An example of contact mode imaging in buffer solution of a nuclear membrane preparation spanned across a polydimethylsiloxane (PDMS) grid [25.29] is presented in Fig. 25.2a. Images at higher magnification nicely resolve the embedded individual donut-shaped nuclear pore complexes (NPCs) with an outer diameter of ≈ 120 nm and inner diameter of ≈ 80 nm. Imaging of soft tissues and usually cells requires the restriction to blunt AFM tips (opening semi-angles 18° or 35°), very low loading forces (< 1 nN) and reduced scan speed (< 1 line/s) to prevent penetration of the cell membrane by the tip.

To overcome the contact mode speed issue and to eliminate frictional forces, intermittent contact or tapping mode was developed [25.33]. A piezoelectric actuator excites the cantilever to oscillate and hence the tip just briefly taps the sample surface, which minimizes the

lateral forces on the sample (Fig. 25.1b). The feedback loop keeps the oscillating amplitude constant by adjusting the distance and thus the acting force between tip and sample. The topography image is generated from the scanner's z-motion. A related dynamic imaging mode is magnetic AC mode (MAC mode) imaging, where a magnetically coated cantilever is excited to vibrate in a magnetic field. In liquid, the amplitude of the cantilevers is, in contrast to tapping mode, well defined by the driven damped harmonic oscillator model and can be easily determined. MAC mode is often the method of choice for the almost unlimited biological applications. Figure 25.2b shows some examples for MAC mode imaging DNA strands (i [25.30]), bacteria (ii, iii [25.31]) and living blood platelets (iv [25.32]). Although dynamic imaging modes induce far less shear force compared to contact mode, the viscoelastic response and dynamic nature of soft samples such as live cells essentially reduce the resolution to approximately 50–100 nm.

A more recent imaging technique is higher harmonics imaging [25.34, 35], which achieves a higher lateral resolution compared to conventional AFM imaging. In liquid, the amplitude of the second harmonic was found to be an order of magnitude higher than in air and thus more sensitive to local variations on the sample surface. Higher harmonic contributions in the movement of an oscillating cantilever are generated by nonlinear tip-sample interactions, yielding additional information on structure and physical properties such as sample stiffness. The second harmonic amplitude image – as well as the topography image – can be recorded simultaneously during scanning in tapping mode and under physiological conditions. With this technique, second harmonic amplitude images of bacterial surface layers and a layer of human rhinovirus serotype 2 (HRV2, Fig. 25.2c) showed detailed substructures with a resolution of about 0.5 nm, which were not visible in topographical images [25.36]. Later approaches used multiharmonic AFM to map local material properties of intact and disrupted virions in vitro at high resolution [25.37] and live cells [25.38].

25.1.2 Sample Preparation and Imaging Conditions

A crucial requirement for successful and reliable biological AFM experiments is proper sample preparation. Although there are many standardized nondestructive approaches for sample immobilization, they are usually only applicable for a specific system and need to be adjusted to the situation. Substrates like muscovite mica, glass and silicon oxide turned out to be the ideal support. The atomically flat mica is suitable for immobilizing e.g., DNA, single proteins or supported lipid films. Glass cover slips are rougher than mica surfaces and are thus mainly used for imaging cells and other large structures. A good alternative for mica can be silicon oxide wafers, which are more expensive but have a much smoother surface than glass [25.39].

For the immobilization of biological samples either covalent or noncovalent (adsorption) protocols can be used. Nonspecific adsorption relies on noncovalent bonds such as hydrophobic interactions, stacking, hydrogen bonds, and electrostatic attraction. Biomolecules can be adsorbed on mica or covalently bound to a chemically modified surface [25.40, 41]. Supported lipid bilayers are often prepared by the fusion of lipid vesicles on solid surfaces or by the Langmuir–Blodgett technique [25.42]. Animal cells have the ability to adhere to solid supports. Coating the surface with adhesive proteins may enhance cell immobilization. Additional chemical fixation with e.g., glutaraldehyde can prevent cell damage or detachment. Microbial cells, such as bacteria, yeast and fungi do not have the ability to spread over a surface. Thus, they have to be bound covalently to the substrate [25.43], physically adsorbed [25.44] or mechanically immobilized in e.g., a porous membrane [25.45]. In general, it is also highly recommended to investigate the effect of pH and ionic strength of the sample buffer on the image quality [25.45]. A more detailed overview of sample preparation protocols and imaging conditions may be found elsewhere [25.39].

25.1.3 Imaging Artifacts

AFM setups are commonly very well shielded against external vibrations (acoustical, mechanical) or electronic malfunctions and AFM imaging of biological specimens is quite straightforward. Nevertheless, imaging artifacts may occur rather frequently and lead to misinterpretation of data if not recognized. To achieve a high-resolution image, all scan parameters must be controlled conscientiously. Setting feedback parameters (i. e., proportional and integral gain) too high during imaging is a common mistake (Fig. 25.3a). Forces acting between the AFM probe and the sample during imaging have to be carefully monitored. Changes of pH and increasing salt concentrations due to evaporation during long-term imaging need to be considered. Temperature drifts especially in heated sample chambers influence imaging stability and the effective force might increase. Large forces can dramatically reduce the image resolution, and apart from causing molecular damage, may lead to tip contaminations, to name a few complications.

Apart from the imaging conditions, the validity of AFM images is significantly influenced by the cantilever tip as well as by the scanner (Fig. 25.3b,c). If

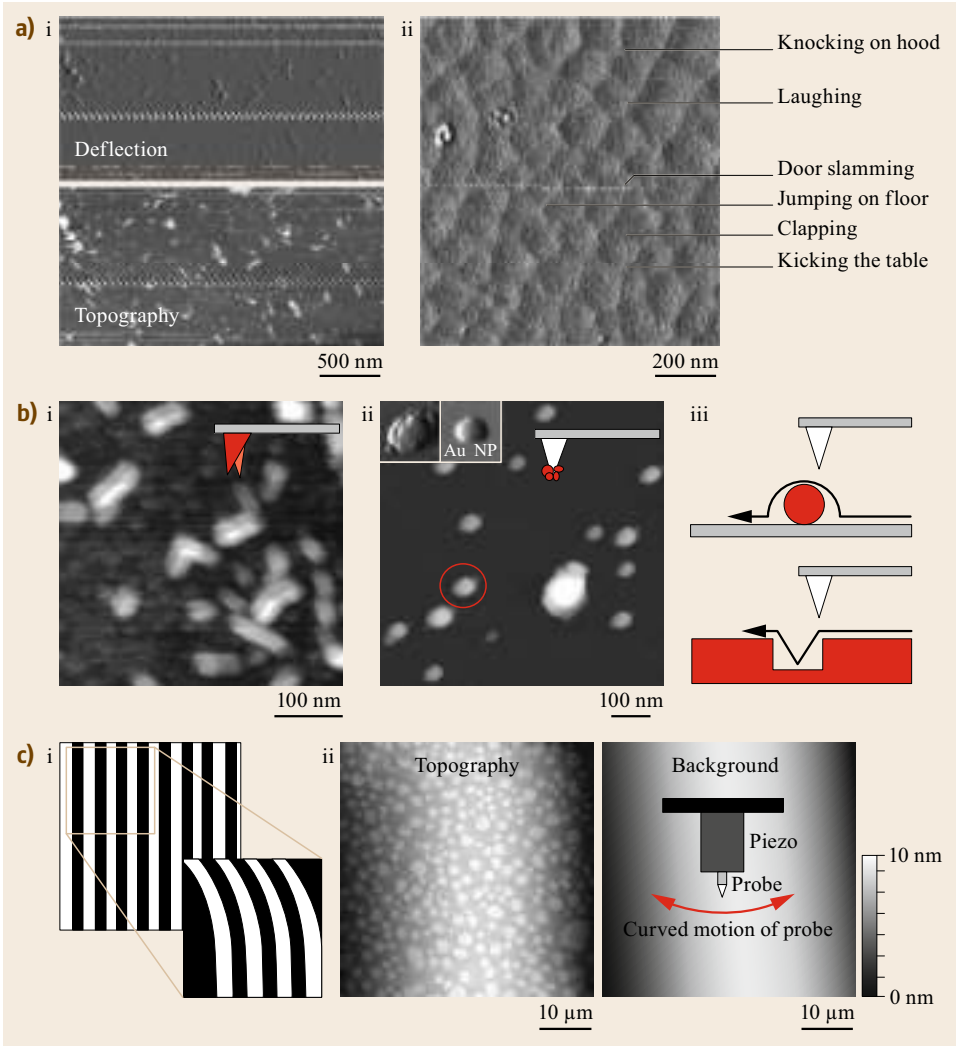

Fig. 25.3a–c Common imaging artifacts. **(a)** (i) The feedback parameters (proportional and integral gain) are set too high leading to *z*-oscillation of the piezoelectric scanner that show as *zebra-stripe*-like artifacts. Scanner oscillations appear stronger in the deflection and become visible in the topography when they are too pronounced. (ii) Perturbations in the acoustical and mechanical frequency range (e.g., vibration) are picked up by the AFM image if setups are not well enough shielded (by e.g., active vibration isolation table, acoustic enclosure). **(b)** AFM tip-associated artifacts commonly appear in the form of (i) doubled structure in the topography image, due to a double tip, or (ii) in shape of a repetitive pattern with a preferential orientation, which is caused by tip contaminations. (iii) The tip geometry radius determines the lateral resolution in AFM imaging and the tip geometry causes a broadening effect and occasionally incorrect recording of the sample features. **(c)** Artifacts caused by the piezoelectric scanner are foremost (i) a so-called scanner creep after zoom-in due to adaption of the piezo crystal to the new set voltage, resulting in stretching and compression of features at the beginning of the new image, and (ii) the nonlinearity of a tube scanner in the *z*-direction, that accounts for a nonlinear (mostly parabolic) background, which is commonly removed by postprocessing of images (flattening). The topographical image shows an overview scan of a phase-separated supported lipid bilayer (DOPC:SM:Chol 2 : 2 : 1). The liquid ordered phase (*round patches*) is about 1 nm higher than the surrounding liquid disordered phase

the tip curvature radius, which is typically between 5 and 10 nm, is comparable or bigger than the structures on the sample surface, the lateral size of the structures appears overestimated. In this case, the full width at half maximum (FWHM) value of the sample features can be determined by analyzing the cross-section of AFM to-

pography images. The following relation connects the FWHM value with the actual diameter d of the investigated structures, by implying the tip radius

$$R : \mathrm{FWHM} = 2\sqrt{d((R+d)/4)}\,.$$

In general, to achieve high-resolution AFM images of biological samples, it is important to use a sharp tip (Fig. 25.3b, iii) and a soft cantilever in order to nondestructively map the sample features on the surface [25.46].

Also the piezoelectric scanner may be directly a source of errors. Especially when imaging large areas, i. e., when the scanner has to expand far, deviations from the linear expansion behavior can occur (Fig. 25.3c). To avoid biased images of the sample topography, the scanner should be perpendicular to the surface. Hysteresis in the response of the piezo element (*piezo creep*) may cause edge overshoots and together with thermal scanner drift may cause image distortion. These effects are often observed when zooming in.

25.2 Single-Molecule Force Spectroscopy (SMFS)

Measurements of interaction forces traditionally rely on ensemble techniques such as shear flow detachment [25.47] and the surface force apparatus [25.48]. Single-molecule techniques, on the other hand, can reveal molecular processes, pathways and rare events that would be masked in ensemble measurements by analyzing individual events in large heterogeneous populations. Though they typically require more effort and time to reliably generate high-quality data, direct measurements can provide invaluable insight into complex systems. In AFM-based force spectroscopy the cantilever is used as a molecular sensor to quantify interaction forces between the tip of the cantilever and the substrate. The deflection of the AFM cantilever Δx relates to the force F acting on the cantilever through Hooke's law $F = k\Delta x$, with the spring constant k of the cantilever. The force resolution of the AFM, $\Delta F = (k_\mathrm{B} T k)^{1/2}$, is limited by the thermal noise of the cantilever, which, in turn, is determined by its spring constant. With commercially available (bio-)cantilevers, interaction forces between single molecules in the range of only a few pico-Newton (pN) [25.21] and adhesion forces between a single cell and a substrate in the order of a few nano-Newton (nN) [25.49] are routinely resolved. For single-molecule force spectroscopy (SMFS) the small size of AFM tips that ranges between 2 and 50 nm provides unprecedentedly high lateral resolution.

Over the past 20 years the technique has been refined constantly and become a versatile tool for characterizing molecular interactions [25.12, 16, 17, 50]. During this time various single-molecular pairs, such as avidin and biotin or streptavidin and biotin, antibodies and their antigens, proteins and specialized aptamers, or DNA and DNA-binding proteins, have been studied with great success [25.51, 52]. Besides the detection of intermolecular forces, AFM also shows great potential in measuring intramolecular forces acting within molecules, e.g., mechanoproteins, membrane proteins, DNA or polysaccharides [25.50, 52–55]. In these experiments, the molecule is clamped between the tip and the surface and its viscoelastic properties as well as unfolding and refolding pathways are studied by force-distance cycles [25.53].

SMFS is not only limited to the reporting of interaction forces either, and can readily be used to obtain interaction rate constants of molecular association and dissociation as well as length scales and relative heights of energy barriers traversing the free energy surface. To this end, the rate at which a pulling force is applied to the bond is varied, revealing a dependence of this *loading rate* and kinetic and thermodynamic parameters. This technique of dynamic force spectroscopy is explained in greater detail in this section.

25.2.1 Basic Principle of SMFS

Basic single-molecule force spectroscopy (SMFS) requires immobilization of one of the binding partners to the apex of the AFM tip and the other to a hard surface such as mica or glass. The functionalized tip is then repeatedly brought into contact with and retracted from the substrate, while recording the cantilever deflection, i. e., the force acting on the cantilever as illustrated in Fig. 25.4a. During most of the approach phase, when the distance of the tip to the surface is sufficiently large (1 to 3), the cantilever deflection remains zero. Upon contact (4) the cantilever bends upwards due to a repulsive force that increases linearly (4 to 5) as the tip is pushed further into the surface. After a predefined contact force (5) has been reached, the cantilever movement is reversed and the deflection relaxes (5 to 6). If binding has occurred, the cantilever will bend downwards as it is further retracted from the surface (6 to 7). In the case where the binding partners were tethered through flexible crosslinkers [25.56, 57], the shape of the attractive force-distance profile is nonlinear. It then depends on the elastic properties of the cantilever

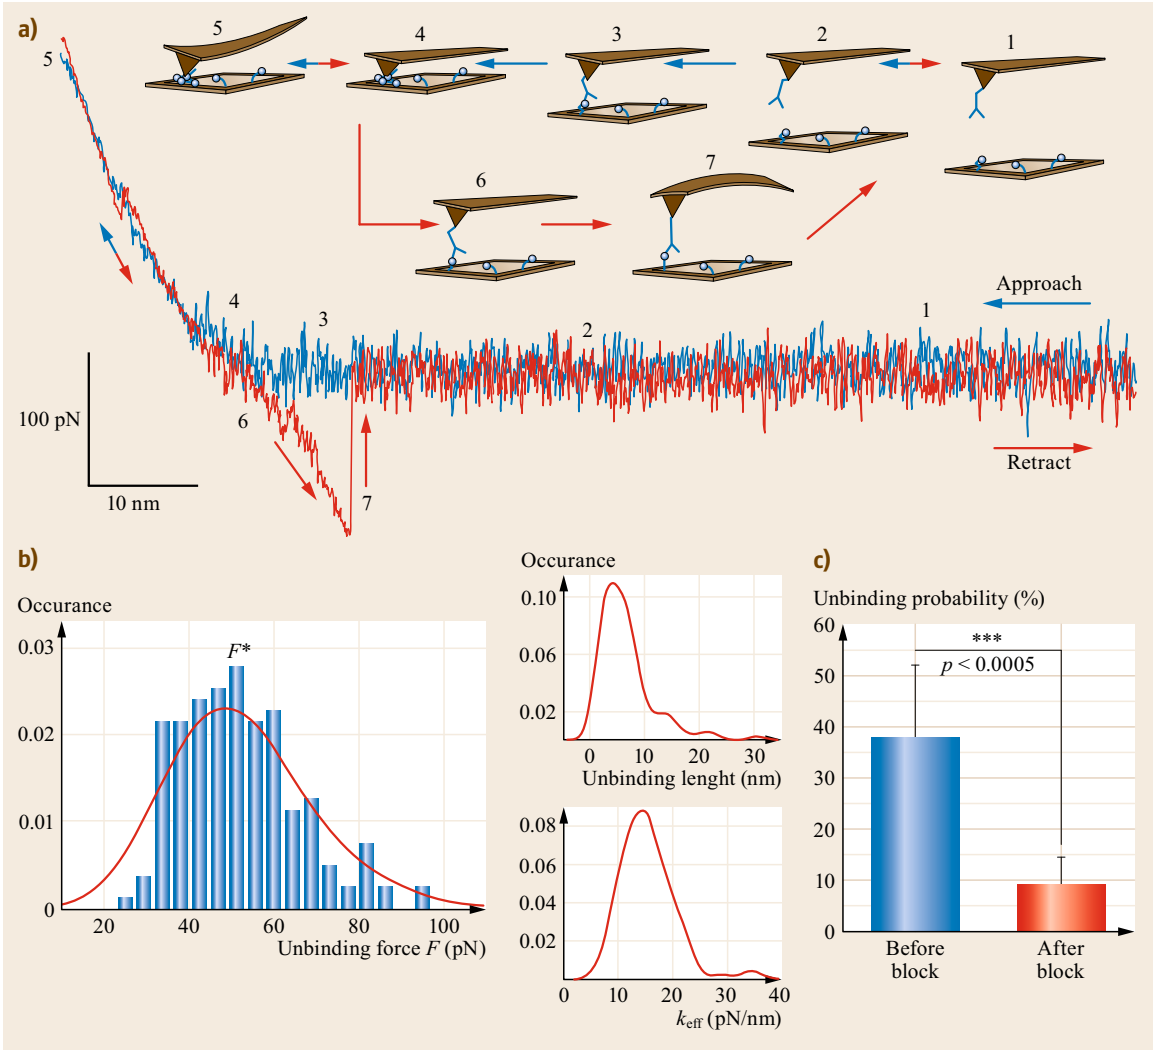

Fig. 25.4a–c Single-molecule force spectroscopy (SMFS). **(a)** A force-distance cycle (FDC) (e.g., sweep rate of 200 nm/s) with a ligand functionalized AFM tip and a dense layer of receptor molecules immobilized on mica. Binding occurs towards the end of the approach phase (1–5) when the tip comes into contact (4) and is pressed into the surface. Under further approach the tip bends upwards exerting a linearly increasing force on the sample (5). During tip retraction the bending relaxes again. When a ligand-receptor bond has formed, the cantilever progressively bends downwards (6), visible as a characteristic parabolic slope in the retract curve reflecting the extension of the distensible crosslinker mediating the ligand-receptor connection. The force increases until rupture (unbinding) of the ligand-receptor bond occurs (7). After rupture the retract curve closely follows the approach curve. **(b)** Statistical analysis of a great number of unbinding events at a given sweep rate and indentation force yields distributions of unbinding force F, unbinding length l and effective spring constant k_{eff} that can be displayed as a histogram (*blue*) or probability density functions (PDF) (*red*). In a PDF the data are weighed by their uncertainty and presented in a continuous curve that offers a measure of reliability not provided by simple binning. This eases determination of the most probable values for each parameter e.g., F^* as the most probable unbinding force. **(c)** The specificity of the ligand-receptor interaction needs to be verified by a block experiment where typically one of the binding partners is saturated by free agonist molecules. This will result in a significant decrease of the number of detected unbinding events i. e., the binding probability. The statistical significance can be rated e.g., by an unpaired two-sample t-test

(commonly modeled as a harmonic spring), and the crosslinker, which exhibits parabolic-like characteristics, reflecting an increase of the spring constant during extension and the bond itself. When the ramping force reaches a critical value the binding partners dissociate and the cantilever jumps back into the resting position (7). The force value at dissociation is termed the unbinding force and is quantified by the vertical distance from the critical bond force to the baseline (7 to 2). Similarly, the unbinding length is given by the horizontal distance from the contact point to the extension at rupture (6 to 7, horizontal component). In the absence of interaction between tip-bound ligand and surface receptors the retract curve will closely follow the approach curve. A typical SMFS experiment at a given pulling velocity comprises 1000 so-called force-distance cycles (FDCs) resulting in a distribution of unbinding forces, which can be either plotted as a histogram or as a continuous probability density function (PDF) (Fig. 25.4b). The maximum of the distribution is termed the most probable unbinding force F^*. The specificity of the observed (un)binding event is usually demonstrated by blocking the interaction either through addition of free ligands to mask receptor sites on the surface, or by saturating the binding partner on the AFM tip, drastically reducing the binding probability (i. e., the number of unbinding events observed per 1000 cycles) (Fig. 25.4c).

25.2.2 Theory of Single-Molecule Binding and Force Spectroscopy

Molecular recognition is mediated by a multitude of noncovalent interactions, the energy of which is only slightly higher than thermal energy. Due to the power law dependence of these interactions on distance, the attractive forces between noncovalently interacting molecules are extremely short ranged. A close geometrical and chemical fit within the binding interface is therefore a prerequisite for efficient association. The weak bonds that govern molecular cohesion are believed to be formed in a spatially and temporarily correlated fashion. Protein binding often involves structural rearrangements, either localized or global, that commonly bear functional significance by modulating the activity of the interaction partners. Signaling pathways, enzyme activity, and the activation and inactivation of genes all depend on conformational changes induced by ligand binding.

The strength of binding is usually given by the binding energy ΔG, which amounts to the free energy difference between the bound and the free state, and which can readily be determined by ensemble measurements. ΔG determines the ratio of bound complexes $[RL]$ to the product of free reactants $[R][L]$ at equilibrium and is related to the equilibrium dissociation constant K_D through $\Delta G = -RT \ln(K_D)$, where R is the gas constant and T the temperature in Kelvin. K_D itself is related to the empirical association (k_{on}) and dissociation (k_{off}) rate constants through $K_D = k_{off}/k_{on}$. In order to get an estimate for the interaction forces F, from binding energies ΔG, the depth of the binding pocket may be used as a characteristic length scale l. Using typical values of $\Delta G = 20 k_B T$ and $l = 0.5\,\text{nm}$, an order of magnitude estimate of $F\ (= \Delta G/l) \approx 170\,\text{pN}$ is obtained for the binding strength of a single molecular pair. Classical mechanics describes bond strength as the gradient in energy along the direction of separation. Unbinding therefore occurs when the applied force exceeds the steepest gradient in energy. This purely mechanical description of molecular bonds, however, does not provide insights into the microscopic determinants of bond formation and rupture.

Bonds will resist detachment when a pulling force is applied. Notably, the unbinding force may approach and even exceed the adiabatic limit given by the steepest energy gradient of the interaction potential if rupture occurs in less time than needed for diffusive relaxation (10^{-10}–10^{-9} s for biomolecules in viscous aqueous medium) and friction effects become dominant [25.58]. Therefore, unbinding forces do not resemble unitary values and the dynamics of the experiment critically affects the measured bond strengths. At the time scale of AFM experiments (milliseconds to seconds), thermal impulses govern the unbinding process. In the thermal activation model, the lifetime of a molecular complex in solution is described by a Boltzmann ansatz, $\tau(0) = \tau_{osc} \exp(E_b/k_B T)$ [25.59], where τ_{osc} is the inverse of the natural oscillation frequency and E_b is the height of the energy barrier for dissociation. This gives a simple Arrhenius dependency of dissociation rate on barrier height.

Force acting on a complex deforms the interaction free energy landscape and lowers barriers for dissociation (Fig. 25.5a). As a result, bond lifetime is shortened. The lifetime $\tau(F)$ of a bond loaded with a constant force F is given by $\tau(F) = \tau_{osc} \exp[(E_b - x_\beta F)/k_B T]$ [25.59], where x_β marks the thermally averaged projection of the energy barrier along the direction of the force.

The Bell–Evans Model

A detailed analysis of the relation between bond strength and lifetime was performed by *Evans* and *Ritchie* [25.60], using Kramers' theory for overdamped kinetics. For a sharp barrier, the lifetime $\tau(F)$ of a bond subjected to a constant force F relates to its characteristic lifetime, $\tau(0)$, according to $\tau(F) = \tau(0) \exp(-x_\beta F/k_B T)$ [25.12]. However, in

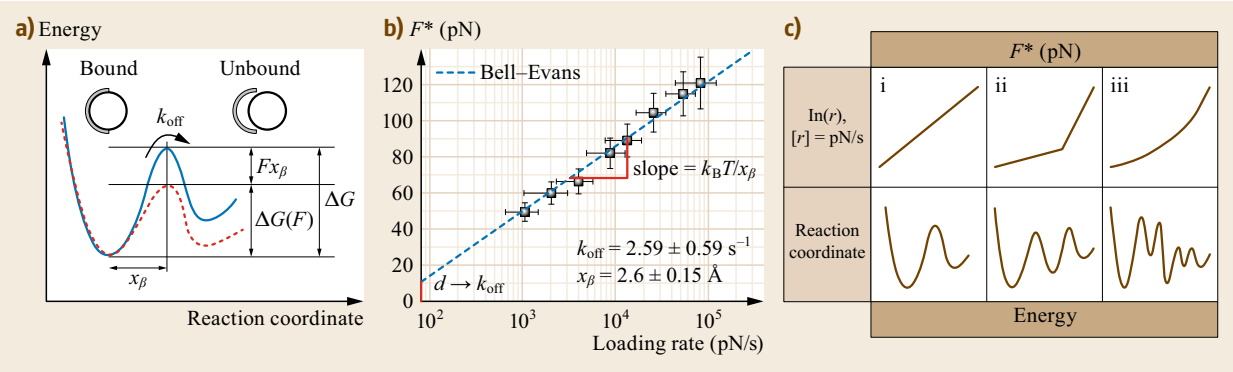

Fig. 25.5a–c Theory and interpretation of single-molecule binding and force spectroscopy. **(a)** In a simple model of molecular dissociation over a single sharp energy barrier, a constant force F lowers the barrier's height proportionally. This gives rise to a characteristic length scale x_β that is interpreted as the distance of the energy barrier from the energy minimum along the projection of the force. The barrier is crossed with the characteristic unbinding rate k_{off} (after [25.51]). **(b)** In the Bell–Evans model the most probable unbinding force F^* scales with the natural logarithm of the loading rate. The intersect with the force axis yields the characteristic unbinding rate k_{off} and the slope reveals the characteristic length scale x_β. **(c)** In the classical Bell–Evans interpretation linear segments in the logarithmic plot of the loading rate dependence reflect multiple independent barriers along the energy profile of a biological bond (ii). For nonlinear curved spectra very complex energy landscapes may result from this interpretation (after [25.51])

most pulling experiments the applied force is not constant but varies with time, and the measured bond strength depends on the loading rate [25.58, 60, 61]. In accordance with this, experimentally measured unbinding forces do not assume unitary values but rather vary with both pulling velocity [25.62, 63] and cantilever spring constant [25.16]. Nevertheless, contributions arising from thermal activation manifest mostly near the point of detachment. Therefore, the change of force with time, i. e. the loading rate r $(= \mathrm{d}F/\mathrm{d}t)$, can be derived from the product of the pulling velocity and the effective spring constant at the end of the force curve, just before unbinding occurs.

Dynamic force spectroscopy (DFS) exploits this dependence of bond strength on the loading rate to obtain detailed insights into intra- and intermolecular interactions. The dependence of the rupture force on the loading rate (force spectrum), in the thermally activated regime was first derived by *Evans* and *Ritchie* [25.60] and described further by *Strunz* et al. [25.64]. Rupture itself is a stochastic process and the likelihood of bond survival is expressed in the master equation as a time-dependent probability $N(t)$ to be in the bound state under a steady ramp of force, namely $\mathrm{d}N(t)/\mathrm{d}t = -k_{off}(rt)N(t)$ [25.64]. This results in a distribution of unbinding forces $P(F)$ parameterized by the loading rate [25.60, 64, 65]. The most probable force for unbinding F^*, given by the maximum of the distribution (Fig. 25.4b), relates to the loading rate through $F^* = F_\beta \ln(rk_{off}^{-1}/F_\beta)$, where the force scale F_β is set by the ratio of thermal energy to x_β (Fig. 25.5a) [25.60, 64]. Thus, the unbinding force scales linearly with the logarithm of the loading rate. This phenomenological approach to relating data from pulling experiments to the innate kinetic and thermodynamic parameters of the probed interaction is commonly referred to as the Bell–Evans model.

For a single barrier, the Bell–Evans model would give rise to a simple, linear force spectrum F^* versus $\ln(r)$ (Fig. 25.5c, i). In cases where the escape path traverses several barriers, the curve will follow a sequence of linear regimes, each marking a particular barrier [25.60, 65, 66] (Fig. 25.5c, ii). Transition from one regime to the other is associated with an abrupt change of slope determined by the characteristic barrier length scale and signifying that a crossover between barriers has occurred. The slopes of the force versus loading rate curves contain information about the length scale x_β of prominent energy barriers along the force-driven dissociation pathway, which may be related to the depth of the binding pocket of the interaction (Fig. 25.5a,b) [25.62].

Limitations of the Bell–Evans Model and New Approaches to DFS Data Analysis

The predicted linear dependence of the unbinding force on the logarithm of the loading rate r holds well when the barriers are stationary with force, as found by a large number of unbinding and unfolding experiments. However, if the position of the transition state is expected to vary along the reaction coordinate with the force,

as for example when the curvature at the top of the barrier is small, this simple dependence gives way to more complex forms. *Schlierf* and *Rief* [25.67] used Kramers' diffusion model to calculate the probability force distributions when the barrier cannot be assumed to be stationary. A failure to fit force distributions at high loading rates using a Bell–Evans model was also reported in by *Neuert* et al. [25.68] for the interaction of digoxigenin and antidigoxigenin. Poor matches were observed in the crossover region between the two linear regimes of the force spectrum as well.

Additionally, fitting each regime in the force spectrum with a separate function according to the Bell–Evans model can lead to very complex underlying energy landscapes even for simple experimental systems. For curved force spectra (Fig. 25.5c, iii) this interpretation may result in an arbitrary number of barriers, each characterized by at least two fit parameters, as well as values for x_β several orders of magnitude below 1 Å [25.51, 69]. Lastly, the phenomenological model described above holds for linear energy surfaces with $\Delta G \to \infty$, a simplification that has been shown to be applicable to a large number of biomolecular interactions. For some systems, however, different energy barrier and energy well geometries might correspond better to experimental data [25.70].

Alternative models that predict inherently nonlinear force spectra have emerged in recent years, extending the framework laid down by Evans and Ritchie. The newer models described below include additional fit parameters, most notably the height of the free energy barrier, which does away with the necessity of estimating ΔG using the Arrhenius equation. *Dudko* et al. [25.70] modified the Bell–Evans model by accounting for the effects of the applied force on the position of the transition state. In their treatment they find that a dependence of the mean rupture force on the loading rate r in the form $(\ln r)^\nu$, with the exponential constant ν allowing for either cusp-like ($\nu = 1/2$) or linear-cubic ($\nu = 2/3$) free-energy surfaces, corresponds more closely to experimental force spectra than a linear approach ($\nu = 1$, corresponding to the Bell–Evans model). They also find the distribution of unbinding forces to be asymmetrical, as indeed has been observed many times. In a subsequent publication *Dudko* et al. [25.71] introduced a method based on transforming rupture force distributions from DFS into force-dependent lifetimes akin to those obtained from constant-force experiments, and show how the molecular linker used in the experiment affects the loading rate.

The model put forward by *Friddle* et al. supports the notion of reversible rebinding at low loading rates when using soft springs [25.69], a process that is not taken into account by the other approaches to DFS presented here. The Friddle model introduces two distinct regimes during molecular unbinding: an equilibrium regime at low loading rates, which supports cycles of reversible unbinding and rebinding, and a kinetic regime at higher loading rates where unbinding is irreversible. In addition to k_{off} and x_β, an additional fit parameter is introduced, the equilibrium force F_{eq}. This is the force where dissociation and association rates are in balance. F_{eq} is the lowest force at which a bond breaks for a given pulling apparatus geometry and pulling speed. This also means that at forces below F_{eq}, no complete dissociation will occur, which marks an important difference between a free ligand-receptor pair, where spontaneous unbinding is possible, and a system where the interaction partners are tethered to force transducers. An interesting application of this model was presented by *Alsteens* et al. [25.72], who used it to analyze DFS data of the protease-activated receptor-1 (PAR1) in native membranes and its ligands. Whereas the majority of DFS models operate on most-probable rupture forces obtained from pooling many hundreds of measurements, Alsteens et al. present a method to apply the work of *Friddle* et al. [25.69] to data clouds of individual unbinding events. In addition to these new models for the analysis of DFS data, several modifications of the Bell–Evans model itself were proposed over the years [25.51, 73, 74]. These reflect new findings about parameters influencing experiments, such as the stiffness of the force transducer [25.74] or the range of loading rates in which this phenomenological approach is applicable [25.73].

25.2.3 Data Evaluation and Determination of Interaction Rate Constants

A comprehensive guide to modern analysis of DFS is given by *Bizzarri* and *Cannistraro* [25.51] and *Noy* and *Friddle* [25.75], whereas *Hane* et al. [25.76] have compared the three dominant models in the field in great detail. The choice of model relies first and foremost on the obtained force spectrum: nonlinear alternatives to the Bell–Evans model should only be used if the forces measured experimentally actually do not scale linearly with $\ln(r)$, since fitting a linear dependence with a nonlinear function, while possible, may result in fit parameters with little to no meaning.

While the dissociation rate constant k_{off} is a fit parameter in DFS models (Fig. 25.5), quantification of the association rate constant k_{on} has to be determined via the interaction time that is required to achieve half of the maximum possible binding probability ($t_{1/2}$). This can be obtained from experiments where the encounter time between receptor and ligand is varied over

a broad range [25.62]. Given that the concentration of ligand molecules on the tip available for interaction with the surface-bound receptors c_{eff} is known, the association rate constant can be derived from $k_{\mathrm{on}} = t_{1/2}^{-1} c_{\mathrm{eff}}^{-1}$. Determination of the effective ligand concentration requires knowledge of the effective volume V_{eff} explored by the tip-tethered ligand which, in turn, depends on the tether length. Therefore, only order-of-magnitude estimates of k_{on} can be gained from such measurements [25.62].

Note that the application of force acts to select the dissociation path. Since the kinetics of reactions are pathway dependent, such a selection implies that kinetic parameters extracted from force-probe experiments may differ from those obtained from assays conducted in the absence of external force. At extremely fast complexation-decomplexation kinetics the forces may be independent of the loading rate, indicating that the experiments were effectively carried out under thermodynamic equilibrium [25.77]. These concerns notwithstanding, SMFS has been demonstrated to be a versatile tool enabling the estimation of association and dissociation rate constants, as well as the measurement of structural parameters of the binding pocket [25.51, 55].

25.2.4 AFM Tip Chemistry

For SMFS experiments, the usually inert AFM tip has to be converted into a (mono)molecular sensor by attaching one or a few ligand molecules to the apex of the tip. Based on the tip surface material, i. e., silicon nitride or gold, different approaches are possible. While the use of gold-coated tips allows functionalization based on self-assembled monolayers (SAMs) of thiolated linker molecules, the common silicon or silicon nitride tips have to be chemically modified in the first step (e.g., by aminofunctionalization protocols). More simple strategies like adsorption or chemisorptions may provide for efficient coupling under suitable circumstances. A more detailed description can be found in [25.43]. Physisorption, meaning the nonspecific adsorption of molecules, which relies on noncovalent bonds including hydrophobic interactions, stacking, hydrogen bonds, and electrostatic attraction, offers an easy but effective coupling strategy. However, AFM tip functionalization requires very firm coupling. Though this might be realized by physisorption (e.g., with the help of crosslinking [25.63, 78]), only covalent attachment protocols will yield reliable and reproducible coupling results that render the tip nonadhesive and introduce a distensible linker between ligand and AFM tip. Figure 25.6 illustrates common strategies for functionalization of commercial silicon-silicon nitride and cold-coated AFM tips.

Functionalization of Silicon or Silicon Nitride Tips

The most common approach to make inert silicon and silicon nitride tips chemically addressable is aminofunctionalization (Fig. 25.6a). The gas-phase protocol using aminopropyl-triethoxy-silane (APTES) as well as the liquid-phase method employing ethanolamine-hydrochloride in dimethyl sulfoxide (DMSO) are frequently used. Both yield sufficient reactive sites ($\approx$ 1000–2000 amino groups/μm^2) while avoiding the formation of sponge-like multilayers, which are not suitable for force spectroscopy experiments [25.79]. A good understanding of the chemical process helps in performing successful aminofunctionalization: under ambient conditions the surface of silicon and silicon nitride tips has a silicon-oxide layer with high numbers of silanol (-Si-OH) groups. APTES, as the most commonly used aminosilanization reagent, reacts with these silanol groups. The reaction itself has to be performed in an argon-flooded desiccator to control the amount of water. The AFM cantilever chips are thoroughly cleaned with chloroform and might be treated by a mild plasma before placing them into the desiccator. In a 6 l argon-filled desiccator typically 30 µl APTES together with 10 µl triethylamine as catalyst are used and allowed to react for 120 min followed by careful purging with argon gas. A two-day *curing* at room temperature ensures sufficient and strong binding of the generated APTES layer on the cantilever. The aminofunctionalization protocol based on ethanol-hydrochloride is a simpler alternative to gas-phase APTES coating, but results in a less well-defined chemical coverage. In a nutshell, ethanolamine-hydrochloride is dissolved in DMSO, molecular sieves are added and the cleaned tips are incubated overnight followed by a careful cleaning procedure [25.80].

In the next step a heterobifunctional cross-linker is bound to the amino residues on the tip. Polyethylene glycol (PEG) consisting of 10–30 ethylene glycol units turned out to be best suited, due the properties of this polymer. PEG itself is an inert, water-soluble, and distensible polymer with the advantage of being protein repulsive. In addition, denaturation of most of the bioligands is markedly lowered compared to coupling with a short linker. Only in very special cases does this linker already contain the ligand molecule itself, e.g., biotin [25.80] or fluorescein [25.81]. These molecules can be bound as part of the linker, since their structure is stable at the typical coupling conditions, e.g., chloroform as a solvent and applying triethylamine as a catalyst.

Most other ligands – usually proteins – require aqueous coupling conditions. Proteins are often coupled to the PEG crosslinker via their lysine residues.

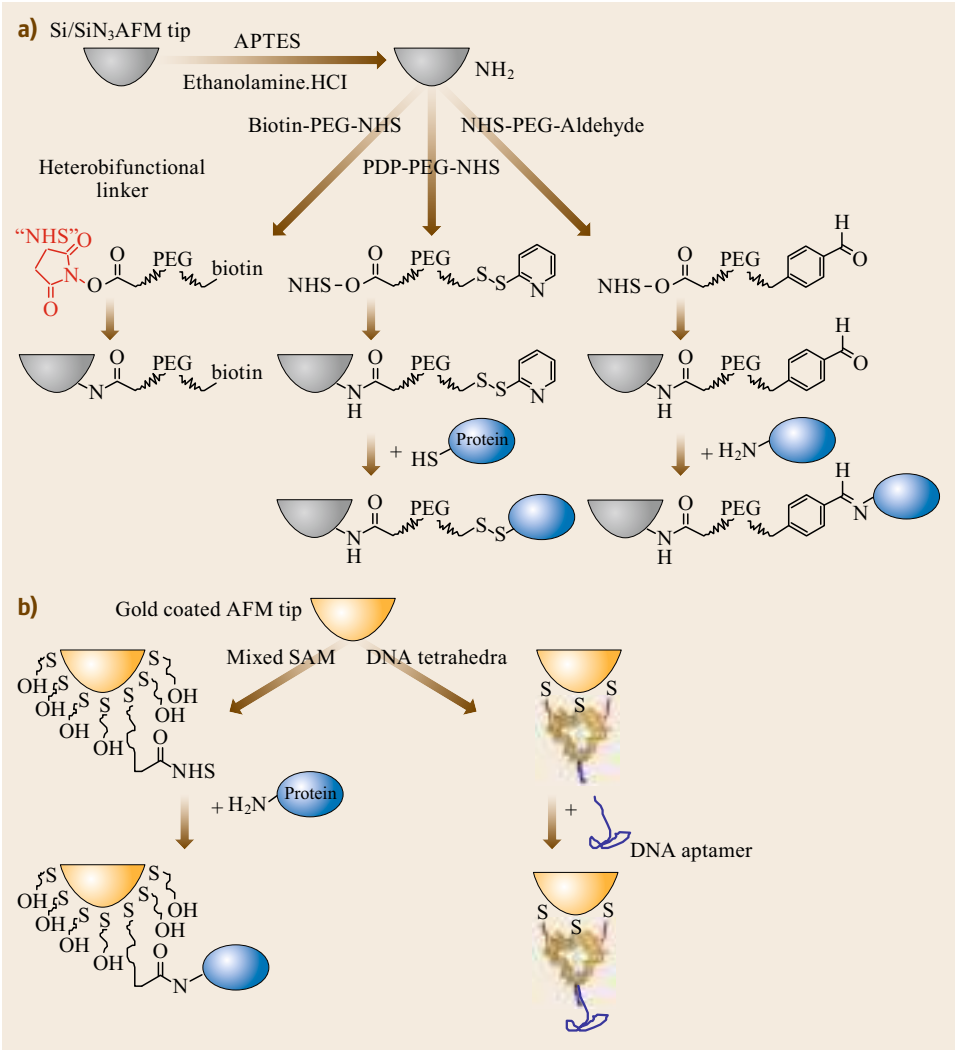

Fig. 25.6a,b Functionalization strategies for the covalent coupling of biological ligands to AFM tips. **(a)** A common approach for silicon and silicon oxide tips requires amino-functionalization of the tip surface for attachment of a heterobifunctional crosslinker that will tether the ligand. **(b)** Functionalization of gold-coated tips exploits thiol chemistry. Building blocks such as mixed self-assembled monolayers or DNA tetrahedra are used to link the ligand to the tip

N-Hydroxysuccinimide (NHS)-PEG-aldehyde [25.82] or NHS-PEG-acetal [25.83] linkers are both well suited, though the former is slightly prone to loop formation. Ligands with a free thiol end (e.g., cysteine mutants) can be tethered by NHS-PEG-PDP linkers [25.84] with the advantage that the bond can be cleaved, or by NHS-PEG-maleimide for noncleavable coupling. A very general strategy is realized by the use of the NHS-PEG-benzophenone linker [25.43]. After binding the linker via its NHS end to the aminofunctionalized tips, benzophenone can be activated by ultraviolet (UV) light (366 nm) and allows stable covalent bond formation with aliphatic carbons. Admittedly, the above-mentioned linkers do not allow for site-directed binding, as a ligand usually offers more than one coupling group, for instance when more than one lysine exists in the amino acid sequence of a protein. Synthetic proteins, however, are often tagged by hexa- or decahistidine for purification (His_6 and His_{12} respectively), which can be exploited for site-directed coupling by the use of nitrile-tri-acetic acid (NTA) functionalized linkers. Here the coupling protocol requires somewhat more effort since the synthesis of an NHS-PEG-NTA linker is not possible. A detailed description can be found in [25.85]. Table 25.1 gives an overview of the described linkers, their reactive sites and the target group in the bioligand. For in-detail AFM tip functionalization protocols the reader may refer to [25.43] and [25.86]. For completeness, it might be added that apart from these most common strategies, a number of other coupling protocols are available that may also yield stable and distensible attachment of ligands to AFM tips, which are covered for instance by [25.87].

Table 25.1 Overview of heterobifunctional PEG linkers for silicon-silicon nitride tips

Typical target molecule	Linker	Reactive site	
Biotin	NHS-PEG-biotin	–	*Ebner* et al. [25.43, 79], *Riener* et al. [25.80]
Protein, R-NH_2	NHS-PEG-aldehyde	Lysine (R-NH_2)	*Ebner* et al. [25.43, 82]
Protein, R-NH_2	NHS-PEG-acetal	Lysine (R-NH_2)	*Ebner* et al. [25.43], *Wildling* et al. [25.83]
Protein, R-SH	NHS-PEG-PDP	Cysteine, R-SH	*Ebner* et al. [25.43], *Kamruzzahan* et al. [25.84]
Protein, R-SH	NHS-PEG-maleimide	Cysteine, R-SH	*Ebner* et al. [25.43], *Lin* et al. [25.88]
Aliphatic carbons (e.g., DNA)	NHS-PEG-benzophenone	Aliphatic carbon	*Ebner* et al. [25.43]
His_6-tagged protein	Multistep procedure	His_6-tag	*Ebner* et al. [25.43], *Tang* et al. [25.85]

Functionalization of Gold-Coated Tips

Gold-coated tips are readily commercially available, but have the drawback that the gold coating, including the precoating with an adhesive layer (e.g., chromium), increases the tip radius by 10 nm or more. Still, gold is an inert noble metal that can be cleaned at harsh conditions without any troublesome effects like surface oxidation. Functionalization can be achieved with an extremely high efficiency utilizing the thiophilic properties of gold (Fig. 25.6b). To ensure sufficiently strong binding of thiolated crosslinkers, either a SAM of bifunctional alky-mercaptanes, or linkers containing a higher number of sulfur residues should be employed. In general, successful SAM formation on the AFM tip is achieved by a mixed SAM, where one component (e.g., a ω-mercaptoalkanol) is used as a nonadhesive part and the other component affords covalent coupling of the ligand of interest. In contrast, the use of thiolated building blocks such as thiolated DNA tetrahedra offers a one- or two-step functionalization procedure for the generation of reactive coatings with highly defined spacing [25.89].

25.3 Simultaneous Topography and Recognition Imaging (TREC)

In addition to measuring interaction forces, mapping the specific recognition sites on biological samples with high spatial accuracy is of great interest in many fields of life science. In contrast to the well-established but rather slow force-volume mode (FV) [25.90–96], the simultaneous topography and recognition imaging (TREC) technique has developed into a versatile tool for quick local mapping of binding sites in molecular biology and bionanotechnology [25.27, 28, 97]. Although a lot of progress has been made in terms of performance and speed [25.98–101], TREC is still considerably faster than many force-volume techniques. For comparison a complete FV image at 30 nm resolution requires typically 20 min and increasing the resolution dramatically lowers the recording speed. In contrast, TREC images with 2 nm resolution are recorded in less than 4.5 min.

25.3.1 Principle of TREC

TREC is based on a dynamic imaging mode in fluid, where the image is generated by oscillating the tip close to its resonance frequency (Sect. 25.1.1). On top of that, the topographical imaging of receptor molecules is combined with molecular recognition by tethering a ligand to the AFM tip using a distensible PEG crosslinker (Sect. 25.2.4). The tip-bound ligand is capable of binding to cognate receptors on the sample surface. With this configuration and a modified feedback loop, two independent images are recorded simultaneously – a topography image of the sample surface and a lateral map of the corresponding receptor recognition sites. The separation into topographical and recognition signals is achieved by splitting the cantilever's oscillation amplitude into downward and upward parts with respect to the cantilever's zero position using a special electronic circuit (PicoTREC, Keysight, formerly Agilent, Santa Rosa, CA, USA) (Fig. 25.7a). Provided that the cantilever's Q-factor is ≈ 1 when in contact with the sample in liquid, the maxima (or peaks) of oscillation are independently influenced by the tip-sample interaction, i. e., topographic features measurably effect only the downward amplitude, whereas the physical connection of the tip to the surface during ligand-receptor binding causes reduction of the upward amplitude of the tip oscillation. Consequently, the envelope of the lower amplitudes generates the topographic image (Fig. 25.7b) and the envelope of the upper amplitudes yields the map of the recognition sites (Fig. 25.7c). As the tip contacts the surface only intermittently, this technique provides very gentle tip-surface interactions and the high oscillation frequency provides for more than a hundred times faster mapping than conventional force-volume techniques.

25.3.2 Parameter Optimization in TREC

In 2004, the first proof of concept on biological samples was realized by visualizing the highly spe-

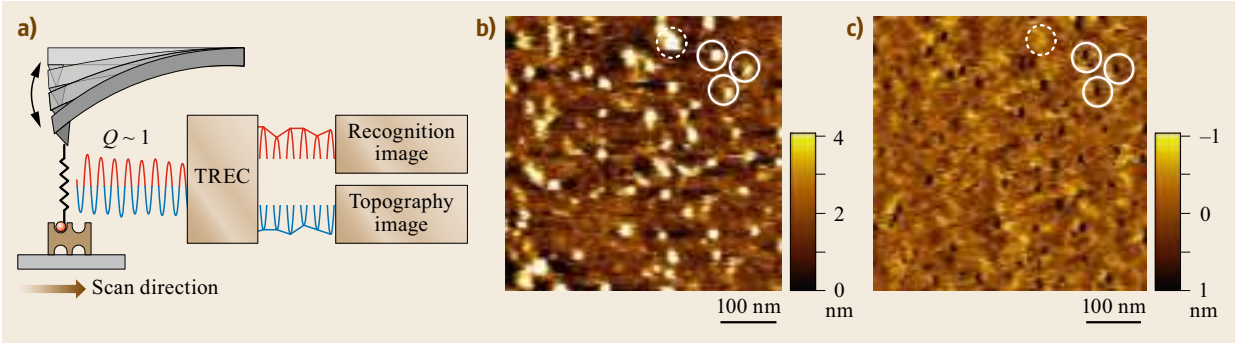

Fig. 25.7a,b Simultaneous topography and recognition imaging (TREC). **(a)** The cantilever oscillation is split into lower and upper parts allowing for simultaneous acquisition of topography and recognition image provided that the cantilever's Q-factor is ≈ 1. **(b)** Topography image of electrostatically adsorbed avidin molecules on a freshly cleaved mica imaged with a biotin-tethered tip. **(c)** Simultaneously recorded recognition image. Topography and recognition show very good correlation with avidin molecules causing corresponding recognition spots (*solid circles*). Some topographical features lack recognition (*dashed circle*) as they do not interact with the tip-bound biotin at all. (Reprinted with permission [25.28, 102])

cific lysozyme-HyHEL5 antibody binding in single-molecule interaction maps while simultaneously carrying out high-resolution topographic imaging [25.97]. Shortly afterwards, *Ebner* et al. [25.102] employed the well-characterized, high-affinity avidin-biotin interaction to determine key factors for stable, robust and reliable recognition imaging results. In 2009, *Preiner* et al. [25.103] investigated the physical properties of the tip-sample ensemble in much detail and established general handling procedures and a protocol for new TREC users to conduct meaningful TREC imaging experiments.

Unbiased values for topographical heights require operation of the feedback loop with only the lower half of the cantilever amplitude, which responds to the topographical features. Use of the full amplitude would include the influence of the recognitions signals, causing faulty height information (Fig. 25.8a). In order to reduce feedback artifacts (termed as topographical crosstalk) and unspecific adhesion in the recognition image, the driving frequency should be adjusted to a value smaller than the cantilever resonance frequency at the surface. The most important factor, however, is the magnitude of the oscillation amplitude itself. A minimum amplitude is required for the linker to exert a measurable force on the cantilever to cause an effect on the top peaks of the oscillations for the generation of the recognition signal (Fig. 25.8b). On the other hand, the receptor-ligand bond is broken at each oscillation cycle when using too large amplitudes, and recognition events pass undetected during scanning. The range of appropriate amplitudes for recognition imaging is determined by the effective linker length (including the position and the length of the molecule attached to the linker), and is therefore rather sharply localized. Variation of the amplitude while keeping the ratio of amplitude set-point and free amplitude constant can thus be used as a quick specificity proof without perturbation of the receptor-ligand system as opposed to the widely applied block of either functionalized AFM tip or surface receptors by incubation with the free analog.

25.3.3 Application of TREC

TREC imaging has become a robust, accurate and reliable technique within the past decade. It has been applied to identify and localize specific receptor binding sites on a variety of isolated systems and more complex heterogeneous biosurfaces such as membranes, cells and whole tissues. On nanoarrays of self-assembled bacterial S-layer proteins *Tang* et al. [25.104] determined the precision of TREC in the detection of recognition sites. Strep-tag II, an eight-amino acid and artificial ligand for *Strep*-Tactin had been fused to a truncated form of the S-layer protein SbpA of *Lysinibacillus sphaericus* CCM 2177. Wild-type SbpA S-layer protein mixed with rSbpA-*Strep*tag II at a ratio of 7 : 1 was brought to self-assemble into a square (p4) lattice. TREC imaging with a *Strep*-Tactin functionalized AFM tip yielded high-resolution maps of the Strep-tag II binding sites with a surprisingly high positional accuracy of 1.5 nm (Fig. 25.9a).

In one of the first medical studies involving TREC, the density of cystic fibrosis transmembrane conductor regulator (CFTR) on the membrane of red blood cells was investigated [25.105]. CFTR is involved in the transport of fluids across epithelia. Mutations in the gene encoding CFTR can lead to dysfunctions and cause cystic fibrosis (CF), which is characterized

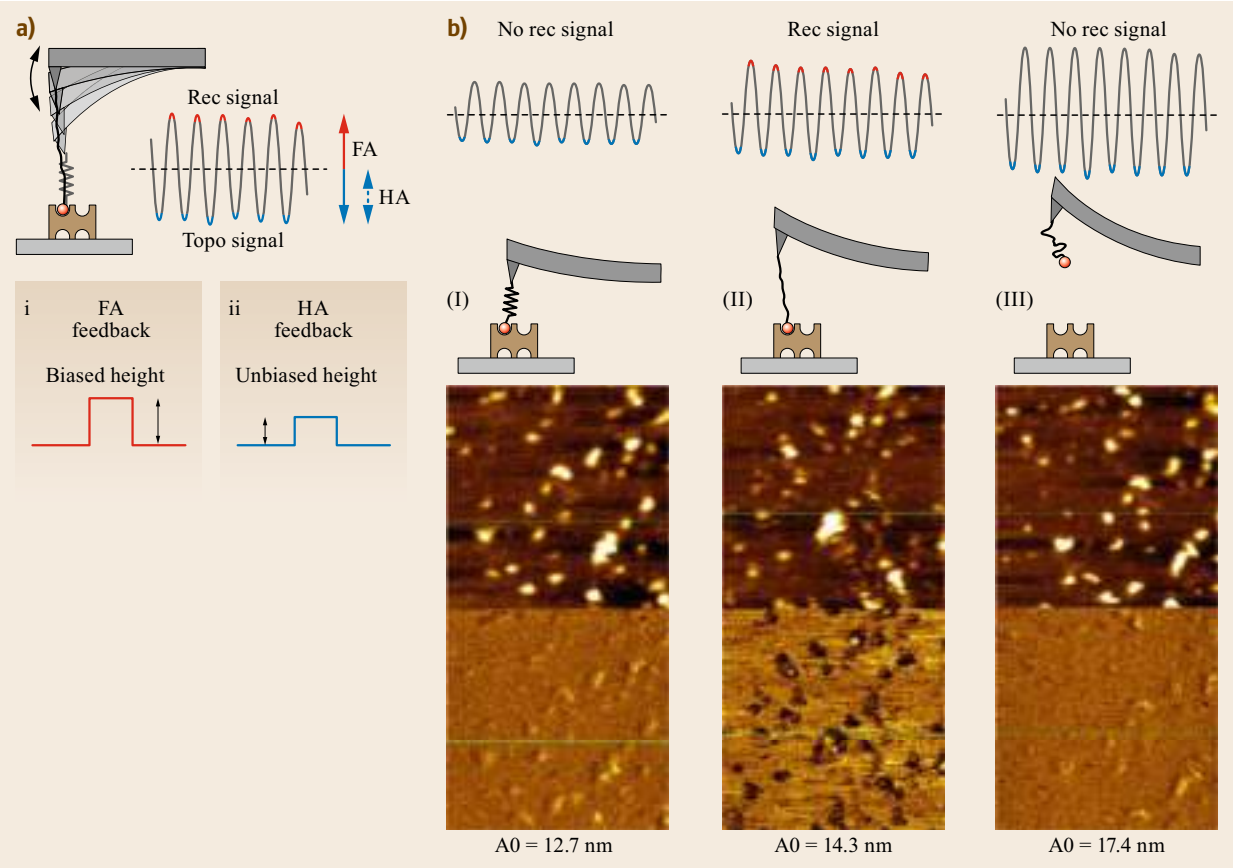

Fig. 25.8a,b Parameter optimization in TREC. **(a)** Comparison of half-amplitude feedback (HA) versus full-amplitude feedback (FA). When the tip-tethered ligand has bound to a surface-attached receptor, the topography is sensed at the bottom of the oscillation (*blue*) and stretching of the linker molecule reduces the movement in the upper parts of the oscillation (*red*). Consequently the FA parameter is biased by the additional amplitude reduction due to molecular recognition. In response the piezo-actuator will exaggerate vertical adjustment, which shows as an increased topographical height of the detected receptor molecule. Only operation of TREC using the lower HA feedback parameter will yield correct height information. **(b)** The oscillation amplitude is the most critical parameter in recognition imaging. If the oscillation amplitude is too small (I) the linker does not exert an efficient force on the cantilever upward swing and no recognition signal is generated. In the second regime (II), the amplitude has been increased, causing an efficient stretching of the linker without rupture of the ligand-receptor complex in the upward swing. This results in a pronounced recognition signal. In the third regime (III), the amplitude is too high, causing the rupture of the bond in every top peak of the oscillation and no stable recognition signal is generated

by a depletion of CFTR in the membrane of cells. A specific role of CFTR in erythrocytes is unknown at the current stage and no major hematological disorders have been reported for CF patients. Nevertheless, TREC confirmed a significant depletion of CFTR in red blood cells. About 800 CFTR proteins were localized in the erythrocyte plasma membranes of healthy donors while in CF patients the number was decreased to about 250. The advantages of TREC over methods relying on for instance quantum-dot-labeled antibodies [25.106] are the prevention of possible steric hindrance during binding of labeled antibodies to the target molecule and a direct visualization of molecules (Fig. 25.9b).

Another medical application for recognition imaging was carried out by *Rankl* et al. [25.107], where the distribution of corneodesmosin on the surface of stratum corneum (SC) was mapped at the nanoscale. Corneodesmosin, a protein known to be present in the SC, plays an important role in its physical integrity. With TREC, it was possible to characterize the morphological changes and the distribution of corneodesmosin on the surface of SC. The results are applied in the de-

(iii) Topography (*top*) and recognition (*bottom*) images of healthy and CF donors reveal fewer recognition events between tip-bound anti-CFTR and CFTR in the erythrocyte membrane as a clear indication of the disease. **(c)** Simultaneous topography and recognition images of the stratum corneum of a skin sample using a tip coupled with an antibody against corneodesmosin, which is implicated in the process of skin peeling. Recognition spots of a few (*dashed arrow*) up to 100 nm (*white arrow*) were found. The overlay of both images shows that most of the recognition spots are located on top of pronounced topographical features ◄

sign of cosmetic compounds that will allow better interaction with the SC to the benefit and improvement of skin appearance (Fig. 25.9c).

Just recently, TREC imaging was applied to visualize uncoupling protein 1 (UCP1) reconstituted into lipid bilayers and to analyze the adenosine triphosphate (ATP)-protein interaction at a single-molecule level [25.113]. UCP1 is a mitochondrial membrane protein and is involved in nonshivering thermogenesis under cold-acclimating conditions. In the last few years, this protein has become increasingly important as a target protein for the therapy of obesity as well as inflammatory, neurodegenerative and ischemic diseases. Based on this system, a new mode for mapping and studying interaction sites at low lateral density was devised by combining recognition imaging and force spectroscopy. This method makes it possible to select a single receptor molecule reconstituted in a supported lipid membrane and then quantify receptor-ligand unbinding forces. Apart from these few selected examples a comprehensive overview of TREC studies can be found in Table 25.2.

Table 25.2 Overview of TREC studies in the years 2006–2016 (no claim to completeness)

Sample	Study	Author, reference
Endothelial cells	Identification and visualization of vascular endothelial (VE)-cadherin that is known to play a crucial role in calcium-dependent, hemophilic cell-to-cell adhesion.	*Chtcheglova* et al. [25.108, 109]
DNA aptamers	In vitro selection and evaluation of DNA aptamers selected to bind histone H4 tails.	*Lin* et al. [25.110]
Red blood cell membranes	Density of cystic fibrosis transmembrane conductor regulator (CFTR) on the membrane of red blood cells was investigated.	*Ebner* et al. [25.105]
Cardiac cells	Inhibition of hERG K^+ channel is major cause of long QT syndromes inducing fatal cardiac arrhythmias mediated by ergtoxin. TREC was used to visualize ergtoxin receptors on the voltage-sensing domain of hERG K^+ channels.	*Chtcheglova* et al. [25.111]
Bacterial surface layer (S-layer)	Visualizing binding sites on bacterial S-layer nanoarrays containing affinity tags (Strep-tag II) to within a positional accuracy of 1.5 nm. The nanoarrays were then used as a template for constructing highly ordered molecular binding blocks.	*Tang* et al. [25.104]
Chromatin	To provide insights into epigenetic processes, Wang et al. used TREC to perform single-epitope recognition imaging of native chromatin.	*Wang* et al. [25.112]
Stratum corneum	Mapping the distribution of corneodesmosin on the surface of stratum corneum (SC) at the nanoscale for designing new cosmetic compounds that will better interact with the SC surface for a specific skin benefit.	*Rankl* et al. [25.107]

Table 25.2 (continued)

Sample	Study	Author, reference
Macrophages	Precise nanomapping revealed compact cluster organization of FcγRs that would favor the rapid recognition of huge pathogens and thus their effective internalization.	*Ahmad* et al. [25.114]
Human eye lens	Recognition imaging of whole, untreated human tissue samples to map the distribution of abnormal protein aggregates on the anterior lens capsule, which is a well-known cause of irreversible blindness.	*Creasey* et al. [25.115, 116]
Protein-nucleic acid interaction	TREC can also be utilized to study protein-nucleic acid interactions, which play important roles in the physiological behavior of living cells and mapped molecular details of the ricin-aptamer interaction.	*Wang* et al. [25.117]
Plant cells	Mapping the structural changes of the cell wall of natural and pretreated plant cells provides better understanding of surface structural changes, which leads to a potential improvement of biomass pretreatment for biofuel production.	*Zhang* et al. [25.118]
Mitochondrial membrane	Visualization of uncoupling protein 1 (UCP1) reconstituted into lipid bilayers and analysis of the ATP-protein interaction at a single-molecule level. Based on this study, TREC was further developed to quantify also binding forces on interaction sites at low lateral density.	*Zhu* et al. [25.119], *Koehler* et al. [25.113]
Monocytes	CD1d molecule, a monomorphic major histocompatibility complex class I-like molecule, presents different types of glycolipids to invariant natural killer T (iNKT) cells that play an important role in immunity to infection and tumors, as well as in regulating autoimmunity. TREC analysis was conducted to nanomap single CD1d molecules on THP1 cells that were loaded with different glycolipids.	*Duman* et al. [25.120]
Bladder cancer cells	Human gonadotropin-releasing hormone receptor (GnRH-R; or type I GnRH-R) that expressed in tumor cells, has gained a great attention as a specific target for cancer therapy. Given the clinical utility, the improved nano-organization of GnRH-R is an important step in the development of more effective and possibly new therapeutic strategies.	*Zhang* et al. [25.121]
Melanoma cells	Hsp70 is known to be present at the extracellular leaflet of the plasma membrane (surface Hsp70, sHsp70) of most tumor cells but not that of the corresponding benign cells. TREC analysis was conducted to elucidate its protumor role.	*Nimmervoll* et al. [25.122]

25.4 AFM Biomedical Sensing – Examples

In the previous sections AFM techniques have been introduced that present a multifunctional toolkit for an ever-increasing diversity of biological and life sciences applications. The AFM has evolved into an enabling instrument to observe structural details of molecular assemblies, isolated membrane preparations and cell surfaces, and to monitor cellular responses to external stimuli such as antibodies or drugs. In the following studies topographical imaging, SMFS, TREC and their combination were employed to answer questions

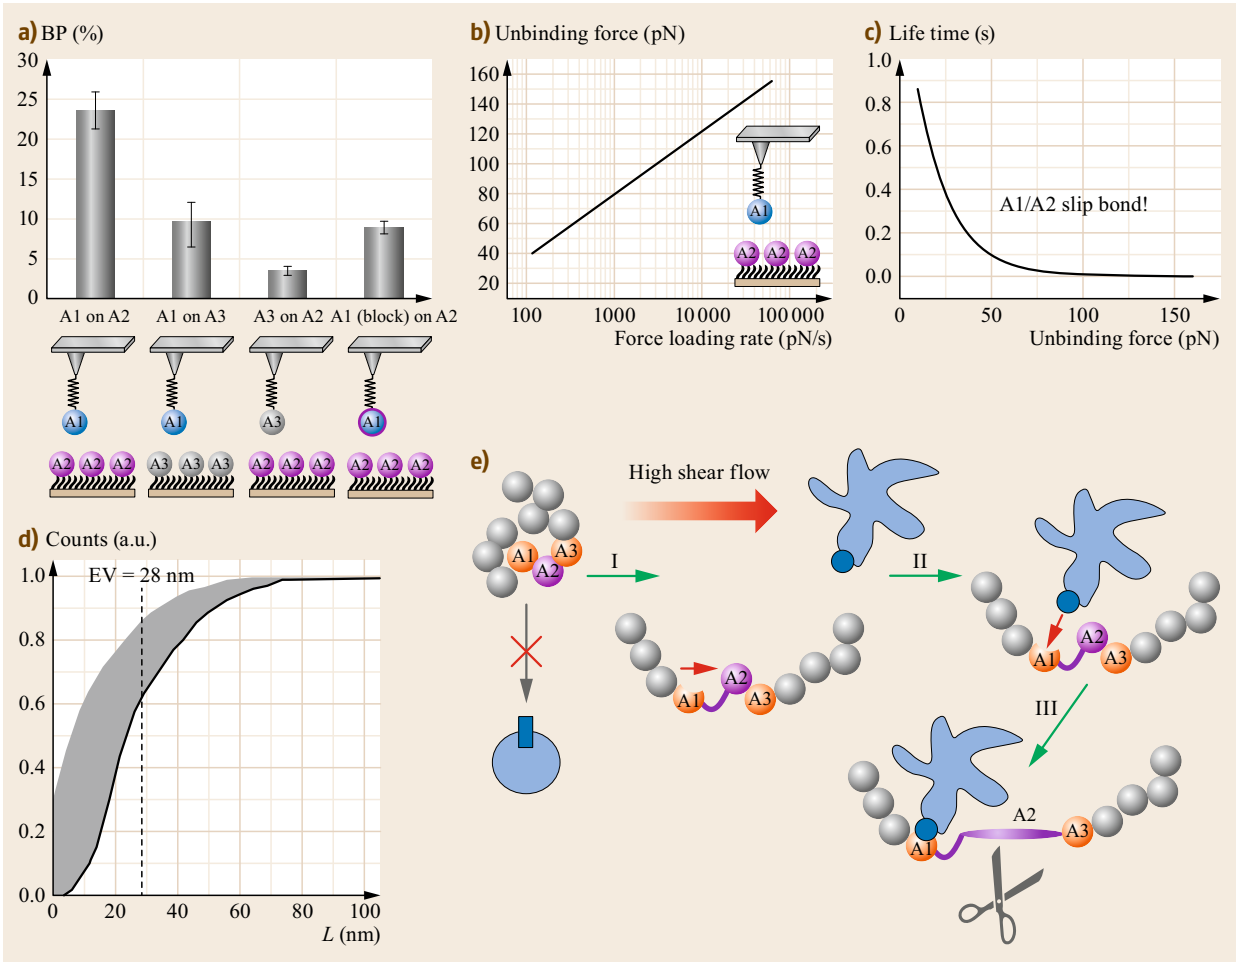

Fig. 25.10a–e **(a–d)** SMFS investigations of the functions of the von Willebrand factor (VWF) in blood coagulation. **(a)** Number of specific binding events between VWF A1 and A2 domains, where A1 was coupled to the AFM tip and A2 was immobilized on the surface. In control experiments either the A2 domains on the surface or the A1 domain at the AFM tip were replaced by the unspecific VWF A3 domain or the tip-bound A1 was saturated by soluble A2. **(b)** Loading rate dependence of the VWF A1–A2 interaction. **(c)** The lifetime versus unbinding force plot clearly indicates slip bond behavior of the A1–A2 interaction. **(d)** Cumulative distribution of the elongation L of the A1-A2 complex prior to dissociation (*black line*) and the corrected value after subtraction of the size of A1 and the linkers (*gray area*). The *dotted line* indicates the expectation value (EV) for L. The measured EV ($\approx$ 28 nm) was substantially lower than the extension of a fully stretched unfolded A2 domain ($\approx$ 80 nm). **(e)** Suggested model for the VWF A1–A2 interaction. Higher shear stress due to e.g., an injury activates VWF to interact with the platelet GPIbα receptor. The GPIbα binding site in domain A1 is made accessible by dissociation of domain A1 from A2 under high shear flow conditions (I, II). Domain A2 remains largely folded during this process protecting it from cleavage and degradation (II). SMFS data imply that dissociation predominantly occurs before exposure of A2 to cleavage. Thus, the A2 domain might prevent platelet binding in a force-dependent manner to ensure that VWF is entirely activated before cleavage

Fig. 25.11a–e Investigation of ATP binding to UCP1 using TREC. **(a)** Illustration of the TREC experiment with the uncoupling protein 1 (UCP1) reconstituted into a supported lipid bilayer on a mica surface and a UCP1-specific antibody or ATP coupled to the AFM tip. **(b)** High-resolution topographical (*top*) and UCP1 antibody-recognition (*bottom*) images. Correlation shows that some UCP1 molecules are recognized (*circles of solid line*), whereas a few remain unrecognized (*dashed*). **(c)** High-resolution ATP-recognition image of UCP1 in the bilayer reveals large (*thick arrows*) and small (*thin arrows*) spots, whereas the molecules' sizes in the topography (not shown) were homogeneous. Evaluation of the diameter of the recognition spots shows a bimodal statistical distribution. **(d)** Schematic illustration of the expected dependence of recognition spot size on the orientation of UCP1 in the bilayer and on the length of the crosslinker that tethers ATP to the AFM tip. **(e)** Proposed mechanism of ATP binding: initial binding from the c-side (I) followed by conformational change of UCP1 (II) and protein inhibition. (III) Protein binding from the m-side without conformational change and inhibition ►

in basic molecular biology, in pharmaceutical science and the medical field that so far were inaccessible by other techniques. Thus, the selected studies illustrate and highlight the biomedical sensing capabilities of the AFM.

25.4.1 Isolated Membranes

SMFS Investigation of Blood Coagulation – von Willebrand Factor

The von Willebrand factor (VWF) is a glycoprotein that plays a central role in hemostasis, the first stage of wound healing. It triggers platelet adhesion in areas of vascular damage by binding to exposed subendothelial collagen and thus causes wound closure. In an initial step the VWF binds to collagen with specific binding sites that are located in domains A1 and A3 of the glycoprotein. Collagen III is believed to interact with the A3 domain, and collagen VI with the A1 domain. The forces and the dynamics involved in these interactions were investigated by SMFS with the VWF tethered to the AFM tip and substrates coated with a dense layer of collagen [25.123]. Different mutations in the A3 domain of the VWF A1-A2-A3 construct were investigated. These mutations (H1786R, Q1734H and S1731T) correspond to the type 2 M of the current von Willebrand disease (VWD) classification system, and are characterized by a defect in the collagen binding domain but exhibit otherwise normal multimeric distribution. Surprisingly, patients carrying these mutations show no or mild symptoms, or have an alternative reason for impeded coagulation. These mutations were diagnosed purely by accident and thus their clinical significance was not clarified up to now. It could be shown that defective interaction between one VWF domain and one type of collagen can be compensated by alternative binding events. This observation might explain the inconspicuous bleeding tendency found in patients carrying these VWF A3 domain mutations.

In a follow-up study the interplay of the VWF domains A1 and A2 during the onset of blood coagulation were investigated more closely [25.124]. The VWF domain A1 is responsible for mediating platelet adhesion under flow through the platelet glycoprotein Ibα (GPIbα). The adjacent VWF domain A2 unfolds under shear, upon which it exposes a cleaving site for the protease ADAMTS13 to prevent thrombosis. A combination of molecular dynamics simulations (MDS), AFM (Fig. 25.10a), and microfluidic experiments, revealed that the A1–platelet interaction is blocked by mutual A1–A2 binding under low shear. In order to elucidate the exact shielding mechanism, SMFS was used to mimic typical elongation forces imposed by the shear flow of blood [25.125]. The interaction strength between the A1 and A2 domain (Fig. 25.10b,c) was probed together with the unfolding behavior of A2 (Fig. 25.10d) as an indicator of the shielding capacity. As a result only a small extent of A2, if at all, unfolded before dissociation from A1. These findings suggest that the platelet binding site in domain A1 is made accessible by the slip-bond dissociation of domain A1 from A2 and that domain A2 remains largely folded during this process, which keeps it protected against cleavage and degradation (Fig. 25.10e).

TREC Studies to Elucidate ATP-Binding to UCP1 in the Mitochondrial Membrane in Non-Shivering Thermogenesis

Uncoupling protein 1 (UCP1) is a transmembrane protein in the mitochondrial membrane of brown adipose tissue (BAT). The protein dissipates the energy of the proton gradient over the inner mitochondrial membrane as heat. This process is also known as non-shivering thermogenesis under cold-acclimating conditions [25.126] and is essential to newborns to counter heat loss, but also prevents energy storage as fat. Thus, UCP1 has been proposed as a pharmaceutical target for the treatment of obesity in adults [25.127, 128]. Long-chain fatty acids activate UCP1 proton transport, whereas purine nucleotides have an inhibitory effect [25.129–133]. Using TREC the mechanism of nucleotide-mediated binding and inhibition of UCP1 inside the mitochondrial membrane was elucidated on a structural level [25.119].

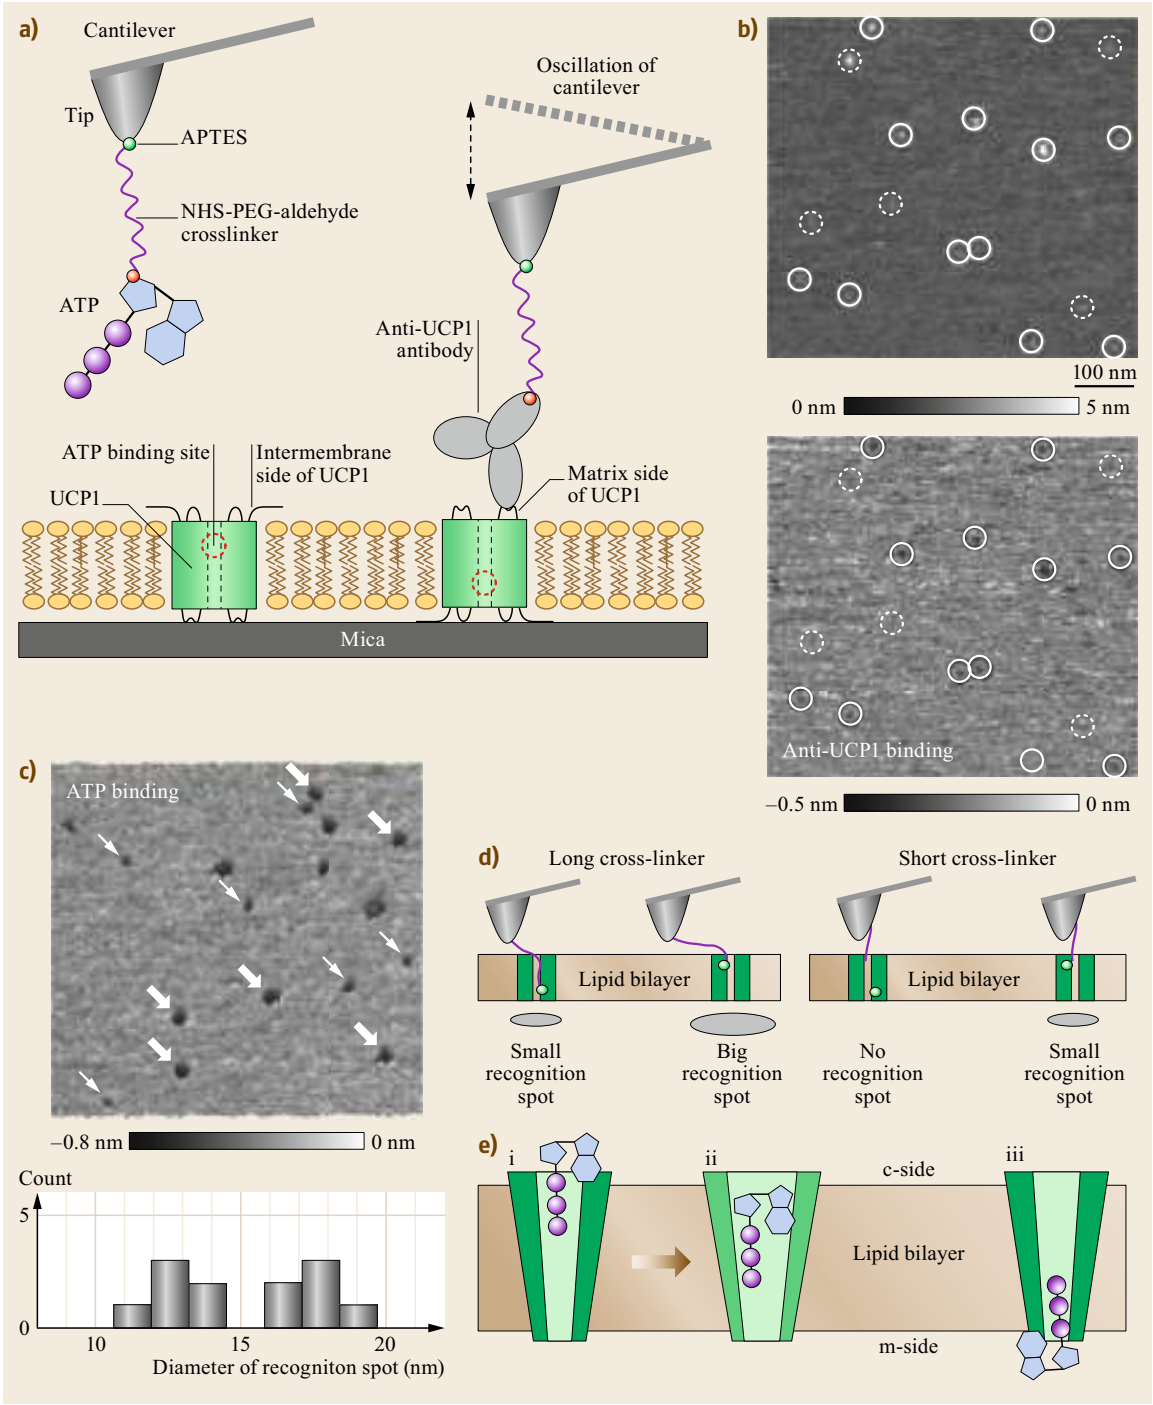

Figure 25.11a shows the experimental setup for TREC measurements of UCP1 reconstituted into lipid bilayers on a mica surface and a cantilever tip functionalized either with ATP or an anti-UCP1 antibody specific to amino acid residues 145–159 of UCP1 using acetal-linker chemistry. Only about half of the protein molecules that were visible in the topographic image were also recognized by anti-UCP1 AB (Fig. 25.11b). This result shows that the orientation of UCP1 protein in the planar lipid bilayer is random, as expected.

The specificity of this interaction was proved by injection of a peptide that competed with UCP1-anti-UCPI AB interaction. Contrarily, when the cantilever was functionalized with ATP instead of the UCP1-AB, colocalization of proteins in the topography and signals in the recognition image was close to 100%. As the orientation of UCP1 in the membrane was determined to be random, this result was unexpected and implies that the nucleotide binding sites are accessible irrespective of the orientation of the protein in the reconstituted membrane. Whereas the size of protein spots in the topographic image was uniform, the size of the recognition spots appeared different. Two groups with mean diameters of 12.65 ± 1.03 and 17.68 ± 0.86 nm were determined (Fig. 25.11c, ii). Given that the ATP binding site remains accessible no matter which side of the protein is immersed in the layer or facing upwards, the existence of two different sizes of recognition spots can be explained by differences in submersion depths of the ATP molecule on the tip and the linker. To estimate the localization of the binding site, ATP-functionalized tips with different lengths of linkers were used (Fig. 25.11d, iii). From these data the depth of the ATP binding site in UCP1 was calculated to be 1.27 ± 0.10 nm from the membrane surface.

Taking the NMR structure of UCP2 (57% homology to UCP1) [25.134, 135] and the proposed three-step purine nucleotide (PN) binding model for UCP1 [25.136] into account, we hypothesized that only binding of ATP to the cytosolic side (c-side) would lead to a conformational change in the protein, which then causes inhibition. PN binding from the matrix-facing side (m-side) would not induce a conformational change and thus not trigger UCP1 inhibition (Fig. 25.11e). This suggestion might plausibly explain one of the unresolved bio-energetical questions: how can the protein be in the active state despite the presence of mM concentrations of ATP in the cytosol? In the absence of the crystallographic structure of UCP1, TREC data yield valuable insights into the nucleotide binding mechanism in the process of nonshivering thermogenesis. High-resolution topographical AFM images provided for the first time visualization of UCPs reconstituted into lipid bilayer membranes. Simultaneously measured recognition images revealed the existence of a single ATP binding site that can be accessed by nucleotides from both the c-side and the m-side.

25.4.2 Mammalian Cells

Drug Binding to the Serotonin Transporter (SERT)

The serotonin transporter (SERT) is a member of the neurotransmitter sodium symporter (NSS) family [25.137] and retrieves extracellular serotonin back into the presynaptic neuron to terminate neurotransmission. Some neurological conditions, e.g., depression, anxiety disorder, attention-deficit hyperactivity disorder (ADHD), autism, Parkinson's disease, and addiction are related to NSS dysregulation. SERT is a target both for therapeutic medicines such as citalopram (CIT) to treat depression and for illicit drugs like cocaine, which induces severe health problems. X-ray analysis of SERT homologues, i. e., bacterial $LeuT_{Aa}$ [25.138] and dDAT (the *Drosophila melanogaster* dopamine transporter) [25.139, 140] indicate a primary binding site (S1-site) for substrates in the membrane-spanning region. Other studies provided hints for a second S2-site, located within the extracellular vestibule [25.141, 142]. To elucidate the number and the mechanism of ligand binding site(s) in SERT, we used SMFS to measure the interaction forces between SERT and S-enantiomers of CIT (S-CIT) [25.143].

An alkyne-modified 5-aminomethyl analogue [25.144] of the S-CIT was covalently conjugated onto the AFM cantilever tip (Fig. 25.12a) using click chemistry. SMFS was conducted on living CHO-K1 cells expressing human SERT [25.145] in 2-[4-(2-hydroxyethyl)-1-piperazinyl]-ethanesulfonic acid (HEPES) buffer at room temperature. Force curves with unbinding events were observed during the repeated measurements, and the experimental probability density function (PDF) of forces was thus generated (Fig. 25.12b, solid curve). The two distinct peaks in the force PDF reflect the S-CIT rupture from binding sites with two different strengths of interaction. To identify the location of the binding sites for the two populations, force measurements were performed on SERT-G402H, which contains a point mutation in the outer vestibule [25.142]. The force PDF from SERT-G402H (Fig. 25.12b, *dotted curve*) showed only a single peak, which corresponded to the second peak in the force PDF from wild-type (wt) SERT. This indicates that the first peak in the force PDF from wt SERT originates from the vestibular S2 site. In addition, we verified that Na^+ ions were important for accessibility to the SERT binding sites by recording forces of S-CIT binding to wt SERT in Li^+ buffer. The PDF showed a single peak in the force PDF (Fig. 25.12c, *dotted curve*) that coincided with the first peak in the force PDF observed in Na^+ buffer (Fig. 25.12c, *solid curve*). The absence of the second peak is consistent with the notion that the central S1 site is Na^+ dependent. The persistence of the first peak implies that access to the vestibule S2 site does not require Na^+.

To examine if there is an allosteric effect [25.146] between the S1 and S2 sites, we performed competition experiments with 30 μM S-CIT in solution so that

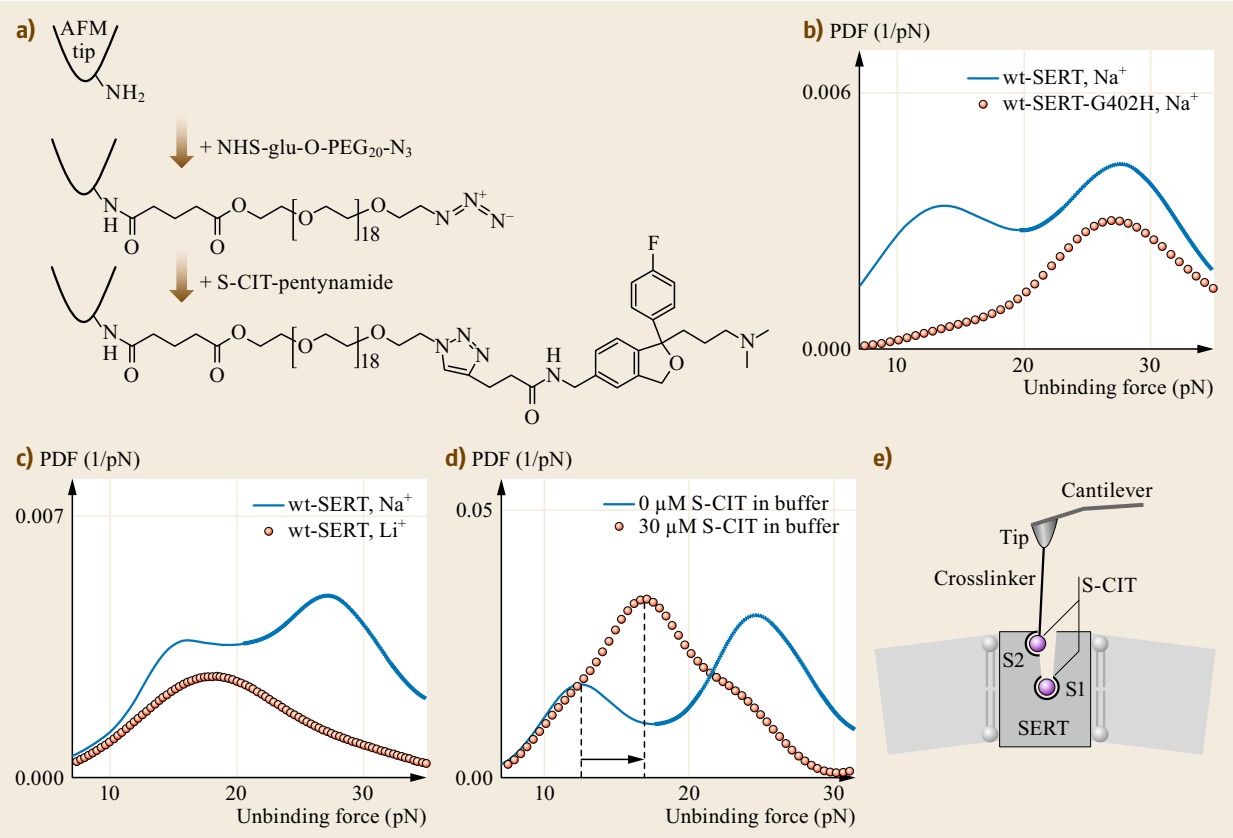

Fig. 25.12a–e Drug binding to the serotonin transporter (SERT). **(a)** Conjugation of S-CIT to the AFM cantilever tip. After the cantilever was aminofunctionalized with gas-phase APTES, it was pegylated with NHS-glu-O-PEG20-N3. The alkyne-modified S-CIT analogue was coupled to the azide-terminated PEG via cocatalyst-accelerated copper(I)-catalyzed azide-alkyne cycloaddition. **(b)** Comparison of force distribution measured on wild type (wt) SERT (*solid line*) and mutant SERT-G402 (*dotted line*). **(c)** Comparison of force distribution measured in Na^+ buffer (*solid line*) and Li^+ buffer (*dotted line*). **(d)** Comparison of force distribution measured on wt-SERT in Na^+ buffer without (*solid line*) or with 30 µM S-CIT (*dotted line*). After the S-CIT in solution bound at S1 site **(e)**, the binding strength between S-CIT and the S2 site was enhanced, shown as the shift of the peak position in **(d)**, indicating a positive allostery

the higher-affinity S1 site was occupied whereas the lower-affinity S2 site was still accessible to S-CIT on the tip. Consequently, only a single peak remained in the force PDF (Fig. 25.12d, *dotted curve*), which was attributed to the S2 site. This is due to the long lifespan (≈ 20 min) of S-CIT at the S1 site [25.141]. Meanwhile, the AFM tip-tethered S-CIT, which has a local concentration of ≈ 3.7 mM (corresponding to one S-CIT molecule within a hemisphere of radius ≈ 6 nm, defined by the length of PEG linker), is likely to effectively compete with the S-CIT in solution for binding to the S2 site. The remaining peak shifted to the right (*arrows* in Fig. 25.12d), indicating that the binding of S-CIT at the central S1 site exerts a positive allosteric effect on the S2 site (Fig. 25.12e). Such an allosterically enhanced binding strength of S-CIT at the S2 site should provide the possibility for x-ray crystallography to capture the S2 site. Three months after the demonstration of the two S-CIT binding sites in SERT by our SMFS study [25.143], the x-ray structure of SERT bound with two S-CIT molecules was published [25.147], which verified our results.

Given the importance of allosteric regulation in biology and pharmacology, the SMFS-based nanopharmacological approach paved a new avenue to exploring transient binding sites in clinically relevant membrane transporters and opened the door to quantitatively addressing the modulation of interaction forces between ligands and allosterically coupled binding sites.

Fluorescence-Guided SMFS to Confirm Increased GLUT4 Translocation

The combination of AFM instrumentation with optical microscopy [25.148] has greatly eased biomedical sensing applications of the AFM on cells with the possibility to correlate independently or simultaneously acquired topographical and optical-fluorescence images [25.149, 150] and to guide the AFM tip in SMFS experiments [25.151]. In a recent application, optically guided AFM was employed to reveal the translocation of glucose transporter 4 (GLUT4) in cells [25.152]. GLUT4 is the key molecule for uptake of glucose into adipocytes and muscle cells and thus reduces blood glucose levels to prevent hyperglycemia. In a basal state, GLUT4 is trapped in intracellular compartments. Insulin induces the translocation of GLUT4 into the plasma membrane and thus triggers glucose uptake. Resistance to insulin, an important parameter of type-2 diabetes, strongly reduces this translocation process [25.153].

There is a great demand for analytical techniques capable of quantifying the GLUT4 translocation efficiency in order to search for compounds that are able to enhance the GLUT4 translocation process in the absence of insulin (insulin mimetics substances). Most approaches such as western blot analysis of membrane fractions, enzyme-linked immunosorbent assay (ELISA)-guided binding assays, flow cytometric analysis [25.154–156] and immunoelectron techniques [25.157] suffer from being indirect, time consuming, nonquantitative and/or more expensive. An important improvement was the insertion of different epitope tags (mainly myc and HA) in the first extracellular loop of the GLUT4 protein in combination with genetically encoded fluorophore molecules (mainly green fluorescent protein(GFP)) at the c-terminus of the transporter [25.158, 159] as depicted in Fig. 25.13a. Here, dual-color total internal reflection fluorescence (TIRF) microscopy has been used to track GLUT4 translocation in the CHO-K1-hIR-GLUT4-myc-GFP cell line. Nevertheless, a critical point of such TIRF experiments is to prove that the increase of fluorescence in the evanescent field in response to insulin or insulin mimetic compounds is solely caused by the increase of GLUT4 molecules in the plasma membrane, and not by the increase of recruited vesicles in the TIRF zone. The use of fluorescently labeled antibodies that target the myc-tag in the first extracellular loop of GLUT4-myc-GFP provides the possibility to further reduce uncertainty. However, before incubation with the reporter molecule, cells are commonly fixed with paraformaldehyde, which may slightly permeabilize the cells, potentially leading to staining of intracellular GLUT4 molecules as well. In order to clarify this uncertainty, fluorescence-guided SMFS experiments were performed with the anti-myc antibody covalently coupled to the AFM tip. In this configuration the antibody can only interact with GLUT4-myc-GFP fraction on the cell membrane.

For SMFS experiments the anti-myc antibody was covalently bound to the AFM tip (nominal spring constant 0.02 N/m, MSCT, Bruker, CA, USA) via a bifunctional NHS-PEG-acetal linker (Fig. 25.13a). Highly contrasted optical (phase contrast) and epifluorescence images were acquired with a 20× objective to enable positioning of the AFM cantilever above CHO-K1 cells that stably express the GLUT4-myc-GFP construct (Fig. 25.13b) and force-distance curves (FDCs) were collected. For each condition, i. e., either deprived of serum (starved) or insulin stimulated, at least three different cells expressing GLUT4 receptors were tested using in sum three different AFM tips. Each AFM/epifluorescence experiment was performed in duplicate using independent cell preparations. For each dataset of FDCs (> 500 FDCs per set) the binding probability (BP) was determined as the number of force curves that show specific unbinding events of anti-myc antibody and GLUT4-myc-GFP molecules on the cell membrane divided by total number of collected force curves. A significant difference between starved (BP ≈ 2.4%) and insulin-stimulated cells (BP ≈ 24.6%) was clearly recognized (Fig. 25.13c).

This fluorescence-guided SMFS study elegantly and decisively confirmed the improved accessibility of the myc-tag in the first extracellular loop of GLUT4 only after insulin stimulation. In a follow-up study additional AFM-based techniques such as TREC will help to uncover the nano-organization of GLUT4 proteins on cell membranes, their oligomeric states, and as well the cortical cytoskeleton rearrangement. A detailed comparison of the effect of insulin and insulin mimetic phytochemicals will help in the identification of new compounds that increase GLUT4 translocation, oligomerization, domain formation, and cytoskeletal coupling for treatment of type 2 diabetes.

25.4.3 Bacteria

For decades, the methods of choice for studying physiology and behavior of prokaryotic organisms were growth in batch cultures and on agar plates [25.160]. In the last few years it has been recognized that apart from chemical cues, mechanical interactions through cell-cell and cell-surface contact also play a significant role in microbial biology on surfaces. Thus, characterization of surface structures, binding mechanisms and identification of the main molecular players has moved into the spotlight for understanding fundamental pro-

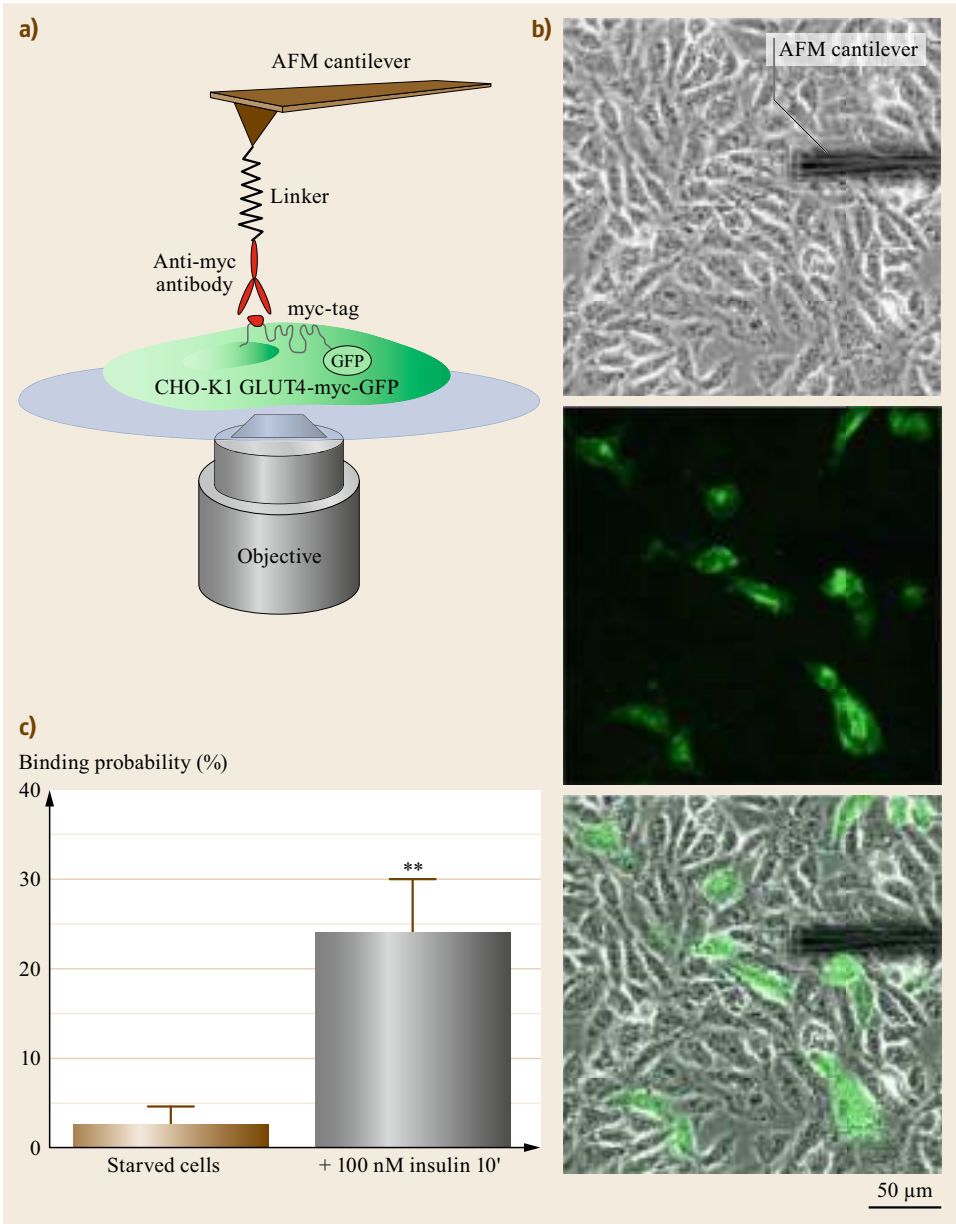

Fig. 25.13a–c Fluorescence-guided AFM force detection of GLUT4 molecules in the membrane of CHO-K1 hInsR/GLUT4-myc-GFP cells. **(a)** Schematic representation of an integrated platform combining an AFM with an inverted light microscope to visualize and recognize the insulin-dependent GLUT4 glucose transporter by using a genetically encoded fluorophore (GFP) at the c-terminus and a myc-tag in the first extracellular loop. An anti-myc antibody functionalized AFM tip was used to exclusively identify membrane-inserted GLUT4 molecules. **(b)** By overlapping highly contrasted optical (phase contrast) and fluorescence images it was possible to visualize the AFM cantilever and thus to guide it on a cell of interest. **(c)** Force measurements results (binding probability) of starved and insulin-treated (cells were incubated with 100 nM of insulin for 10 min) GLUT4-myc-GFP hInsR cells. $^{**}P < 0.01$, significant increase with respect to the starved cells

cesses such as bacterial adhesion, surface recognition, biofilm development, and the incipient stage of infection.

Advances in AFM techniques provide us with powerful tools to explore the physical and mechanical properties of bacteria in unprecedented detail. Apart from analyzing nanostructures on the cell surface by topographical imaging, indentation measurements yield physical properties of single bacteria such as cell wall stiffness, Young's modulus, internal turgor pressure, and the stretching modulus as a function of environmental conditions like medium ionic strength. Such measurements have revealed that the nanomechanical properties of bacteria can impose mechanics to drive the adaptive behavior [25.161]. Additionally, force indentation and force spectroscopy approaches using AFM to study these effects have become available only recently by measuring processes occurring at the interface between microorganisms and cells [25.162, 163].

Bacterial Surface Layer (S-Layer) of *Tannerella Forsythia*

Crystalline bacterial cell surface layers (S-layer) are the most common surface structure in bacteria. S-layers may hold great merit in nanotechnology due to their inherent ability to self-assemble into an ordered protein lattice on solid surfaces [25.164]. However, from a clinical point of view the outermost cell surface is a virulence factor, as it mediates adhesion to and invasion of host cells. Thus, it is an important task to characterize the biochemical nature and structure of S-layers in pathogenic bacteria under live cell conditions. *Tannerella forsythia* (*T. forsythia*) is a gram negative oral pathogen belonging to the so-called *red-complex* bacteria together with *Porphyromonas gingivalis* and *Treponema denticola*, and has been implicated in onset and development of periodontal diseases in humans [25.165]. Clinical evidence accumulates that *T. forsythia* also impacts systemic health, but the underlying mechanisms of pathogenicity are only slowly beginning to unravel [25.166].

MAC-mode imaging was employed to determine the S-layer ultrastructure on intact *T. forsythia* cells at the nanometer scale (Fig. 25.14) [25.167, 168]. For noninvasive imaging, 1 ml of *T. forsythia* culture was collected, washed and immobilized by mechanical trapping on 0.8 µm polycarbonate membranes. The wild-type (wt) cells are $3.5 \pm 1\,\mu m$ in length and $0.6 \pm 0.1\,\mu m$ in width, resulting in a large curvature that makes proper scaling of the height image difficult. Hence, the amplitude image provides significantly better local contrast and the fine structure in the surface topology is more clearly resolved (Fig. 25.14b). The *T. forsythia* wt bacteria S-layer possesses a distinct, periodic square (p4) lattice, as clearly seen in the high-resolution reconverted three-dimensional (3-D) fast Fourier transform (FFT) image obtained from an enlarged topography (Fig. 25.14c). Peaks are due to surface periodicities, which are represented in the power spectra as the bright peaks near to the origin (*inset* in Fig. 25.14c). The S-layer lattice periodicity is 8.74 ± 0.35 nm with an angle of $90 \pm 4°$, which is comparable to earlier observations made by electron microscopy on freeze-fractured, freeze-dried and ultrathin sectioned preparations [25.167].

The AFM data clearly indicate that the outer membrane of intact live *T. forsythia* wt bacteria has a continuous, symmetrical two-dimensional lattice structure built by two distinct S-layer protein species (*TfsA* and *TfsB*). In order to further explore the arrangement of *TfsA* and *TfsB*, SMFS was used to identify the specific interactions between an anti-*TfsA* antibody and the *TfsA* glycoprotein (*TfsA*-GP) within the *TfsA/TfsB* S-layer lattice. The anti-*TfsA* antibody was tethered to the AFM tip via a standard NHS-PEG-aldehyde linker utilizing a lysine residue as a reactive site in the antibody. Force-distance curves were measured on intact *T. forsythia* wt cells indicating specific binding of the antibody to *TfsA*-GP on the bacterial S-layer (Fig. 25.14d). Each rupture event was used to calculate the distribution of specific unbinding forces, fitted with a Gaussian function, and added up to yield the empirical density function (PDF) as shown in Fig. 25.14e. The most probable unbinding forces between the anti-*TfsA* and S-layer *TfsA*-GP at a retraction velocity of 1000 nm/s were 41 pN with wt cells and 56 pN with *TfsB*-GP-deficient cells, where only the *TfsA*-GP is exposed on the cell surface. Differences of unbinding forces between wt and *TfsB*-deficient cells may occur due to the orientation and flexibility of the binding site of the *TfsA*-GP on the bacterial cell surface. The *TfsA*-GP on wt bacteria is embedded in the S-layer lattice structure, whereas the *TfsA*-GP does not appear to be that strictly fixed on the surface of the *TfsB*-deficient mutant where the space-filling counterpart (*TfsB*-GP) is missing. Binding was also highly specific, as verified from the binding probability (Fig. 25.14f).

AFM Indentation Experiments to Measure Physical Properties of *Escherichia coli*

Bacteria produce various types of filamentous structures such as flagella, pili, and curli that promote bacterial adhesion onto the surface. In AFM indentation experiments the effects of curli on the physical properties of the bacterial membrane in *Escherichia coli* (*E.coli*) and the two mutant strains curli fibre protein CsgA deficient mutant ($CsgA^-$) and CsgA overexpressed mutant ($CsgA^+$) were studied [25.161]. Figure 25.15a shows

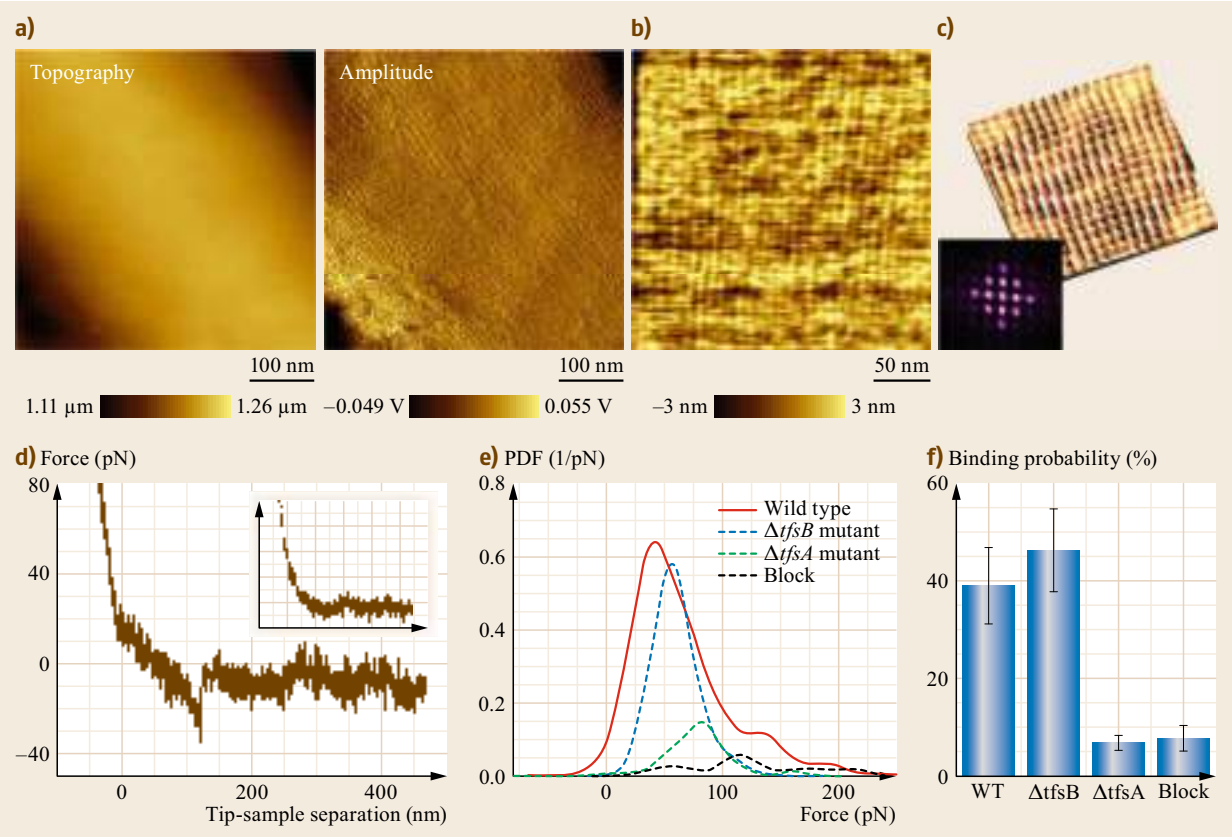

Fig. 25.14a–f Bacterial surface layer (S-layer) of *Tannerella forsythia*. **(a–d)** MAC-mode imaging of *T. forsythia* wild-type bacteria: **(a)** topography and amplitude image, **(b)** magnified topographic image and **(c)** reconverted FFT 3-D image of topography; inset, power spectrum of lattice. **(d–f)** SMFS to identify the specific interactions between anti-*TfsA* antibody and *TfsA* glycoprotein (*TfsA*-GP) in the S-layer lattice. **(d)** Typical unbinding event in a force-distance cycle (inset, blocking of the specific interaction by injecting of recombinant *TfsA* protein into the bath solution), **(e)** distribution of unbinding forces between anti-*TfsA* antibody and the bacterial cell surface (wild type, *TfsA*-deficient mutant (ΔtfsA) and *TfsB*-deficient mutant (ΔtfsB)) at a retraction velocity of 1000 nm/s and **(f)** comparison of binding probabilities of the anti-*TfsA* antibody-conjugated AFM tip to wild type, ΔtfsB and ΔtfsA cells, as well as the blocking experiment

typical approach curves measured on the bacterial cell surfaces that reflect well the different stiffness values of the three strains in relation to the production of curli structures. The measured curves were fitted using the Hertz model for a conical tip to extract the Young's modulus values [25.169–171] (Fig. 25.15b).

The effective spring constant of the cell wall and the decay length of the steric force sensed upon approaching the bacterial surface are a measure for the cell's turgor pressure [25.170, 172] and the thickness of the protruding proteins on the bacterial surface respectively. The late linear parts of the approaching force-indentation curves were used to calculate the bacterial spring constant (effective spring constants), which were fitted using the models of *Alexander* and *de Gennes*, as modified for AFM analysis to quantify the steric interactions (e.g., decay lengths) [25.173–176] (Fig. 25.15c). The data show that the effective spring constant, i. e., the turgor pressure of the bacterial cells, was not affected by bacterial surface structures such as flagella and curli fibers. Since there was no change in bacterial turgor pressure of the mutants compared to that of wt *E.coli*, this parameter most likely reflects the mechanical properties of the cell wall. Consequently, the observed decrease in Young's modulus has been induced by changes in bacterial surface properties. The decay length of the bacterial surface was clearly affected by CsgA curli production. These differences evidently indicate the presence of the CsgA protein on $CsgA^{+}$ overexpressed mutant after curli expression and the presence of flagella-like structure on $CsgA^{-}$ curli deficient mutant respectively, which

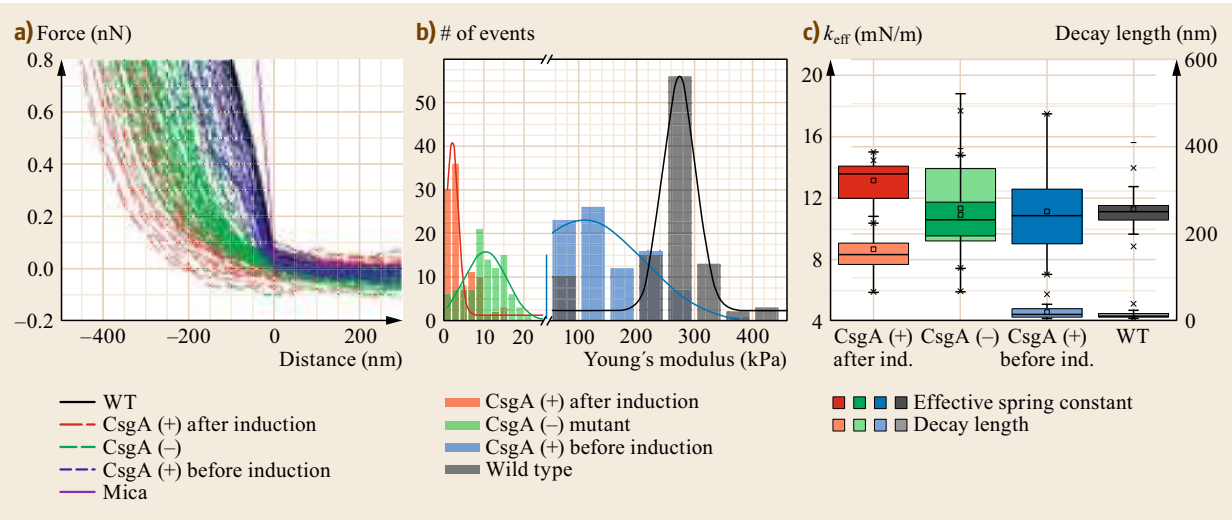

Fig. 25.15a–c AFM indentation measurements to determine the physical properties of *Escherichia coli* bacteria depending on their capacity to produce curli. **(a)** Approach indentation curves measured on a mica surface, wild type, CsgA knock-out mutant ($CsgA^-$) and CsgA overexpressed mutant ($CsgA^+$) before curli expression and after curli expression (by isopropyl-β-D-thiogalactoside (IPTG) induction) on the bacterial surface. **(b)** Distribution of Young's modulus for the different mutant strains. **(c)** Calculated effective spring constant and decay length for the different mutants

both act as a polymer brush on the bacterial cell surface.

Overall the curli overexpressed mutant after IPTG induction produced protruding CsgA protein structures that affected cell wall mechanical properties. This overproduction of curli fiber decreased Young's modulus but increased the decay length on the bacterial surface, while maintaining the inner turgor pressure. This quantitative information obtained by AFM suggests that many critical issues of how mechanical parameters influence cellular behavior can be properly addressed using this method.

25.5 Perspectives and Concluding Remarks

A few years ago live cell AFM experiments still required a high level of expertise and technologically advanced AFM equipment, and consequently were restricted to a few laboratories. Today, several manufacturers offer highly developed bio-AFM setups that are mounted on inverted optical microscopes or provided with upright optical configurations. They are equipped with environmental chambers and sample stages that offer great flexibility and control of experimental conditions. Data processing and analysis also for SMFS is being simplified more and more, as increasingly adequate software is integrated directly into the AFM instrumentation and specialized software has become available from different companies. All these advancements greatly facilitate operation of an AFM by scientist from various life science disciplines. Nevertheless, a basic understanding of the techniques and critical assessment of recorded data remain crucial to AFM experiments. Proper sample preparation and control of environmental conditions, surface chemistry, and the quality of the AFM probe, are equally important and may change over the course of an experiment (e.g., due to contamination) [25.177]. Live-cell experiments in buffer or medium, for instance, have become a routine task and temperature control is available to most setups. However, such experiments continue to require a great deal of patience and newcomers to AFM will generally need to practice before obtaining good data.

SMFS experiments are straightforward, but careful sample and AFM tip preparation together with critical data evaluation are of high importance [25.178, 179]. While standardized tip-functionalization protocols have become more and more available [25.180], validation of successful tip functionalization, i. e., that the ligand is attached and oriented correctly for binding usually happens during the actual experiment. As the interaction force is calculated from the bending of the cantilever, the spring constant has to be calibrated properly

for each cantilever and may vary tremendously from the reported manufacturer value [25.181]. Further considerations in SMFS include the separation of specific (wanted) interactions from nonspecific (unwanted) interactions. Their distinction can be facilitated through the use of defined PEG-crosslinkers as described further above, but may remain challenging even under well-controlled conditions. Unequivocal demonstration of binding specificity by blocking experiments remains absolutely necessary. Finally, data interpretation and automation of force-spectroscopy analyses continue to be time-consuming tasks that (partially) require in-house programmed algorithms. However, many AFM manufacturers have started to implement analysis algorithms into their data-processing software and continue to develop automated routines that will contribute to the simplification of SMFS data evaluation.

Apart from its capabilities, AFM remains primarily a surface technique. Ligand receptor interactions on rigid surfaces and on cell membranes were acquired *blindly* in the past, meaning that force curves were collected at individual, randomly selected sites, with no corresponding image of receptor distribution. The combination of AFM instrumentation with optical microscopy has eliminated this shortcoming and improved imaging and force spectroscopy applications on cells, with the possibility of correlating independently or simultaneously acquired topographic and fluorescence images. The continued development of combined AFM and optical techniques like confocal laser scanning microscopy (CLSM) [25.182–184] and high-resolution correlative microscopy methods such as total internal reflection fluorescence (TIRF) [25.185, 186] or stimulated emission depletion (STED) and stochastic optical reconstruction microscopy (STORM) [25.187] will further improve live-cell applications and allow sophisticated experimental settings. In addition, remarkable advances have been made in developing AFM instruments with increased data acquisition rates, giving access to unprecedented timescales (millisecond resolution) [25.188]. Time resolution is a crucial factor that currently limits investigation of rapid and highly dynamic biological processes with conventional AFM instrumentation. Acquisition of *high*-resolution images takes several minutes, whereas dynamic processes in biology usually occur at much shorter timescales. The ongoing improvements in the field of high-speed AFM open up fascinating new perspectives on the exploration of cellular dynamics and monitoring of molecule interactions with receptors [25.8–10, 189–191]. In the future, high-speed AFM force-distance-based imaging modes will become more and more important in this field. These techniques will allow direct observations of individual molecules in action at high spatiotemporal resolution and provide simultaneous nanoscale mapping of their properties.

To summarize this chapter, we have provided a snapshot of AFM techniques with a special focus on force spectroscopy and recognition imaging for biomedical sensing applications. Our declared aim was to introduce researchers of life sciences in particular, who may be new to these techniques, to the wealth of experimental possibilities provided by the AFM toolbox. The highlighted examples in the last section illustrate the considerable potential of the force-measuring tool SMFS and the recognition-imaging technique TREC to decipher receptor and cell responses to external stimuli and to explore the interaction of cell receptors with individual (drug) molecules. Studies on artificial and native membranes, tissue samples and live cells hold great promise for increasing our understanding of medically relevant molecular processes in disease patterns or pathogen invasion and may help in the development of new therapeutic approaches and pharmaceuticals.

26. Superresolution Microscopy

Tom D. Milster

There are many types of optical microscopy systems that produce superresolution. This discussion centers on optical microscopy techniques that have the potential to extract features from objects that are one the scale of 100 nm or less, which is much smaller than what can be achieved with a classical optical microscope.

In order to achieve resolution on the order of 100 nm with visible-light photons, more information must be obtained from the system than a single image using classical illumination can produce. In some cases, the extra information is in the form of a series of images with a customized illumination pattern. In other systems, the object displays response characteristics that effectively reduce the size of the scanning laser spot used to illuminate it. In yet other systems, light is forced through a nanosized aperture and then scanned over the object.

None of the systems described in this chapter actually change the characteristics or physics of the optical systems used to collect photons. Instead, classical optical systems are cleverly combined with advanced illumination techniques and postprocessing that produce superresolution images.

In the introduction, basic concepts regarding classical resolution are reviewed, and terms are defined that are important with respect to understanding how superresolution microscopy works. Subsequent sections describe superresolution techniques, including scanning aperture techniques, 4-Pi microscopy, enhancement/depletion techniques, photoactivated localization, lattice light-sheet microscopy, and structured illumination. A short comparison of techniques for live-cell imaging is also provided. Although examples of the techniques are given, this chapter is not intended to be a state-of-the-art review inclusive of all variations. Instead, the intent is to provide a basic understanding of the primary classes of superresolution microscopy techniques.

It is notable that work in this area has generated several recent Nobel prizes, because of the importance to science of being able to resolve structures and physiology at the nanoscale [26.1].

26.1 Overview

26.1.1 Review of Classical Resolution

It is well known that the physical effects of diffraction limit the image size of a point source object, as shown in Fig. 26.1. When a monochromatic point source is imaged by an optical system with a limiting aperture of radius a in the space of the image, the Airy disk pattern is observed at the image plane with an irradiance

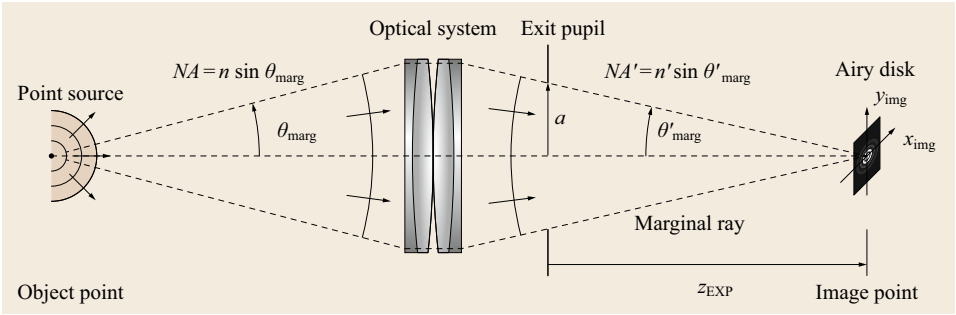

Fig. 26.1 Imaging a point source. The image of an expanding point source in an ideal classical optical system is an Airy disk

distribution

$$I_{img}\left(x_{img}, y_{img}\right) = I_0 \,\mathrm{somb}^2\left(\frac{2an'\rho_{img}}{\lambda z_{EXP}}\right) = I_0 \,\mathrm{somb}^2\left(\frac{2NA'\rho_{img}}{\lambda}\right), \quad (26.1)$$

where $\left(x_{img}, y_{img}\right)$ are coordinates of the image plane with $\rho_{img} = \sqrt{x_{img}^2 + y_{img}^2}$, z_{EXP} is the distance between the limiting aperture and the image plane, I_0 is the peak irradiance, n' is the refractive index of the image space, and λ is the source wavelength. In (26.1), somb(r) is the sombrero function, which is defined by

$$\mathrm{somb}(r) = \frac{2J_1(\pi r)}{\pi r}, \quad (26.2)$$

and J_1 is a first-order Bessel function. The limiting aperture could be in the space of the image, as shown in Fig. 26.1, or it could be internal to the optical/lens system. In either case, the image of the limiting aperture in image space is the *exit pupil*, which defines the size of the Airy disk on the image detector.

It is more common in microscope systems to consider the *numerical apertures* in object and image spaces, rather than the physical aperture diameter a. As shown in Fig. 26.1, the numerical aperture in image space is defined by

$$NA' = n' \sin \theta'_{marg}, \quad (26.3)$$

where θ'_{marg} is the marginal ray angle that passes through the edge of the exit pupil, and n' is the refractive index. A similar definition for numerical aperture is used in object space, where the marginal ray angle and NA are used without primes ($'$). In well-behaved optical imaging systems, NA and NA' are related to each other by the transverse magnification m_T, where

$$NA' = \frac{NA}{m_T}. \quad (26.4)$$

The Airy disk is displayed in Fig. 26.2. Interestingly, *nanometer-size sources of light, like fluorescent molecules, effectively produce the same Airy disk in the image plane as an ideal point source.* A Gaussian approximation for the Airy disk profile is also shown with

$$I_{Gaus}\left(\rho_{img}\right) = I_0 \,\mathrm{gaus}\left(\frac{2NA'\rho_{img}}{\lambda}\right) = I_0 \exp\left[-\pi\left(\frac{2NA'\rho_{img}}{\lambda}\right)^2\right]. \quad (26.5)$$

The Gaussian approximation is important, because it simplifies development of superresolution algorithms.

Now consider two points in object space that are incoherent point emitters, like those generated from fluorophore molecules in a biological experiment. The emitters themselves are much smaller than the wavelength of light emitted from them, and there is no correlation in time between the wavefronts generated by the two emitters. Figure 26.3 shows how the two points are imaged onto a camera. Irradiances from the two Airy disks combine to produce the total image. The effect is a blurring between image points. If the object points are too close together, it is difficult to tell from the image distribution if there is one point or two. At the *Rayleigh criterion*, image separation is such that the first zero of one Airy disk overlaps at the peak of the second Airy disk. At the Rayleigh separation shown in Fig. 26.3, a small dip is present between the two peaks. Mathematically, the Rayleigh criterion specifies that two points are resolved if their separation is

$$\rho_{RES} = 0.61\frac{\lambda}{NA'} = 0.61\, m_T \frac{\lambda}{NA}. \quad (26.6)$$

When imaging an extended object with a classical optical system, it is difficult to discern features separated in the object by distances less than ρ_{RES}/m_T. For example, an ideal $NA = 1.2$ water immersion microscope using $\lambda = 400\,\mathrm{nm}$ light produces a Rayleigh resolution

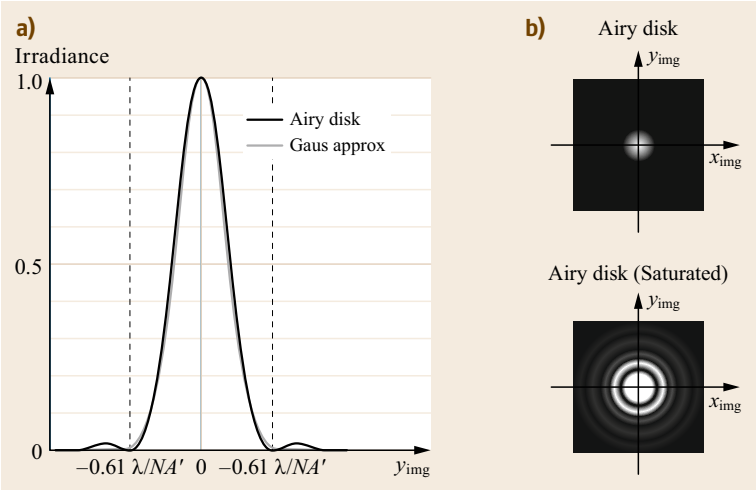

Fig. 26.2 **(a)** Focused laser spot profiles, including the Airy disk and a Gaussian approximation to the Airy disk. **(b)** Airy disk as it appears in the image plane with a linear irradiance scale, and Airy disk with 50X saturation, where the plot is increased in scale by a factor of 50. The saturated Airy disk image highlights the rings present in the Airy disk, which are not present with the Gaussian approximation

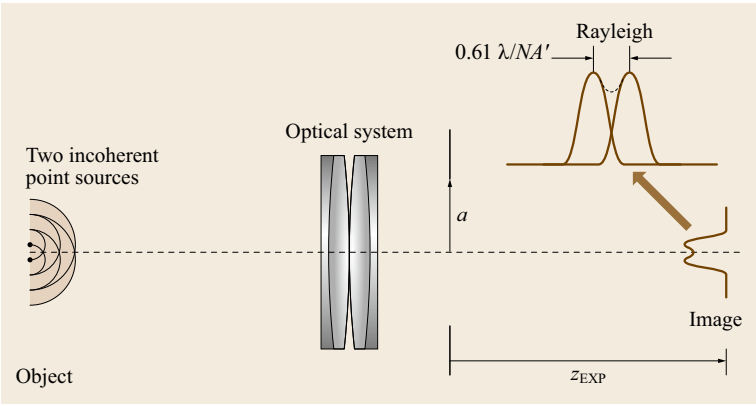

Fig. 26.3 Rayleigh resolution. Two points are said to be just resolved according to the Rayleigh criterion if the separation of their Airy disks in the image plane is such that the peak of one Airy disk falls on the zero of the adjacent disk, as shown in the inset figure. At this separation, the combined irradiance of the two Airy disks has a slight dip in the center

of 203 nm, and the width of the Airy disk in object space is about 407 nm. *The goal of superresolution microscopy is to improve the imaging-system resolving capability to orders of magnitude smaller than the classical Rayleigh criterion.*

26.1.2 Point Spread Function (PSF) and Frequency Response

If the object structure under investigation is given by the function $o\left(x_{\text{obj}}, y_{\text{obj}}\right)$, uniform incoherent illumination produces an irradiance distribution at the object given by

$$I_{\text{obj}}\left(x_{\text{obj}}, y_{\text{obj}}\right) = I_{\text{ill}} o\left(x_{\text{obj}}, y_{\text{obj}}\right) \ , \tag{26.7}$$

where I_{ill} is a constant irradiance value in W/m^2. Under these conditions, the object irradiance is considered as a continuous collection of incoherent point emitters, where the object irradiance function I_{obj} and image irradiance function I_{img} are related by

$$I_{\text{img}}\left(x_{\text{img}}, y_{\text{img}}\right) = CI_{\text{obj}}\left(\frac{x_{\text{img}}}{m_{\text{T}}}, \frac{y_{\text{img}}}{m_{\text{T}}}\right) **h_{\text{incoh}}\left(x_{\text{img}}, y_{\text{img}}\right) \ . \tag{26.8}$$

The *incoherent point spread function* (PSF) of the system is $h_{\text{incoh}}\left(x_{\text{img}}, y_{\text{img}}\right)$, where $(**)$ represents convolution of the two functions, C is a constant, and it is assumed that the optical system is linear and shift invariant. Equation 26.8 also represents the relationship between object and image if the object is self-luminous, like a fluorescent biological sample, where $o\left(x_{\text{obj}}, y_{\text{obj}}\right)$ is the object function that describes the distribution of fluorophores throughout the object. In optical systems with a round exit pupil, like most microscopes, the Airy disk in (26.1) divided by I_0 is the incoherent point spread function h_{incoh}.

Application of the properties of Fourier transforms to (26.8) allows the *frequency response* of the system to

be written as [26.2]

$$\mathcal{I}\left(\xi',\eta'\right)=\mathcal{O}\left(\xi',\eta'\right)\mathcal{H}_{\mathrm{OTF}}\left(\xi',\eta'\right)\ , \tag{26.9}$$

where (ξ',η') are spatial frequency variables that correspond to the $\left(x_{\mathrm{img}},y_{\mathrm{img}}\right)$ directions, $\mathcal{I}\left(\xi',\eta'\right)$ is the Fourier transform of I_{img}, $\mathcal{O}\left(\xi',\eta'\right)$ is the Fourier transform of I_{obj} scaled with the transverse magnification to the image plane, and $\mathcal{H}_{\mathrm{OTF}}\left(\xi',\eta'\right)$ is the Fourier transform of h_{incoh}. $\mathcal{H}_{\mathrm{OTF}}\left(\xi',\eta'\right)$ is called the *optical transfer function* (OTF), because it relates the spatial frequency content of the image to the spatial frequency content of the object. An ideal classical optical system with a round exit pupil and an Airy disk point spread function exhibits an OTF like that shown in Fig. 26.4.

Notice that improving resolution defined by (26.6) is obtained by increasing NA, which also increases the maximum incoherent spatial frequency that can be passed through the optical system. The classical limit for the highest incoherent spatial frequency that can be passed through the system is called the *incoherent cutoff frequency*, which is given by $\xi'_{\mathrm{incoh}}=2NA'/\lambda$. In terms of object spatial frequencies, the incoherent cutoff frequency is $\xi_{\mathrm{incoh}}=2NA/\lambda$.

Several superresolution microscopy techniques implement illumination conditions that transmit higher spatial frequencies through the optical system than what can be achieved with uniform incoherent illumination. An appropriate linear systems mathematical model for irradiance generated at the object is

$$I_{\mathrm{obj}}\left(x_{\mathrm{obj}},y_{\mathrm{obj}}\right)= I_{\mathrm{ill}}\left(x_{\mathrm{obj}}-x_{\mathrm{src}},y_{\mathrm{obj}}-y_{\mathrm{src}}\right)o\left(x_{\mathrm{obj}},y_{\mathrm{obj}}\right)\ , \tag{26.10}$$

where I_{ill} is now a function of position and is shifted by the scan values $(x_{\mathrm{src}},y_{\mathrm{src}})$. Information is detected from multiple scan values to reconstruct an image with high resolution.

In terms of spatial frequencies at the objects, the Fourier transform of (26.10) is $\mathcal{O}\left(\xi,\eta\right)$, which is expressed by

$$\mathcal{O}\left(\xi,\eta\right)=S\left(\xi,\eta;x_{\mathrm{src}},y_{\mathrm{src}}\right)**\tilde{o}\left(\xi,\eta\right)\ , \tag{26.11}$$

where $S\left(\xi',\eta;x_{\mathrm{src}},y_{\mathrm{src}}\right)$ is the frequency spectrum of the illumination and is the Fourier transform of $I_{\mathrm{ill}}\left(x_{\mathrm{obj}}-x_{\mathrm{src}},y_{\mathrm{obj}}-y_{\mathrm{src}}\right)$. $\tilde{o}\left(\xi,\eta\right)$ is the frequency spectrum of the object and is the Fourier transform of $o\left(x_{\mathrm{obj}},y_{\mathrm{obj}}\right)$. Ideally, all object spatial frequencies would be recovered by the imaging system in order to completely reconstruct $o\left(x_{\mathrm{obj}},y_{\mathrm{obj}}\right)$.

For uniform incoherent illumination described by (26.7), I_{ill} is a constant and $S\left(\xi,\eta;x_{\mathrm{src}},y_{\mathrm{src}}\right)=\delta\left(\xi,\eta\right)$, where $\delta\left(\xi,\eta\right)$ is a delta function. Evaluation of the convolution in (26.10) yields

$$\mathcal{O}\left(\xi,\eta\right)=\tilde{o}\left(\xi,\eta\right)\ . \tag{26.12}$$

The spatial frequency content transmitted to the image plane is governed by the OTF through (26.9) with the scaling relationships $\delta'=\xi/m_{\mathrm{T}}$ and $\eta'=\eta/m_{\mathrm{T}}$. For example, in ideal $NA=1.2$ water immersion microscope using $\lambda=400\,\mathrm{nm}$ would not be able to transmit periodic object structures with periods smaller than $\lambda/2NA=167\,\mathrm{nm}$, which is slightly smaller than the Rayleigh resolution of 203 nm.

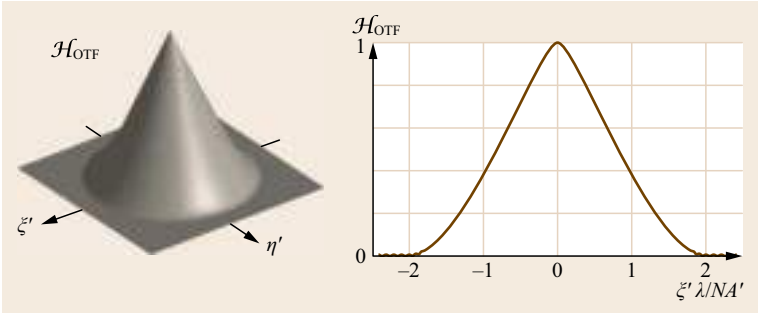

Fig. 26.4 The optical transfer function (OTF) relates the incoherent spatial frequency content of the object to the spatial frequency content of the image. In an ideal classical optical system with a round exit pupil, the OTF is the Fourier transform of the Airy disk

26.2 Scanning Aperture Techniques

There are several superresolution microscopy techniques that rely on limiting the illumination function I_{ill} to a nanoscopic size and scanning the illumination over the sample to collect information for reconstructing the object. One way to reduce the size of the illumination function is to force light through a small hole [26.3]. In practice, most aperture-type scanning instruments use an optical fiber that has been drawn to a small diameter and coated with a metal like aluminum on all but a very small diameter of the tip, as shown in Fig. 26.5 [26.4]. This type of scanning microscopy is called scanning near-field optical microscopy (SNOM) or near-field scanning optical microscopy (NSOM). Its main attraction is the ability to probe optical characteristics of a sample on the nanoscale.

Ideally, the illumination function is a point, where

$$I_{\mathrm{ill}}\left(x_{\mathrm{obj}}-x_{\mathrm{src}}, y_{\mathrm{obj}}-y_{\mathrm{src}}\right) = \delta\left(x_{\mathrm{obj}}-x_{\mathrm{src}}, y_{\mathrm{obj}}-y_{\mathrm{src}}\right) . \tag{26.13}$$

Consider a grating-like object simplified to one dimension with

$$o\left(x_{\mathrm{obj}}\right) = \frac{1}{2}+\frac{1}{2}\cos\left(\frac{2\pi x_{\mathrm{obj}}}{T}\right) , \tag{26.14}$$

where T is the grating period. Application of (26.10) and (26.11) results in

$$\mathcal{O}\left(\frac{1}{T}\right) = \frac{1}{2}+\frac{1}{2}\cos\left(\frac{2\pi x_{\mathrm{src}}}{T}\right) , \tag{26.15}$$

which is only a function of the scan coordinate x_{src} and the grating period T. *The OTF does not affect the signal*, other than to increase the number of photons for improved signal-to-noise ratio, because the data signal is only a function of x_{src}. In fact, a simple photomultiplier tube placed close to the object is often used for data collection, rather than a more complicated optical system. Also, there is no conceptual lower limit on the grating period T, which can be much smaller that the Rayleigh resolution from (26.6). Of course, the time required to obtain enough data to reconstruct an image depends on the scanning speed of the illumination function.

In practice, nanoscopic scanning light sources are of finite width. Due to the skin depth and other electromagnetic properties of the metal cladding, the geometric form of the illumination function is sometimes approximated by a Gaussian distribution. In terms of the one-dimensional grating example of (26.14), a Gaussian illumination function of width d_{ap}, where $d_{\mathrm{ap}} \ll \lambda/NA$, results in an object frequency spectrum

$$\begin{aligned}\mathcal{O}(\xi) \propto\ & \mathrm{gaus}\left(d_{\mathrm{ap}}\xi\right) \\ & + \mathrm{gaus}\left[d_{\mathrm{ap}}\left(\xi-\frac{1}{T}\right)\right]\exp\left(\frac{\mathrm{i}2\pi x_{\mathrm{src}}}{T}\right) \\ & + \mathrm{gaus}\left[d_{\mathrm{ap}}\left(\xi+\frac{1}{T}\right)\right]\exp\left(-\frac{\mathrm{i}2\pi x_{\mathrm{src}}}{T}\right) ,\end{aligned} \tag{26.16}$$

which is shown conceptually in Fig. 26.6 with fre-

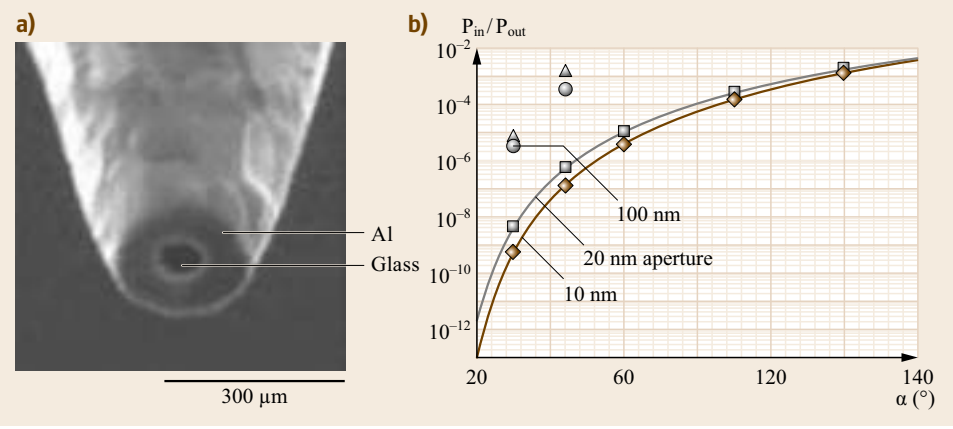

Fig. 26.5a,b SNOM aperture tip fabricated on the end of an optical fiber. **(a)** Construction of the tip involves drawing an optical fiber and partially coating the end with a metal, like aluminum. The diameter of the glass opening roughly corresponds to d_{ap}. Scale bar is 300 nm. **(b)** The power throughput of a SNOM tip is limited, because the aperture is much smaller than the wavelength of light. This plot shows the calculated ratio of input to output power for 10 and 20 nm diameter apertures, along with scaling of these results to a 100 nm aperture. The horizontal axis is the taper angle of the tip. Reprinted from [26.4] with the permission of AIP Publishing

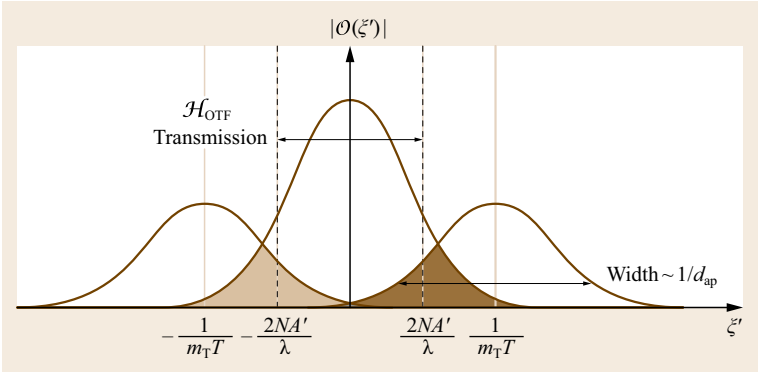

Fig. 26.6 SNOM signal generation. For a cosine object and a small Gaussian aperture of width d_{ap}, object frequencies distribution consist of three Gaussian distributions, as described by (26.16). Two Gaussians distributions are offset from the center by $\pm 1/m_{\mathrm{T}}T$. As the aperture is scanned, modulation between the central Gaussian distribution and the shifted Gaussian distributions occurs in the regions of overlap due to the exponential phase factors. Modulation below the incoherent cutoff frequency $2NA'/\lambda$ is transmitted to the detector as the scanning signal

quency variables scaled by $1/m_{\mathrm{T}}$ for image space. In (26.16), $\mathrm{i} = \sqrt{-1}$, and the second and third terms contain complex phase exponentials that depend on the scan coordinate of the illumination function. The three Gaussian distributions in (26.16) are separated in the frequency domain according to $1/T$. As T decreases, the separation becomes larger. Gaussian distribution widths are proportional to $1/d_{\mathrm{ap}}$, so small illumination functions produce wide Gaussian distributions. As the illumination function is scanned in x_{src}, interference between the exponential phase terms in (26.16) and the central Gaussian distribution produces modulation in the region below the incoherent cutoff frequency $\pm 2\lambda/NA$. That is, the *shaded regions* in Fig. 26.6 become brighter or darker as the aperture is scanned over the object. The integrated signal transmitted through $\mathcal{H}_{\mathrm{OTF}}$ contains this modulation, and the image is reconstructed from the accumulated signal. The smallest period that can be resolved depends on the width of the Gaussian illumination function. Smaller d_{ap} produces finer superresolution, because the amount of overlap increases for large $1/\mathrm{T}$ as d_{ap} becomes smaller.

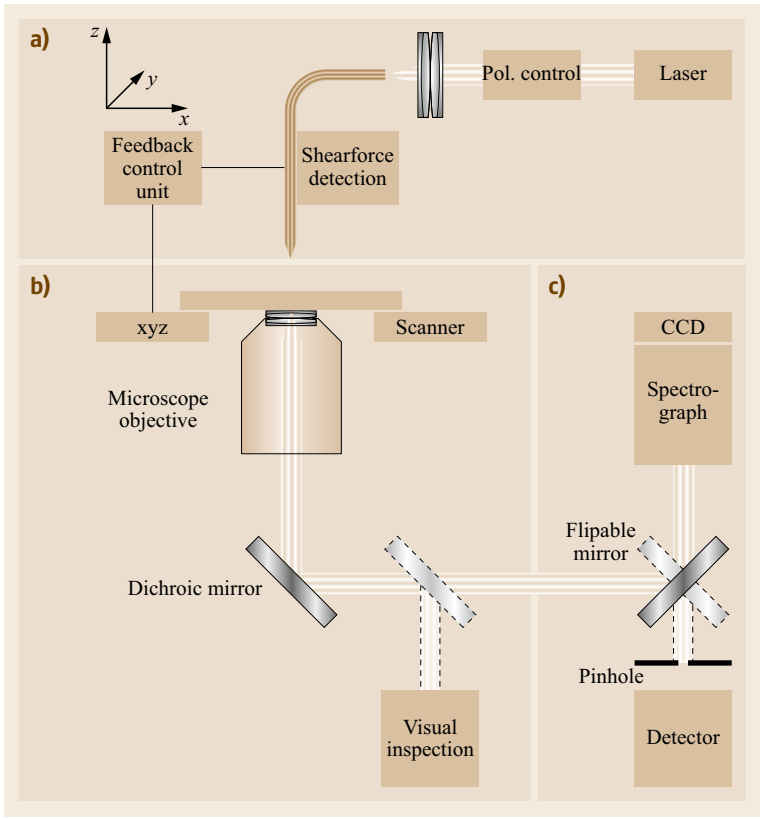

Fig. 26.7a–c A typical SNOM system (after [26.4]) **(a)** illumination unit; **(b)** collection and redistribution unit; and **(c)** detection module

One complication of the small tip diameter is that the transmission of light through holes with diameters less than the wavelength of light is very low. As shown in Fig. 26.5b, a 100 nm diameter tip with a 30° cone angle only emits one photon for every 10^6 photons incident upon the tip through the fiber [26.4]. In practice, d_{ap} is limited to a minimum of 80–100 nm, because of the poor signal-to-noise ratio and long scan times required for smaller apertures. Unfortunately, increasing the incident laser power level to improve signal-to-noise ratio has an upper limit, due to ablation of the metal tip where most of the incident photons are absorbed, so systems using d_{ap} smaller than about 80 nm are not practical.

Another complication with scanning optical probe techniques is that the illumination function needs to be in near contact with the object. Techniques similar to those used for atomic force microscopy are used to successfully regulate SNOM tip position above the sample. A typical arrangement for a SNOM device is shown in Figure 26.7 [26.4]. The illumination unit (a) directs the laser beam through polarization control into the proximal end of the fiber. The fiber tip is placed in proximity to the sample, and shear-force detection is used

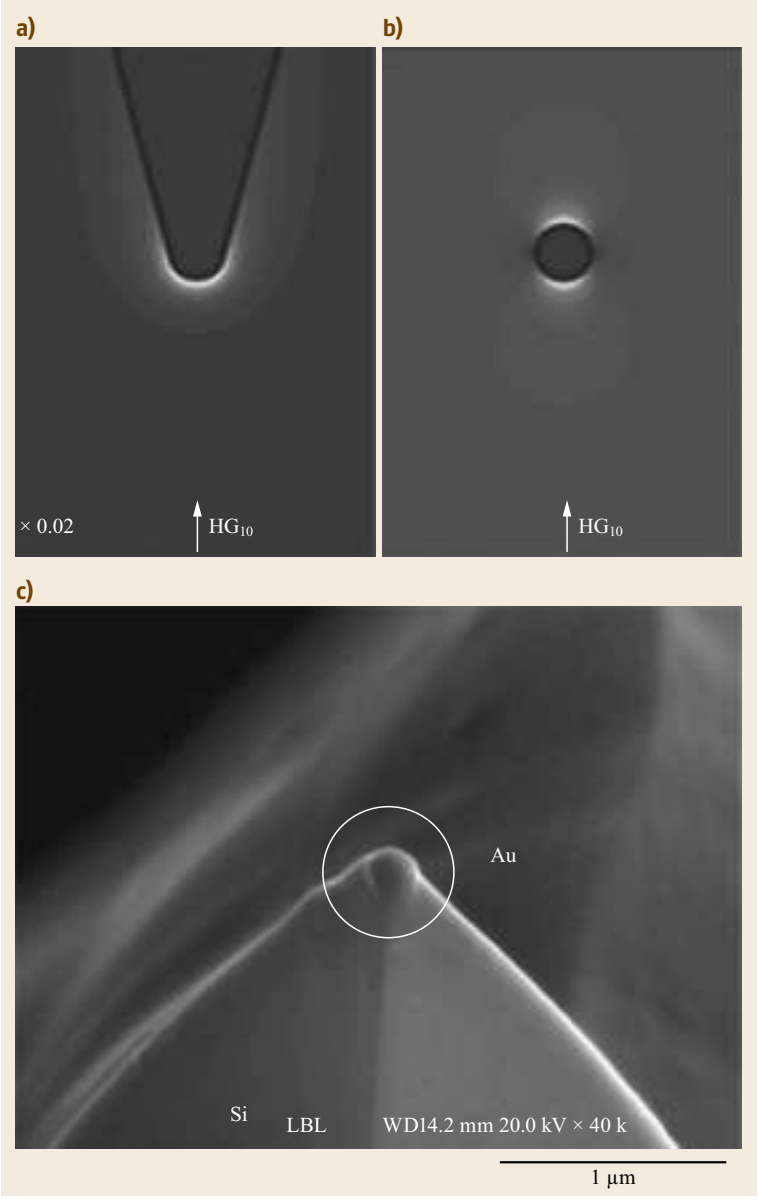

Fig. 26.8a–c Aperturless scanning near-field optical microscopy (ASNOM), where lighter shading indicates higher field strength; **(a)** field strength of a tapered probe; **(b)** field length of an isolated gold nanosphere excited by a vertically polarized laser beam as indicated by the *small arrow*; **(c)** fabrication of an ASNOM tip using a 50 nm gold nanosphere attached to a tapered silicon probe. **(a,b)** from [26.5], copyright Lukas Novotny and Bert Hecht 2012, published by Cambridge University Press. **(c)** reprinted with permission from [26.6], copyright 2006 American Chemical Society

to regulate the tip-to-sample distance through a feedback control unit [26.7]. Collection is in transmission through the object with a standard microscope objective lens in the collection and redistribution unit (b), which also contains the mechanical scanner for the sample stage. The detection module (c) can contain spectrographic and photon-counting detectors. Other modes of operation include using the tip in *collection* mode, where the tip is scanned over a light field and photons are collected through the fiber onto a detector, and *illumination/collection* mode, where the tip both illuminates the object and collects photons back through it.

An alternative to launching light into the fiber and forcing photons through the aperture is to illuminate a sharpened tip externally with a laser beam, as shown in Fig. 26.8. In Fig. 26.8a, excitation of a sharpened gold tip with an end radius of 10 nm is compared to excitation of a gold nanosphere [26.5]. The excitation is polarized in the vertical direction, and the gray scale indicates field strength. Clearly, fields are well confined near the tip. Maximum field strength near the tapered tip is 50 times the strength of the isolated gold nanosphere, because the tapered tip acts like an antenna for the electric field. The use of the externally activated tip to scan a surface and collect image information is called *apertureless scanning near-field optical microscopy* (ASNOM). The primary advantage to ASNOM over SNOM is that field confinement depends on the tip radius, which can produce optical resolution in the range of 30 nm. In Fig. 26.8b, a 50 nm gold nanosphere is attached to a tapered silicon probe for ASNOM studies [26.6].

Examples of SNOM studies are shown in Fig. 26.9 that illustrate the diversity of applications [26.8].

26.3 4-Pi Microscopy

4-Pi microscopy is based on the discovery that the three-dimensional PSF of a confocal microscope is improved by interference of two coherent wavefronts at the focal plane of the microscope [26.9]. As shown in Fig. 26.10, two microscope objectives (OL1 and OL2) illuminate a sample from both sides with coherent light at a common focal plane in the sample. Light from OL1 and OL2 interferes in the focus volume and produces a standing wave illumination pattern. Fluorescent emission is received by a detector that includes a pinhole conjugate to the focal plane through both Paths 1 and 2. (The additional relay optics are not shown in Fig. 26.10.) The axial extent of the effective confocal point-spread function is significantly reduced, which is equivalent to an improved axial resolution.

The effective PSF is given by the product of the illumination PSF and the PSF of the pinhole detector, where

$$h_{4\text{-Pi}} = h_{\text{ill}} h_{\text{det}} \,. \tag{26.17}$$

The function $h_{4\text{-Pi}}$ is proportional to the probability of an illumination photon both exciting a fluorophore in the vicinity of focus and detecting a photon emitted from the same position. Depending on the choice of pinhole size, $h_{4\text{-Pi}}$ produces better resolution in the transverse plane when compared to standard illumination and Rayleigh resolution, and the axial resolution is significantly improved.

4-Pi confocal fluorescence microscopy is used primarily in two different configurations [26.10]. The Type A configuration utilizes interference of the laser in the focal volume and only collects fluorescence from Path 1. The Type C configuration also utilizes interference of the laser from Paths 1 and 2, but it collects fluorescence from both paths at the detector pinhole. When arranged properly, the combination of fluorescence from both paths also creates an interference signal at the pinhole. Due to the combination of the interference in excitation and detection, the Type C configuration exhibits lower side lobes in the axial direction

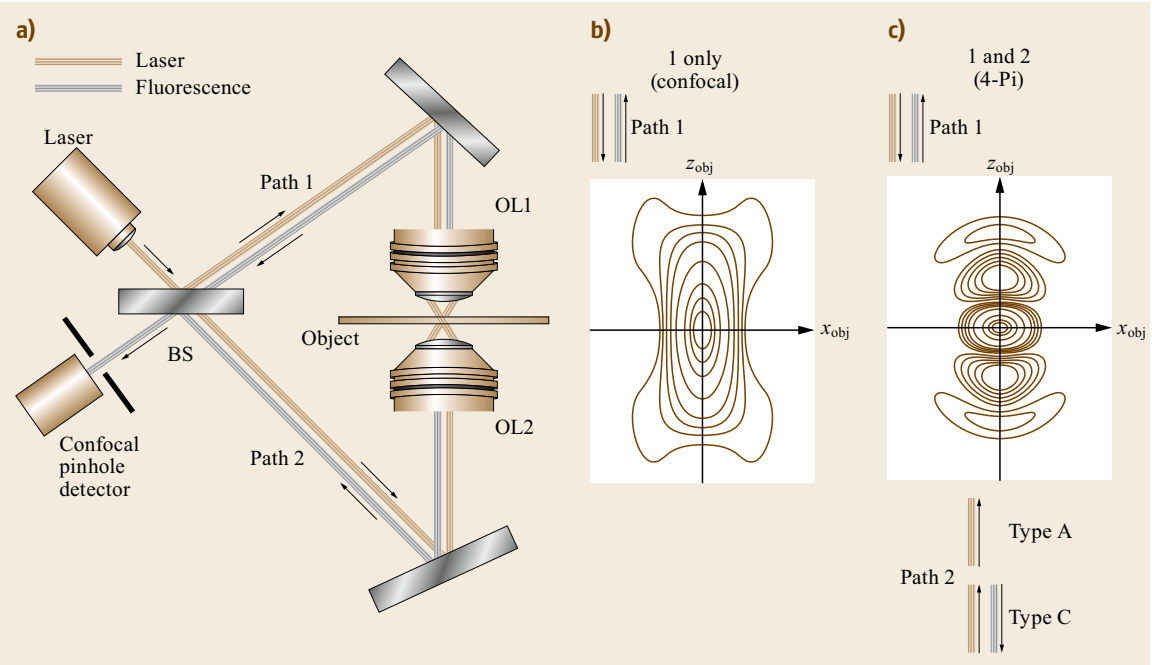

Fig. 26.10a,b,c 4-Pi Microscopy. **(a)** A confocal microscope is modified to use two counter-opposed illumination objective lenses (OL1 and OL2). A laser beam is directed into each lens, and the combination of the focused spots creates a standing wave pattern that dramatically reduces the axial extent of the illumination volume. Effective PSFs from [26.9] are shown in **(b)** for a confocal arrangement (*Path 1* only) and in **(c)** for the 4-Pi arrangement using *Path 1* and *Path 2*. Type A 4-Pi microscopy uses only the fluorescence signal from *Path 1*, while Type C 4-Pi microscopy uses the fluorescence signal from both paths. Interference fringes are clearly visible in the effective PSF for the 4-Pi geometry

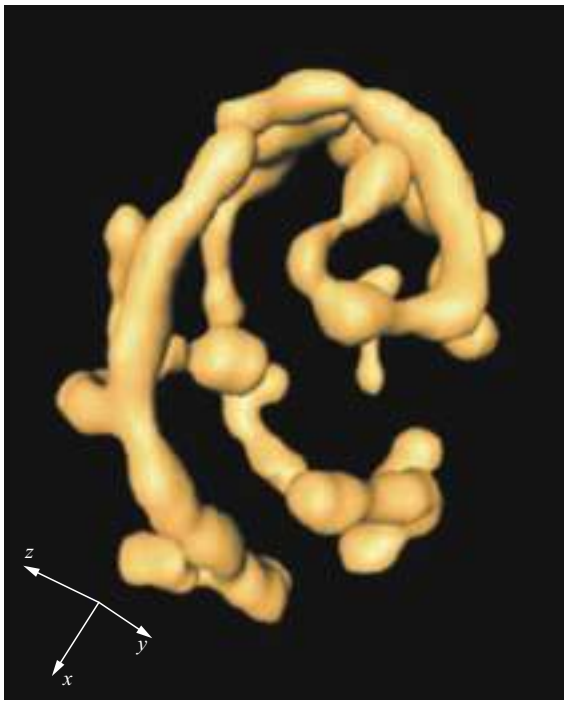

Fig. 26.11 3-D image of the mitochondrial compartments of a yeast cell taken with a Type C 4-Pi microscope. The extent of the cell is ≈ 5 μm (after [26.10]) ◀

of the effective PSF and increased axial resolution compared to Type A.

Figure 26.11 displays a three-dimensional (3-D) image of a living yeast cell labeled with green fluorescent proteins that targeted the mitochondrial compartments in the cell [26.10]. A series of scanned image planes was obtained with a Type C 4-Pi confocal microscope, and then postprocessing was applied to render the three-dimensional distribution of fluorescence above a threshold value.

Two-photon 4-Pi fluorescence microscopy can improve axial resolution to 100 nm, because the energy in the first higher and lower axial lobes is insufficient to produce two-photon fluorescence [26.11]. Both axial and lateral resolution can be additionally improved to as little as 75 nm using image restoration techniques [26.12].

26.4 Enhancement/Depletion Techniques

The concept behind enhancement/depletion techniques is very similar to the idea of SNOM/NSOM, except the size of the illumination function is reduced photochemically in the sample, rather than with a physical aperture. Optically, information is transmitted through the microscope using an effectively nanoscopic illumination function, as shown in Fig. 26.6. Stimulated emission depletion fluorescence microscopy (STED) uses two lasers focused to the same location in the sample, where the focused spot from one laser excites fluorescence, and the second laser inhibits spontaneous fluorescence, as shown in Fig. 26.12 [26.13, 14]. Clever engineering of the spot shapes allows superresolution to be achieved. For two-dimensional (2-D) STED, the first laser pulse (shown in green in Fig. 26.12) generates an unaltered Airy or Gaussian focus distribution, which excites fluorophore molecules in the focus area. After a short time delay Δt, the second laser pulse (shown in red) generates a donut-shaped focus distribution due to the 0 to 2π spiral phase optical filter. The second laser beam depletes the carriers through stimulated emission or transition to a nonradiative mode before excited carriers decay with fluorescence. The remaining distribution of fluorescent molecules are contained in an area that is effectively the subtraction of the two laser focus distributions, which is much smaller than the Airy disk. This effective PSF contains fluorescent molecules that emit at wavelength λ_{em}, which is longer that the excitation laser wavelength. By increasing the power of the STED laser beam, the effective PSF becomes smaller. Lateral resolutions of 25 nm and below have been demonstrated [26.15, 16].

Applied to three dimensions, STED creates a 3-D PSF that localizes fluorescence information to the nanoscale in x, y and z dimensions, as shown in Fig. 26.12 [26.17]. In this case, the optical phase filter consists of a small, circular π phase retarder in the illumination path of the STED laser, which produces zero optical field at the center of the 3-D distribution. A measured 3-D STED PSF is shown in the lower-right portion of Fig. 26.12. Experimental localization is nearly 100 nm in all three dimensions and is significantly smaller than the effective PSF of the same microscope in a confocal configuration.

STED is a type of reversible saturable optical fluorescence transition (RESLOFT) microscopy, where resolution is given by

$$\rho_{\mathrm{RESLOFT}} \approx \frac{\lambda_{\mathrm{exc}}}{2NA\sqrt{1+\zeta}}\,, \tag{26.18}$$

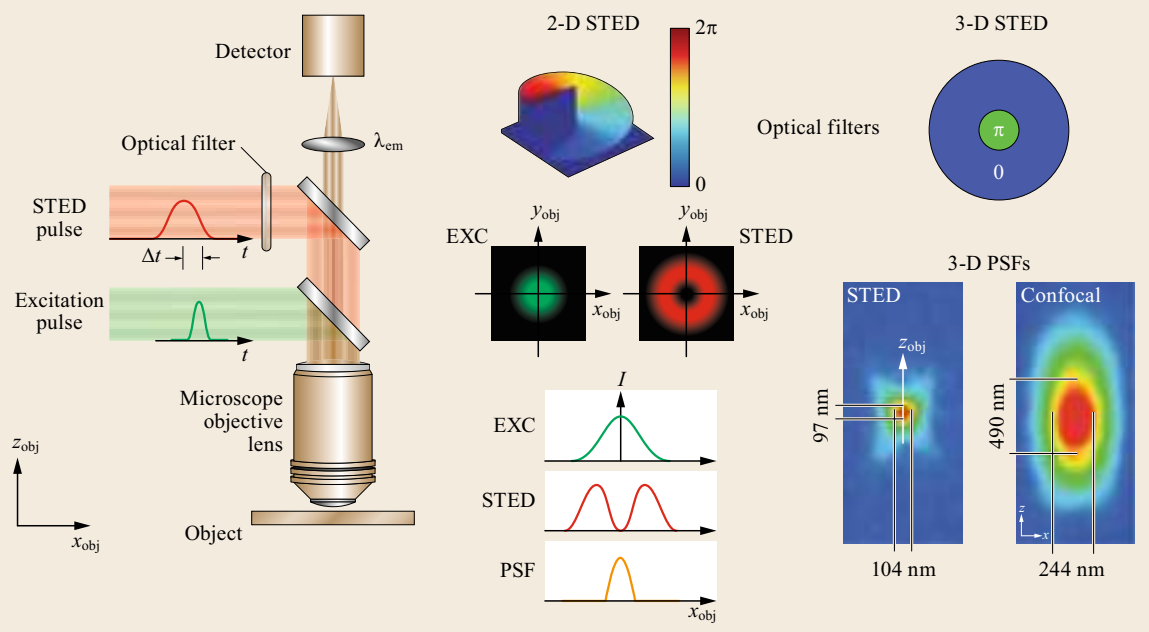

Fig. 26.12 Stimulated emission depletion superresolution microscopy. Two laser beams of different colors are passed through a microscope objective lens and focused onto the sample. The 2-D STED laser beam is modified with an optical filter to produce a donut-shaped focus irradiance. Due to properties of the fluorescent molecules, the excitation laser beam excites carriers that are depleted with the STED beam before they fluoresce in regions where the STED beam irradiance is high enough. The net result is a PSF that is the subtraction of the excitation (EXC) beam and the STED beam, which is considerably smaller than either the EXC or STED profiles. If the optical filter is changed to a simple circular π phase delay, the STED focus in 3-D contains a zero in the center and can deplete fluorescence except in the very center of the volume. Lower-right effective PSF distributions derived from [26.17]

where λ_{exc} is the excitation wavelength and ζ is the saturation factor given by

$$\zeta = \frac{I_{max}}{I_{sat}} , \qquad (26.19)$$

I_{sat} is the saturation power per unit area of the fluorophore, and I_{max} is the maximum value of the irradiance in the STED laser spot [26.18]. Equation (26.18) is smaller than the Rayleigh resolution in (26.6) by a factor of $\sqrt{1+\zeta}$. As STED-beam laser power I_{max} increases compared to the saturation irradiance, the resolution improves.

STED fluorophores exhibit a lifetime in the excited state of only a few nanoseconds, so the probability of depleting the fluorescent transition is relatively low with a correspondingly high value of I_{sat} required for saturation. Typically, picosecond lasers are used in STED with power densities of hundreds of MW/cm^2. In order to increase the probability of depletion, different fluorophores with a triplet state between the ground state and the excited state are utilized, which last for periods of microseconds, thus lowering I_{sat} by a factor of 1000. This variation of STED is called ground-state depletion (GSD) microscopy, and it is advantageous for live-cell imaging due to the dramatically lower power levels required for I_{max} [26.19]. STED can also be carried out with continuous wave (CW) depletion lasers, but the laser power needed for reaching the same resolution is much higher with CW STED compared to pulsed STED [26.20]. Time-gated detection, which precisely times detection with duration of the STED effect to achieve better rejection on spontaneous emission, can greatly improve the resolution under the same I_{sat} value [26.21].

26.5 Photoactivated Localization

Localization microscopy uses a classical microscope system with a special illumination system that limits the number of emitting fluorescent molecules during each frame of the imaging camera. Individual fluorescent molecules are so small that an image of a molecule is essentially the width of the microscope PSF. For each frame, pulses of short wavelength excitation light are used to photochemically activate molecules from a dark state to a bright longer-wavelength fluorescent state. The irradiance of the switching pulse is adjusted so that the fraction of molecules in the bright state is relatively small, and therefore the average spacing between molecules in the bright state is much larger than the width of the PSF in a single frame. There are many variations of localization microscopy, which mainly have to do with the type fluorophore and illumination scheme.

The concept of localization microscopy is shown in Fig. 26.13. Fluorophore molecules are distributed in the object plane, where six individual molecules are identified in this example. In Frame 1, molecules 2 and 6 are actively emitting photons, as indicated by the *open circles*. Molecule 1, and molecules 3–5 are inactive (*dark*). PSF images of molecules 2 and 6 are measured on the camera, where about 1000 detected photons comprise each PSF. The image is processed by fitting the Gaussian approximation of (26.5) to determine centroids of the component PSFs. Assuming that the image is only limited by photon noise, the precision of localizing PSF centroids is approximately [26.22]

$$\sigma_{xy} \approx \frac{\sigma_{\mathrm{PSF}}}{\sqrt{N}} , \tag{26.20}$$

where N is the number of photons in the PSF and σ_{PSF} is the width of the PSF.

Processing continues by replacing each PSF with a smaller Gaussian distribution of width σ_{xy} at the calculated centroid positions. The processed image frame is complete when all PSFs are replaced with their narrower versions. With $N = 1000$, the localization precision is smaller than the PSF by a factor of nearly 32. That is, a good quality microscope with a Rayleigh resolution of 279 nm would exhibit a theoretical processed resolution of 8.8 nm.

After Frame 1 is collected, an illumination mechanism is introduced that switches off molecules 2 and 6 and allows a few inactive molecules, which were dark in Frame 1, to actively emit photons. In Frame 2 of Fig. 26.13, molecules 1 and 5 are emitting photons. The Frame 2 image data are processed in a similar way, and reduced-width Gaussian distributions are positioned according to the component PSF centroids. The processed Frame 2 is then added to the processed Frame 1 to produce a composite superresolved image. Notice that the separation of molecules 5 and 6 would be indistinguishable with standard incoherent illumination. Molecules 1 and 2 would also be indistinguishable with uniform incoherent illumination,

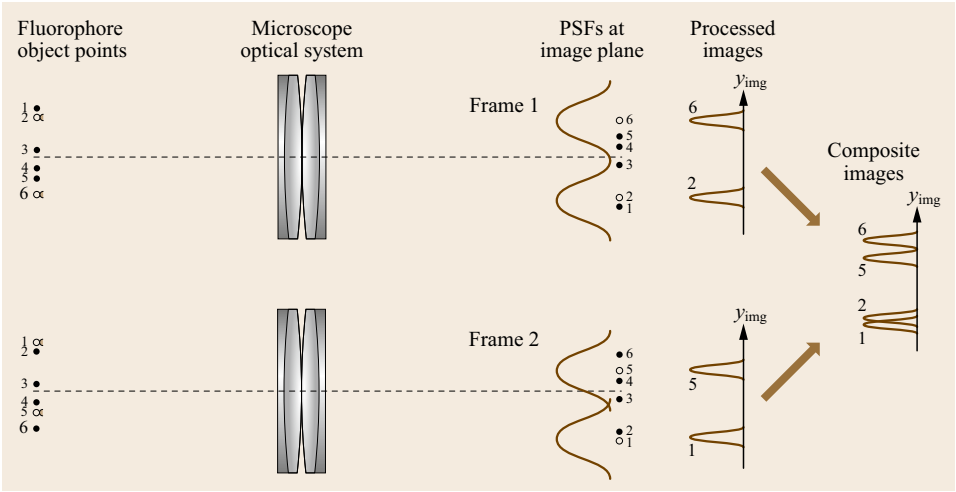

Fig. 26.13 Localization microscopy. Illumination of a distribution of fluorophores in an object is tailored to active emission from only a few molecules at a time, such that the image-lane PSFs are clearly separated. The center of each PSF is determined and replaced by a Gaussian distribution that represents uncertainty of the centroid. Successive frames accumulate the processed images to obtain a complete composite image

and the processed composite image exhibits these two reduced-width Gaussian distributions at the superresolved resolution limit. Consecutive image frames continue with the same process steps until enough data are acquired.

A characteristic of localization microscopy is that each image frame contains only a small number of localizations, so a large number of image frames are required to collect enough data to be scientifically interesting. With an individual frame integration time of 0.5 s, it is not unusual to collect data for one sample in 10^4–10^5 frames over a few hours or even up to twelve hours, depending on the number of frames and fluorophore emission.

For localization microscopy to work, the fluorophores being imaged must exhibit a contrast in photon emission between the *on* (actively emitting photons) and *off* states. This contrast is critical to the performance of the technique. If the off state produces too many photons, the density of fluorophores could be limited, due to fluorescence background noise. Consideration of resolving image structures from the Nyquist sampling theorem [26.23] dictates that the smallest resolvable structure Δ_{Nyquist} is defined by

$$\Delta_{\text{Nyquist}} = \frac{2}{\Sigma^{1/D}} , \qquad (26.21)$$

where Σ is the density of fluorophores and D is the dimension of the structure. For example, $\Delta_{\text{Nyquist}} = 20\,\text{nm}$ for a two-dimensional object requires $\Sigma = 10^4$ per μm^2, in general. However, due to the heterogeneity of biological structures, a high local density is often observed with a low overall areal and/or volumetric density. The types of fluorophores used for localization microscopy are limited by the contrast they provide and by the switching mechanism between on and off states. The following paragraphs briefly describe the differences between a few of the major localization microscopy techniques.

Photoactivated localization microscopy (PALM) is a technique using photoactivatable protein fluorophores (PA-PFs), like photoactivatable green fluorescent protein (PA-GFP) [26.25]. Proteins are continuously excited by a laser, with a power level that allows frames to contain sparse fields with individually resolvable single molecules on a weaker background. Additional frames are captured until single molecule bleaching results in a mean molecular separation that is much larger than that required for isolation. Then, a shorter wavelength laser is pulsed to activate remaining inactive PA-FP molecules at a duration and intensity chosen so that overall density of PA-FP molecules is increased to a higher, but still resolvable level. The fluorescent photoactivated localization microscopy (fPALM) technique uses a similar protocol, but PALM uses total-internal-reflection fluorescence (TIRF) illumination, while fPALM uses a standard wide-field illumination geometry [26.26, 27].

Like with STED microscopy, the invention of PALM/fPALM and related techniques created an abundance of interest in the scientific community. Although many significant advances with this technology have been documented, there is not space in this article to review them in detail. However, it is worth noting some specific examples, at the least for historical reasons. For example, Fig. 26.14 shows an early comparison between TIRF and PALM for clus-

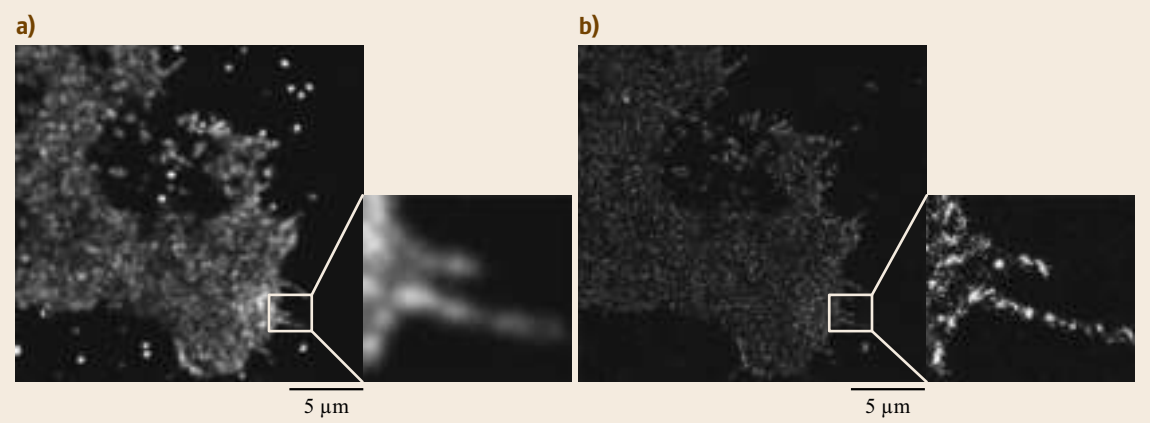

Fig. 26.14a,b Comparison of TIRF and PALM for cluster analysis of LckN10-tdEos. **(a)** Conventional TIRF image; **(b)** PALM image of the same section. Zoomed regions of the images are indicated with *boxes*. Reprinted with permission from [26.24]

ter analysis of LckN10-tdEos [26.24]. PALM localizes peak emission of molecules to about 20 nm. PALM has also been applied to single-particle tracking (spt-PALM) [26.28] and centroid localization techniques have incorporated optimized PSF and advanced statistical methods [26.29].

Stochastic optical reconstruction microscopy (STORM) is a localization microscopy technique that uses pairs of photoswitchable dyes, like a *switch* pair of Cy3 and Cy5 dyes [26.30]. The Cy5 dye can be switched between the on and off states in a controlled and reversible manner by using light of different wavelengths. For example, red light that produces emission from Cy5 dye can also be used to switch the dye to an off state. Exposure to green light converts the Cy5 dye back to an on state, but the recovery rate critically depends on proximity of the Cy5 molecule to a Cy3 secondary dye molecule. When attached to nucleic acids or proteins, illumination conditions appropriate for localization microscopy allow the switch to be cycled on and off hundreds of times before permanent photobleaching occurs.

Direct stochastic optical reconstruction microscopy (dSTORM) uses conventional, standalone carbocyanine dyes, like Cy5 and AlexaFluor 647, that can be switched on and off with a single laser [26.31]. In dSTORM, PA-FPs are genetically fused to target proteins and endogenously expressed in cells and organelles. dSTORM is not limited to biological samples, so it can be used to study polymers or nonbiological optically transparent samples.

Superresolution optical fluctuation imaging (SOFI) is a localization microscopy technique that uses a conventional wide-field microscope and takes advantage of the blinking or intermittency of the emission from fluorophores [26.32]. Like other localization techniques, SOFI requires two states of emission from the fluorophore. Emitters must switch between states repeatedly and independently in a stochastic way. Image acquisition is made with rapid successive frames over a period of time, where emitters can fluctuate over many cycles. To process data, second-order correlation of the dataset provides localization data. Higher-order cumulant calculations provide greatly improved localization precision, including three-dimensional information, and resolution improvement by a factor of five has been achieved.

26.6 Structured Illumination

In structured illumination microscopy, the illumination function I_{ill} in (26.10) is a cosine function. By acquiring a series of images and processing data, improvements of a factor of two in resolution can be obtained. If nonlinear excitation is used, the resolution improvement factor can be several times higher. An advantage to using structured illumination over localization microscopy techniques is that the energy dose for live cell imaging is much lower, so the potential for photodamage is reduced. In the following paragraphs, the experimental configuration, theory and algorithm for structured illumination microscopy are reviewed, and a few examples are provided.

The basic concept for structured illumination is shown in Fig. 26.15. A cosine function I_{ill} illuminates the object for Frame 1 of the image sequence. In biological applications, a distribution of fluorescent molecules defines the object function $o\left(x_{\text{obj}}, y_{\text{obj}}\right)$. Fluorophore molecules are bright, dark or in between as a function of position due to the cosine. The cosine pattern can be generated by imaging a simple grating onto the object, or more complicated holographic methods may be used. The image is collected with a standard high-NA microscope system onto a good-quality camera. For Frame 2, the cosine is shifted slightly by an amount x_{src}, which can be accomplished with a galvanometer mirror. The distribution of brightness from the fluorescent molecules changes, due to the shifted cosine illumination pattern. Several images in a series with small shifts between them are collected. The cosine illumination pattern is rotated in the $\left(x_{\text{obj}}, y_{\text{obj}}\right)$ plane at least two times, with a similar series of images collected for each rotation. The image sequences are then processed in the spatial frequency domain, and a superresolved image is reconstructed.

The illumination function is written

$$I_{\text{ill}}\left(x_{obj} - x_{src}\right) = 0.5 I_0 \left\{1 + \cos\left[\frac{2\pi\left(x_{obj} - x_{src}\right)}{T}\right]\right\}, \tag{26.22}$$

where T is the period of the illumination in the object plane. The frequency spectrum of the illumination is the Fourier transform of the illumination, where

$$\begin{aligned} S\left(\xi, \eta; x_{src}\right) = 0.5 I_0 \{ & \delta\left(\xi\right) \\ & + 0.5\left[\delta\left(\xi - \xi_0\right)\exp(-j\phi)\right. \\ & \left. + \delta\left(\xi + \xi_0\right)\exp(j\phi)\right]\}\delta(\eta) \end{aligned} \tag{26.23}$$

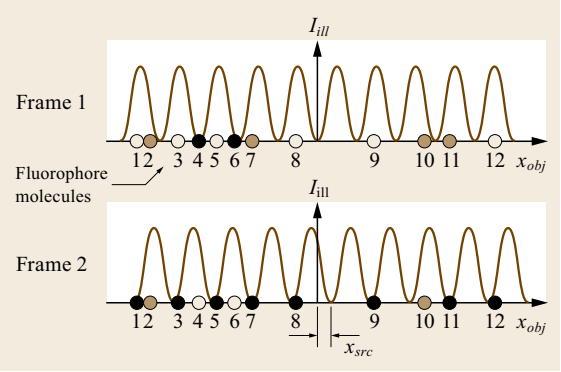

Fig. 26.15 Basic concept of structured illumination imaging. A cosine irradiance illumination pattern is imaged onto the object that excites fluorophores in the tissue. The resulting emission is imaged by a standard microscope onto a good-quality camera. Successive images are acquired, where the cosine illumination is shifted between them. After at least two rotations of the illumination pattern and a shifted image sequence for each rotation, the entire image data set is processed to produce a superresolved image

in which $\phi = 2\pi x_{src}/T$, and $\xi_0 = 1/T$. Application of (26.11) then gives

$$\mathcal{O}(\xi,\eta) = 0.5I_0\{\tilde{o}(\xi,\eta) + 0.5\left[\tilde{o}(\xi-\xi_0,\eta)\exp(-j\phi) + \tilde{o}(\xi-\xi_0,\eta)\exp(j\phi)\right]\}. \quad (26.24)$$

That is, the incoherent spatial frequency content of the light transmitted through the object consists of a central order, which is the object spatial frequency distribution $\tilde{o}(\xi,\eta)$, and two shifted versions of the same distribution. The shifted orders exhibit a phase shift ϕ that is proportional to the grating shift. A graphical interpretation of (26.24) scaled to image frequency space is shown in Fig. 26.16, where the illumination cosine distribution is modified to have components along both unit Cartesian unit vectors $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{y}}$ defined by the orientation of vector $\boldsymbol{\xi}_0' = \xi_0'\hat{\boldsymbol{x}} + \eta_0'\hat{\boldsymbol{y}}$. The three orders are shown in separate subfigures, although they are all present in the total frequency distribution. The OTF diameter of the microscope imaging system is shown as a *dashed circle*, where *light shading* represents spatial frequencies that are transmitted through the exit pupil. The transmitted portion of the central order is limited by the OTF and is the same content that would be transmitted from uniform incoherent illumination described by (26.9). The upshifted order transmits a small portion of the spatial frequency spectrum that is not transmitted by the central order, as indicated by the *darker shading*. Note that this portion contains higher spatial frequency content than is transmitted by uniform incoherent illumination. The downshifted order also transmits spatial frequencies that are not transmitted with uniform incoherent illumination.

Successive images taken at different (x_{src}, y_{src}) shifts contain overlapped frequency information and must be processed. Conceptually, the algorithm is shown in Fig. 26.17. In a computer, an image is Fourier transformed to produce its spatial frequency distribution, which is inside the OTF. Information is divided according to the grating orientation and period, and higher spatial frequency information is moved to appropriate regions in the frequency plane. Multiple images are obtained with different shifts of the illumination grating to change ϕ in (26.24), and the images are processed to retrieve correct phase values for the translated frequency information. Multiple orientations of the grating are used to fill in other portions of the frequency plane, and normalization of the OTF shape shown in Fig. 26.4 is included in the processing algorithm.

A representative experimental demonstration is shown in Fig. 26.18, where three orientations of the grating are used to produce a total of six shifted components [26.33]. Figure 26.18a shows the incoherent

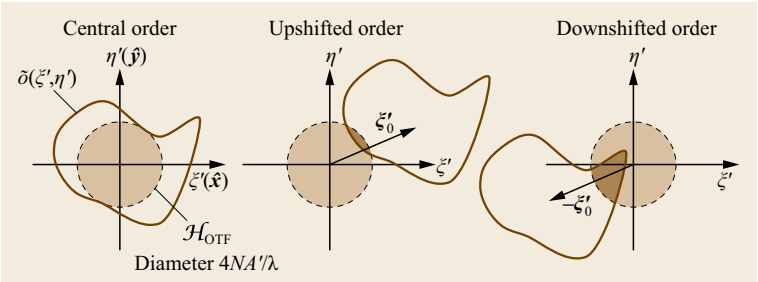

Fig. 26.16 Conceptual distribution of incoherent spatial frequency information with cosine structured illumination. The object's spatial frequency content $\tilde{o}(\xi',\eta')$ is distributed in three orders. The boundary of $\mathcal{H}_{\mathrm{OTF}}(\xi',\eta')$ is indicated by the *dashed circle* and *light shading*. Portions of upshifted and downshifted object spatial frequency distributions are transmitted through $\mathcal{H}_{\mathrm{OTF}}(\xi',\eta')$, as indicated by the *darker shading*

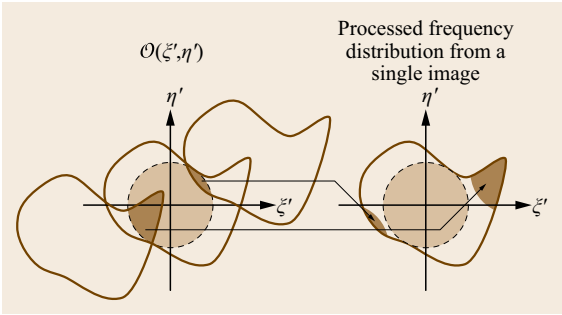

Fig. 26.17 Algorithm of structured illumination. The incoherent object frequency spectrum $\mathcal{O}(\xi', \eta')$ is the combination of the central and shifted orders. For each image, overlapped frequency components are moved to appropriate locations in the frequency plane. Multiple shifts of the illumination cosine provide the phase information for these components. Several orientations of the cosine fill in more space in the frequency plane, and the Fourier transform of the frequency plane is the enhanced-resolution reconstructed image

spatial frequency plane with standard incoherent illumination. Figure 26.18b shows the frequency plane using the illumination cosine at one orientation and shift. Note that the maximum spatial frequency transmitted by the optical system is the same in each case, but the illumination cosine distribution contains information that has been upshifted and downshifted, as indicated by the small arrows. This information is separated and moved in a computer, and it is used to form two of the additional shifted components in Fig. 26.18c, which are then combined to produce the enhanced frequency plane pattern shown in Fig. 26.18d. It is this final enhanced frequency plane pattern that is Fourier transformed to produce the enhanced-resolution image. Resolution enhancement is achieved because the frequency content of the image is effectively doubled. Conceptually, the width of the OTF is doubled and results in an improvement in resolution by a factor of two.

Images are shown in Fig. 26.19 for uniform incoherent illumination and for cosine structured illumination [26.33]. The object is a sample of a HeLa cell, and the image illustrates the actin cytoskeleton at the edge of the cell.

Cosine structured illumination resolution enhancement is limited to a factor of two. However, nonlinear illumination can produce an illumination function resembling

$$I_{\text{ill}}\left(y_{\text{obj}} - y_{\text{src}}\right) = 0.5 I_0 \left(1 + \cos^p \times \left[2\pi \frac{\left(y_{\text{obj}} - y_{\text{src}}\right)}{T}\right]\right), \quad (26.25)$$

where the factor p is the nonlinear enhancement factor. For example, $p = 2$ for a second-order response, like two-photon emission, and $p = 3$ for a third-order response, like three-photon emission. Equation 26.25 now contains harmonic components that expand shifts in the frequency plane, as shown in Fig. 26.20 [26.34]. If $p = 2$, the resolution improvement is a factor of three. If $p = 3$, the resolution improvement is a factor of four. Conceptually, large p could provide extremely high nonlinear enhancement factors. However, the diffraction efficiency from practical illumination patterns limits the number of harmonic components that can be used.

As shown in Fig. 26.20d, the overlapped orders of a nonlinear structured illumination image extend much further into the frequency plane than with cosine structured illumination [26.34]. The processing algorithm is much more complicated, but similar in concept, to the ideas shown in Fig. 26.17. Figure 26.20e shows the frequency space coverage for $p = 4$ with 12 grating

positions that would theoretically provide a resolution improvement factor of five. Figure 26.20f shows line-profile images from a nonlinear structured illumination experiment. The reconstruction from a 50 nm-diameter bead using the nonlinear technique is compared to the profile from a bead using standard incoherent illumination. The measured resolution improvement factor for this example is $265/59 = 4.5$.

26.7 Light-Sheet Microscopy

In several of the superresolution techniques described above, out-of-plane emitters are present that produce a background signal that limits the achievable signal-to-noise ratio [26.35]. Light sheet microscopy, also known as selective plane illumination microscopy (SPIM) [26.36], is a technique for increasing the contrast of points in a thin layer of a sample by illuminating it with a thin in z and wide in xy light beam that is projected through the sample at an angle, as shown in Fig. 26.21. Regardless of the imaging technique, light-sheet illumination effectively increases the contrast of fluorescent emitters within a given light sheet by eliminating out-of-plane emitters [26.37]. In biological applications, SPIM provides a way to optically section living tissue [26.36].

The use of SPIM does not give rise to superresolution by itself. However, when used with techniques like structured illumination [26.38] object features can be distinguished with superresolution deep within the object volume. SPIM is used with one or more fluorophores. The illumination typically uses wavelengths of 532 and 488 nm, which selectively excite fluorophores of interest [26.39]. The molecules to which the fluorophores are attached are distinguished by separation or color of the fluorescence, or both.

In addition to the higher signal-to-noise ratio achieved with light sheet microscopy and the inherent optical sectioning in biological applications, two additional compelling advantages of light-sheet microscopy in biological applications are (1) that broad-field imaging may be used to acquire large datasets simultaneously, thereby allowing high-speed data acquisition of live samples; and (2) avoiding illumination of sections of the sample that are not actively being imaged minimizes photobleaching and phototoxicity in live samples [26.40].

One common way to accomplish light-sheet illumination is to illuminate the sample with a Gaussian beam, as shown in Fig. 26.21a, whose z boundary $w\left(y_{\text{obj}}\right)$ is a function of distance from the focus at $y_{\text{obj}} = 0$ and is described by the hyperbolic function

$$w^2\left(y_{\text{obj}}\right) = \left(\frac{\lambda_{\text{exc}}}{NA_{\text{ill}}}\right)^2 + \left(\frac{NA_{\text{ill}}}{\pi}\right)^2 y_{\text{obj}}^2 , \qquad (26.26)$$

where λ_{exc} is the excitation wavelength and NA_{ill} is the numerical aperture of the illumination [26.38]. This illumination pattern substantially limits the effective z thickness of the sample over the width $w\left(y_{\text{obj}}\right)$ of the beam waist. The xy field is limited to the length of the waist in y_{obj} before it expands to the point where out-of-plane emitters reduce signal-to-noise ratio to an unacceptable level and by the width of the waist produced by the illumination system in the x_{obj} direction. In practice, the Gaussian beam light sheet may be produced by a laser source and a cylindrical lens, or it may be produced by laterally scanning a symmetric Gaussian laser beam.

Transverse spatial resolution of Gaussian SPIM is determined by the NA of the microscope objective lens,

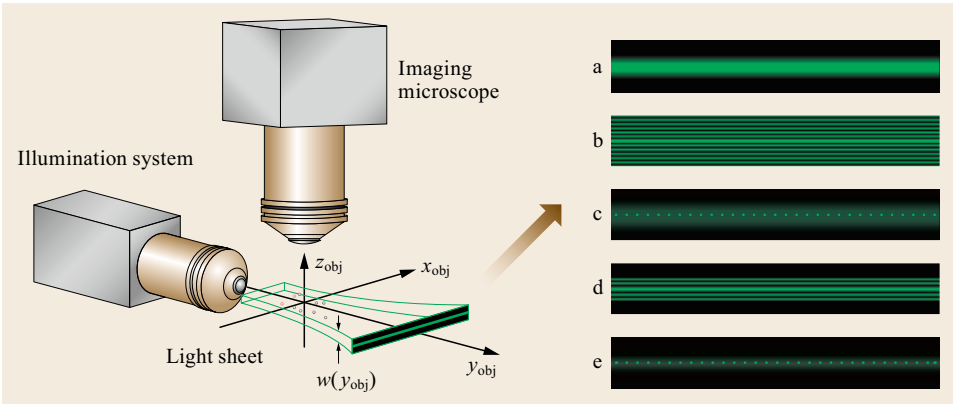

Fig. 26.21 Lattice light-sheet microscopy. A shaped laser beam illuminates a sample volume to excite fluorophores in a thin section that is then imaged by the microscope. Several types of light-sheet illumination patterns are used, which include combining the light sheet sectioning capability with techniques like SIM

Table 26.1 Attributes of advanced light-sheet microscopy techniques

Attribute	Bessel beam plane illumination	Bessel SIM	Two-photon Bessel beam plane illumination	Two-photon Bessel SIM
Typical spatial resolution	$x \approx 230$ nm $y \approx 230$ nm $z \approx 600$ nm	$x \approx 180$ nm $y \approx 230$ nm $z \approx 350$ nm	$x \approx 230$ nm $y \approx 230$ nm $z \approx 350$ nm	$x \approx 180$ nm $y \approx 230$ nm $z \approx 450$ nm
Optical sectioning capability	Fair	Good	Excellent	Excellent
Typical imaging speed	≈ 40 planes/sec	10–20 planes/sec	≈ 40 planes/sec	10–20 planes/sec
Multicolor imaging	Yes	Yes	No	No
Fluorophore brightness requirement	Low	Low	High	High
Photodamage	Low	Fair	Low	High

and is the same as the classical diffraction-limited resolution limit of a wide-field microscope described by (26.6). Axial resolution is related to both the thickness of the illumination light sheet $w\left(y_{\text{obj}}\right)$ and the axial resolution of the detection objective $\lambda_{\text{em}}/n\left(1-\cos\theta_{\text{marg}}\right)$, where n is refractive index of the sample, λ_{em} is the emission wavelength, and θ_{marg} is the marginal ray angle.

A way to accomplish light-sheet illumination over a longer y_{obj} distance is to generate a thin Bessel beam. An ideal Bessel beam propagates indefinitely with no change in its cross-sectional intensity profile $I(r) \propto |J_0(\alpha r)|^2$, where $J_0(\alpha r)$ is a zero-order Bessel function of the first kind. However, because an ideal Bessel beam is created by a spherical lens illuminated at its back focal plane with an infinitesimal annulus of light, an ideal Bessel beam cannot be realized, and a virtual Bessel light sheet must be created by scanning a symmetric Bessel beam. When the scan in the x_{obj} direction is synchronized with the recording camera, the result is an effective Bessel light sheet, as shown in Fig. 26.21b. The Bessel beam is typically produced by an axicon (conically shaped prism) located at the back focal plane of the objective lens. The axicon in combination with scanning produces a light sheet whose width remains constant as it propagates through a substantial distance in the y_{obj} direction, which increases the y_{obj} distance over which individual objects may be distinguished. In reality, an ideal symmetric Bessel beam cannot be achieved due to the limited overlap of the component waves from the axicon and scattering in the sample, so in practice the goal is to produce a beam that is only as long as is needed to cover the field of view. However, a Bessel beam includes concentric rings surrounding the central lobe that also excite molecules to fluoresce, which reduces signal-to noise ratio due to out-of-plane emitters.

Combination of a Bessel beam array, as shown in Fig. 26.21c, with structured illumination (SIM) provides superresolution in the transverse plane, high signal-to-noise ratio and optical sectioning. The array can be formed with a Dammann-type grating in combination with the axicon. In operation, the array is scanned in discrete steps in the x_{obj} direction between each image frame, and images are processed, as discussed in Sect. 26.6, to reconstruct a superresolved image.

Nonlinear, two-photon excitation is used to improve resolution and overcome effects produced by out-of-plane background light caused by rings of the Bessel beam. By using an intense infrared wavelength to supply sufficient energy in the central lobe of the Bessel beam to cause fluorescence through two-photon, nonlinear excitation of the fluorophores. Fluorescence is produced by the central lobe but not by the surrounding rings, as shown in Fig. 26.21d. When used with structured illumination in fluorescence microscopy, excellent optical sectioning and high transverse resolution is achieved. A two-photon Bessel beam array is shown in Fig. 26.21e.

A comparison of attributes for the various advanced light-sheet microscopy techniques is shown in Table 26.1 [26.38].

26.8 Comparison of Techniques for Live-Cell Imaging

A comparison of stimulated-emission depletion (STED/RESLOFT), localization microscopy and structured illumination microscopy (SIM) is shown in Table 26.2 [26.41, 42]. Although reported resolutions of STED and localization microscopy are smaller than for SIM, rapid acquisition time and lower irradiance required for imaging live cells with SIM is particularly advantageous. The required photon flux rate increase of each technique is also compared to conventional microscopy.

Table 26.2 Comparison of superresolution techniques for live-cell imaging

Technique	Reported resolution (nm)	Photon flux increase required	Irradiance (W/cm^2)	Acquisition time (s)
STED/RESLOFT	*xy*: 20 nm *xyz*: 30 nm	100 1070	10^4–10^9	> 60 ≈ 1000
Localization microscopy	*xy*: 20 nm *xy*: 10 nm, *z*: 20 nm	100 14 400	10^3–10^4	> 20 1500
SIM	*xy*: 100 nm *xy*: 100 nm, *z*: 370 nm	4 8	10–10^2	0.1–1 ≈ 10

26.9 Summary

Superresolution optical microscopy has been under modern development since the early 1990s. The six major categories outlined in this chapter provide an overview of field, although there are a large number of variations not discussed that are also interesting. Each of the listed categories has demonstrated resolution well beyond the classical Rayleigh limit, and often object features are resolved to better than 100 nm using visible-light photons. In each case, no new information is created by the microscope optical system compared to when standard uniform illumination is used. Instead, clever ways to increase the transfer of information from the object to the reconstruction algorithm are implemented. Therefore, the imaging process necessarily involves longer acquisition time to achieve adequate signal-to-noise ratio. Trade-offs between how the object or illumination is modified to produce this superresolution have important implications for what type of objects can be imaged. For example, concern about photobleaching or phototoxicity can limit the use of some techniques with live cells. Development in this field continues with the popular goal to see deep within living tissue with optical photons at the resolution of a scanning electron microscope. Although industrial applications are also important, they are overshadowed by the momentum of the biological community. The interested reader is referred to recent reviews and certain microscopy websites for more general information [26.43–46].

27. Nanotribology, Nanomechanics and Materials Characterization

Bharat Bhushan

Nanotribology and nanomechanics studies are needed to develop a fundamental understanding of interfacial phenomena on a small scale, and to study interfacial phenomena in micro/nanoelectromechanical systems (MEMS/NEMS), magnetic storage devices, and many other applications. Friction and wear of lightly loaded micro/nanocomponents are highly dependent on surface interactions (a few atomic layers). These structures are generally coated with molecularly thin films. Nanotribology and nanomechanics studies are also valuable in the fundamental understanding of interfacial phenomena in macrostructures, and provide a bridge between science and engineering. An atomic force microscope (AFM) tip is used to simulate a single-asperity contact with a solid or lubricated surface. AFMs are used to study the various tribological phenomena, which include surface roughness, adhesion, friction, scratching, wear, detection of material transfer, and boundary lubrication. In situ surface characterization of local deformation of materials and thin coatings can be carried out using a tensile stage inside an AFM. Mechanical properties such as hardness, Young's modulus of elasticity, and creep/relaxation behavior can be determined on micro- to picoscales using a depth-sensing indentation system in an AFM. Localized surface elasticity and viscoelastic mapping near surface regions can be obtained with nanoscale lateral resolution. Finally, an AFM can be used for nanofabrication/nanomachining.

The mechanisms and dynamics of the interactions of two contacting solids during relative motion, ranging from atomic scale to microscale, need to be understood in order to develop a fundamental understanding of adhesion, friction, wear, indentation, and lubrication processes. For most solid–solid interfaces of technological relevance, contact occurs at multiple asperities. Consequently, the importance of investigating single-asperity contacts in studies of the fundamental micro/nanomechanical and micro/nanotribological properties of surfaces and interfaces has long been recognized. The emergence and proliferation of proximal probes, in particular scanning probe microscopies (the scanning tunneling microscope and the atomic force microscope), the surface force apparatus, and computational techniques for simulating tip–surface interactions and interfacial properties, allowed systematic investigations of interfacial problems with high resolution as well as ways and means for modifying and manipulating nanoscale structures. These advances led to the appearance of the field of nanotribology. The word nanotribology was used for the first time in the title of a research paper by *Bhushan* et al. [27.1] and a first book on the field by Bhushan in 1995 (first edition of [27.2]). The first dedicated international meeting on the topic was organized in 1996 in Sesimbra, Portugal [27.3].

Nanotribology pertains to experimental and theoretical investigations of interfacial processes on scales ranging from the atomic- and molecular scale to the microscale, occurring during adhesion, friction, scratching, wear, indentation, and thin-film lubrication at sliding surfaces [27.1–14]. Proximal probes have also been used for mechanical and electrical characterization, in situ characterization of local deformation, and other nanomechanics studies [27.8, 11, 14, 15].

Nanotribological and nanomechanical studies are needed to develop a fundamental understanding of interfacial phenomena on a small scale, and to study interfacial phenomena in nanostructures used in magnetic storage devices, micro/nanoelectromechanical systems (MEMS/NEMS), and other applications [27.1–3, 7–20]. Friction and wear of lightly loaded micro/nanocomponents are highly dependent on surface interactions (a few atomic layers). These structures are generally coated with molecularly thin films. Nanotribological and nanomechanical studies also are valuable in the fundamental understanding of interfacial phenomena in macrostructures, and provide a bridge between science and engineering.

The surface force apparatus (SFA), the scanning tunneling microscopes (STMs), and atomic force and friction force microscopes (AFM and FFMs) are used widely in nanotribological and nanomechanical studies. Typical operating parameters are compared in Table 27.1. The SFA, developed in 1968, is commonly employed to study both static and dynamic properties of molecularly thin films sandwiched between two molecularly smooth surfaces. The STM, developed in 1981, allows the imaging of electrically conducting surfaces with atomic resolution, and has been used for the imaging of clean surfaces as well as of lubricant molecules. The introduction of the AFM in 1985 provided a method for measuring ultrasmall forces between a probe tip and an engineering (electrically conducting or insulating) surface. AFM has been used for morphological and surface roughness measurements of surfaces on the nanoscale, as well as for adhesion measurements. Subsequent modifications of the AFM led to the development of the FFM, designed for atomic- and microscale studies of friction. This instrument measures forces in the scanning direction. The AFM is being used

Table 27.1 Comparison of typical operating parameters in SFA, STM, and AFM/FFM used for micro/nanotribological studies

Operating parameter	SFA	STM[a]	AFM/FFM
Radius of mating surface/tip	≈ 10 mm[b]	5–100 nm	5–100 nm
Radius of contact area	10–40 μm	N/A	0.05–0.5 nm
Normal load	10–100 mN	N/A	< 0.1–500 nN
Sliding velocity	0.001–100 μm/s	0.02–200 μm/s (scan size ≈ 1 nm × 1 nm to 125 μm × 125 μm; scan rate < 1–122 Hz)	0.02–200 μm/s (scan size ≈ 1 nm × 1 nm to 125 μm × 125 μm; scan rate < 1–122 Hz)
Sample limitations	Typically atomically smooth, optically transparent mica; opaque ceramic, smooth surfaces can also be used	Electrically conducting samples	None of the above

[a] Can be used for atomic-scale imaging.
[b] Since stresses scale inverse of tip radius, SFA can provide very low stress measurement capabilities.

for various investigations including scratching, wear, indentation, detection of transfer of material, boundary lubrication, and fabrication and machining [27.1, 2, 14, 15]. Meanwhile, significant progress in understanding the fundamental nature of bonding and interactions in materials, combined with advances in computer-based modeling and simulation methods, has allowed theoretical studies of complex interfacial phenomena with high resolution in space and time. Such simulations provide insights into atomic-scale energetics, structure, dynamics, thermodynamics, transport, and rheological aspects of tribological processes.

The nature of interactions between two surfaces brought together closely, and those between two contacting surfaces as they are separated, have been studied experimentally with the SFA. This has led to a basic understanding of the normal forces between surfaces and the way in which these are modified by the presence of thin liquid or a polymer film. The frictional properties of such systems have been studied by moving the surfaces laterally. Such experiments have provided insights into the molecular-scale operation of lubricants such as thin liquid or polymer films. Complementary to these studies are those in which the AFM tip is used to simulate a single-asperity contact with a solid or lubricated surface (Fig. 27.1). These experiments have demonstrated that the relationship between friction and surface roughness is not always simple or obvious. AFM studies have also revealed much about the nanoscale nature of intimate contact during wear, indentation, and lubrication.

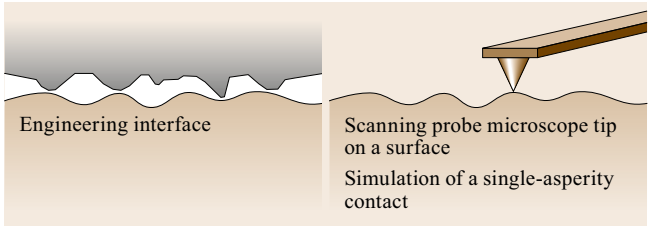

Fig. 27.1 Schematics of an engineering interface and scanning probe microscope tip in contact with an engineering interface

In this chapter, we present a review of significant aspects of nanotribological, nanomechanical, and materials characterization studies conducted using AFM/FFM.

27.1 Description of AFM/FFM and Various Measurement Techniques

The AFM was developed by Gerd Binnig et al. in 1985. It is capable of investigating surfaces of scientific and engineering interest on an atomic scale [27.21, 22]. The AFM relies on a scanning technique to produce very high-resolution, three-dimensional images of sample surfaces. It measures ultrasmall forces (less than 1 nN) present between the AFM tip surface mounted on a flexible cantilever beam and a sample surface. These small forces are obtained by measuring the motion of a very flexible cantilever beam having an ultrasmall mass, by a variety of measurement techniques including optical deflection, optical interference, capacitance, and tunneling current. The deflection can be measured to within 0.02 nm, so for a typical cantilever spring constant of 10 N/m, a force as low as 0.2 nN can be detected. To put these numbers in perspective, individual atoms and human hair are typically a fraction of a nanometer and about 75 μm in diameter, respectively, and a drop of water and an eyelash have a mass of about 10 μN and 100 nN, respectively. In the operation of high-resolution AFM, the sample is generally scanned rather than the tip because any cantilever movement would add vibrations. AFMs are available for the measurement of large samples, where the tip is scanned and the sample is stationary. To obtain an atomic resolution with the AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. A cantilever beam with a spring constant of about 1 N/m or lower is desirable. For high lateral resolution, tips should be as sharp as possible. Tips with a radius ranging from 5 to 50 nm are commonly available. Interfacial forces, adhesion, and surface roughness, including atomic-scale imaging, are routinely measured using the AFM.

A modification to the AFM providing a sensor to measure the lateral force led to the development of the friction force microscope (FFM) or the lateral force microscope (LFM), designed for atomic- and microscale studies of friction [27.1–3, 7, 9, 10, 14, 23–38] and lubrication [27.12, 20, 39, 39–54]. This instrument measures lateral or friction forces (in the plane of the sample surface and in the scanning direction). By using a standard or a sharp diamond tip mounted on a stiff cantilever beam, AFM is used in investigations of scratching and wear [27.1, 2, 7, 8, 11, 28, 55–58], nanoindentation [27.1, 11, 18, 28, 59–63], and nanofabrication/machining [27.2, 20, 28]. An oscillating cantilever is used for localized surface elasticity and viscoelastic mapping, referred to as dynamic AFM [27.36, 64–72]. In situ surface characterization of local deformation of materials and thin coatings has been carried out by imaging the sample surfaces using an AFM, during tensile deformation using a tensile stage [27.73–75].

27.1.1 Surface Roughness and Friction Force Measurements

Surface height imaging down to atomic resolution of electrically conducting surfaces is carried out using an STM. An AFM is also used for surface height imaging and roughness characterization down to nanoscale. Commercial AFM/FFM are routinely used for simultaneous measurements of surface roughness and friction force [27.2, 14]. These instruments are available for the measurement of small samples and large samples. In a small-sample AFM shown in Fig. 27.2a, the sample, generally no larger than 10 mm × 10 mm, is mounted on a piezoelectric crystal in the form of a cylindrical tube (referred to as a PZT tube scanner) which consists of separate electrodes to scan the sample precisely in the x–y plane in a raster pattern and to move the sample in the vertical (z) direction. A sharp tip at the free end of a flexible cantilever is brought into contact with the sample. The normal and frictional forces being applied at the tip–sample interface are measured using a laser beam deflection technique. A laser beam from a diode laser is directed by a prism onto the back of a cantilever near its free end, tilted downward at about 10° with respect to the horizontal plane. The reflected beam from the vertex of the cantilever is directed through a mirror onto a quad photodetector (a split photodetector with four quadrants). The differential signal from the top and bottom photodiodes provides the AFM signal which is a sensitive measure of the cantilever vertical deflection. Topographic features of the sample cause the tip to deflect in the vertical direction as the sample is scanned under the tip. This tip deflection will change the direction of the reflected laser beam, changing the intensity difference between the top and bottom sets of photodetectors (the AFM signal). In the AFM operating mode called the height mode, for topographic imaging or for any other operation in which the applied normal force is to be kept constant, a feedback circuit is used to modulate the voltage applied to the PZT scanner to adjust the height of the PZT, so that the cantilever vertical deflection (given by the intensity difference between the top and bottom detector) will remain constant during scanning. The PZT height variation is thus a direct measure of the surface roughness of the sample.

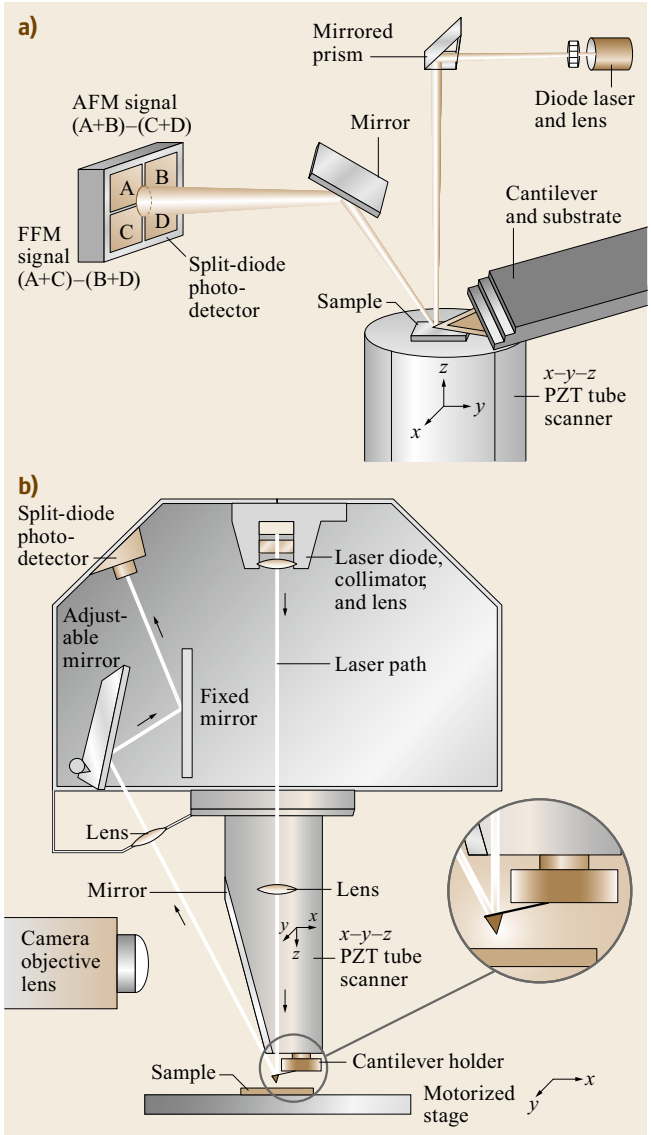

Fig. 27.2a,b Schematics **(a)** of a commercial small-sample atomic force microscope/friction force microscope (AFM/FFM), and **(b)** of a large-sample AFM/FFM

In a large-sample AFM, both force sensors using the optical deflection method and a scanning unit are mounted on the microscope head (Fig. 27.2b). Because of vibrations caused by the cantilever movement, lateral resolution of this design can be somewhat poorer than the design in Fig. 27.2a in which the sample is scanned instead of the cantilever beam. The advantage of the large-sample AFM is that large samples can be measured readily.

Most AFMs can be used for surface roughness measurements in the so-called tapping mode (TM) (intermittent contact mode), also referred to as dynamic (atomic) force microscopy. In the tapping mode, during scanning over the surface, the cantilever/tip assembly with a normal stiffness of 20–100 N/m (Bruker tapping mode etched Si probe or TESP) is sinusoidally vibrated at its resonance frequency (350–400 kHz) by a piezo mounted above it, and the oscillating tip slightly taps the surface. The piezo is adjusted using the feedback control in the z-direction to maintain a constant

(20–100 nm) oscillating amplitude (setpoint) and constant average normal force (Fig. 27.3) [27.2, 14]. The feedback signal to the z-direction sample piezo (to keep the setpoint constant) is a measure of surface roughness. The cantilever/tip assembly is vibrated at some amplitude, here referred to as the free amplitude, before the tip engages the sample. The tip engages the sample at some setpoint, which may be thought of as the amplitude of the cantilever as influenced by contact with the sample. The setpoint is defined as a ratio of the vibration amplitude after engagement to the vibration amplitude in free air before engagement. A lower setpoint gives a reduced amplitude and closer mean tip-to-sample distance. The amplitude should be kept large enough so that the tip does not get stuck to the sample because of adhesive attractions. Also the oscillating amplitude applies less average (normal) load as compared to the contact mode and reduces sample damage. The tapping mode is used in topography measurements to minimize the effects of friction and other lateral forces and to measure topography of soft surfaces.

To measure the friction force at the tip surface during sliding, the left hand and right hand sets of quadrants of the photodetector are used. In the so-called friction mode, the sample is scanned back and forth in a direction orthogonal to the long axis of the cantilever beam. A friction force between the sample and the tip will produce a twisting of the cantilever. As a result, the laser beam will be reflected out of the plane defined by the incident beam and the beam reflected vertically from an untwisted cantilever. This produces an intensity difference of the laser beam received in the left hand and right hand sets of quadrants of the photodetector. The intensity difference between the two sets of detectors (FFM signal) is directly related to the degree of twisting and hence to the magnitude of the friction force. One problem associated with this method is that any misalignment between the laser beam and the photodetector axis would introduce error in the measurement. However, by following the procedures developed by *Ruan* and *Bhushan* [27.25], in which the average FFM signal for the sample scanned in two opposite directions is subtracted from the friction profiles of each of the two scans, the misalignment effect is eliminated. This method provides three-dimensional maps of friction force. By following the friction force calibration procedures developed by *Ruan* and *Bhushan* [27.25], voltages corresponding to friction forces can be converted to force units [27.76, 77]. The coefficient of friction is obtained from the slope of friction force data measured as a function of normal loads typically ranging from 10 to 150 nN. This approach eliminates any contributions due to the adhesive forces [27.28]. To calculate the coefficient of friction based on a single point measurement, friction force should be divided by the sum of the applied normal load and intrinsic adhesive

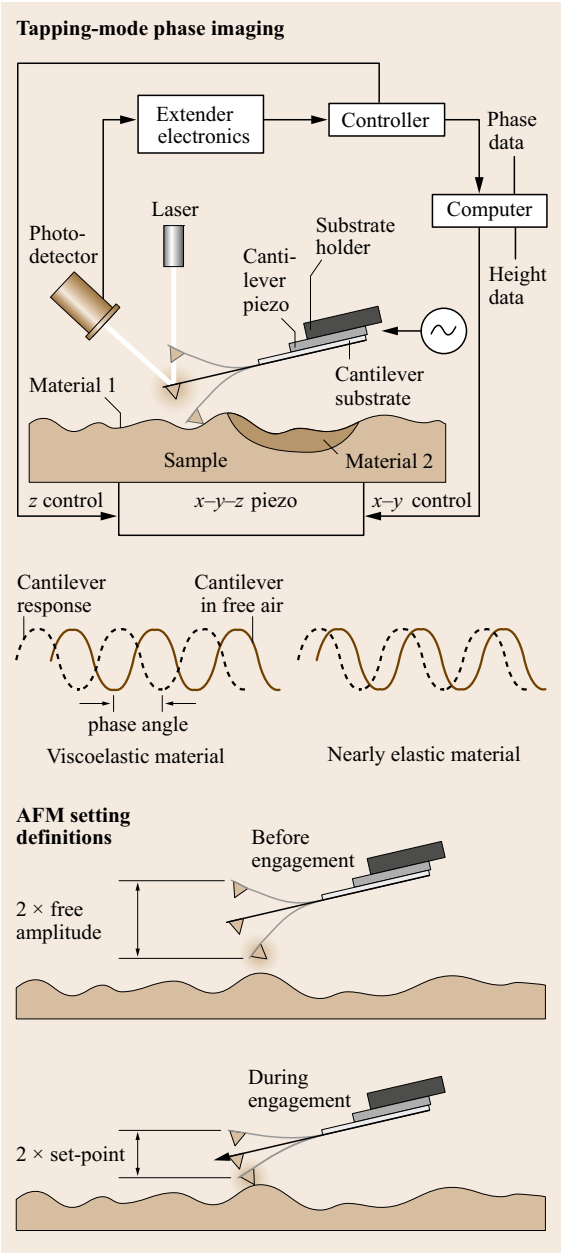

Fig. 27.3 Schematic of tapping mode used to obtain height and phase data and definitions of free amplitude and setpoint. During scanning, the cantilever is vibrated at its resonance frequency and the sample x–y–z piezo is adjusted by feedback control in the z-direction to maintain a constant setpoint. The computer records height (which is a measure of surface roughness) and phase angle (which is a function of the viscoelastic properties of the sample) data

force. Furthermore, it should be pointed out that for a single-asperity contact, the coefficient of friction is not independent of load (see discussion later).

Surface roughness measurements in the contact mode are typically made using a sharp, microfabricated square-pyramidal Si_3N_4 tip with a radius of 30–50 nm on a triangular cantilever beam (Fig. 27.4a) with normal stiffness on the order of 0.06–0.58 N/m with a normal natural frequency of 13–40 kHz (Bruker silicon nitride probe or NP) at a normal load of about 10 nN, and friction measurements are carried out in the load range of 1–100 nN. Surface roughness measurements in the tapping mode utilize a stiff cantilever with high resonance frequency; typically a square-pyramidal etched single-crystal silicon tip, with a tip radius of 5–10 nm, integrated with a stiff rectangular silicon cantilever beam (Fig. 27.4a) with a normal stiffness on the order of 17–60 N/m and a normal resonance frequency of 250–400 kHz (DI TESP), is used. Multiwalled carbon nanotube (MWNT) tips having a small diameter (few nm) and a length of about 1 μm (high aspect ratio) attached on the single-crystal silicon, square-pyramidal tips are used for the high-resolution imaging of surfaces and of deep trenches in the tapping mode (noncontact mode) (Fig. 27.4b) [27.78]. The MWNT tips are hydrophobic. To study the effect of radius of a single asperity (tip) on adhesion and friction, microspheres of silica with radii ranging from about 4 to 15 μm are attached at the end of cantilever beams. Optical micrographs of two of the microspheres at the ends of triangular cantilever beams are shown in Fig. 27.4c.

The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern (Fig. 27.5). Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. Scan sizes ranging from less than 1×1 nm to 125×125 μm and scan rates from less than 0.5 to 122 Hz typically can be used. Higher scan rates are used for smaller scan lengths. For

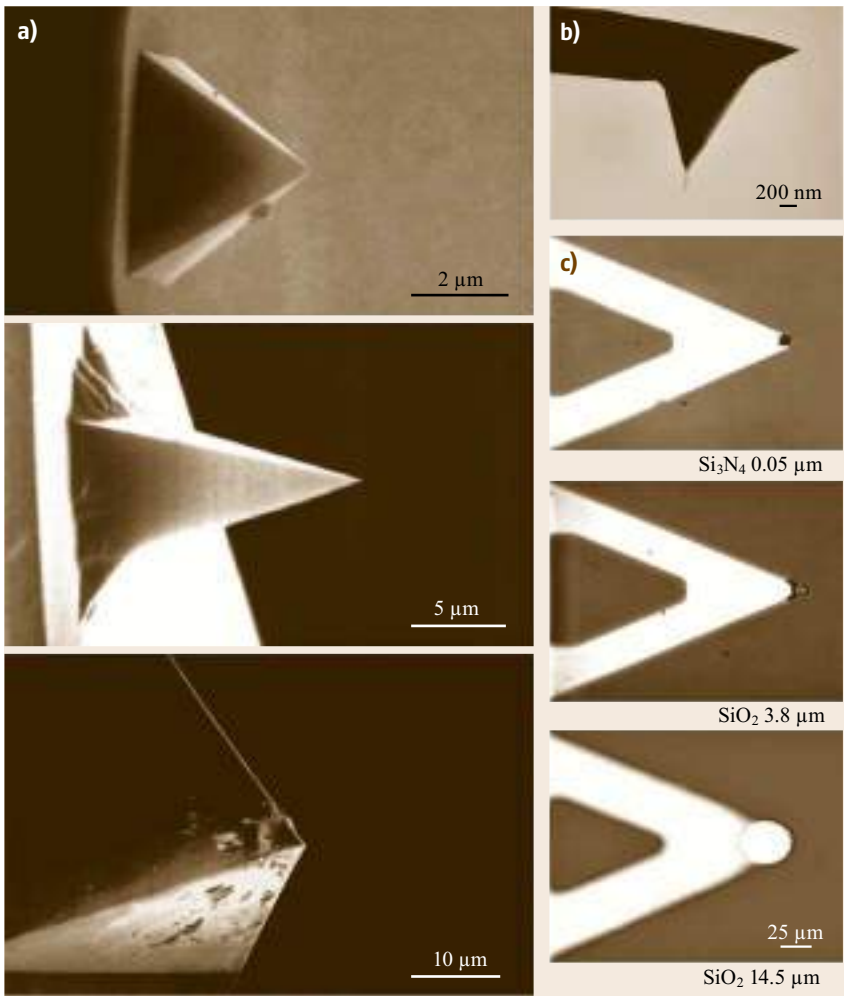

Fig. 27.4 **(a)** SEM micrographs of a square-pyramidal plasma-enhanced chemical vapor deposition (PECVD) Si_3N_4 tip with a triangular cantilever beam, a square-pyramidal etched single-crystal silicon tip with a rectangular silicon cantilever beam, and a three-sided pyramidal natural diamond tip with a square stainless steel cantilever beam. **(b)** SEM micrograph of a MWNT physically attached on the single-crystal silicon, square-pyramidal tip, and **(c)** optical micrographs of a commercial Si_3N_4 tip and two modified tips showing SiO_2 spheres mounted over the sharp tip, at the end of the triangular Si_3N_4 cantilever beams (radii of the tips are given in the figure)

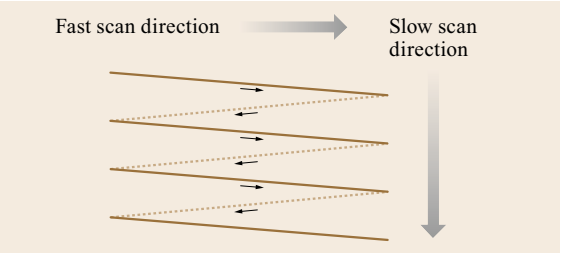

Fig. 27.5 Schematic of triangular pattern trajectory of the tip as the sample (or the tip) is scanned in two dimensions. During scanning, data are recorded only during scans along the *solid scan lines*

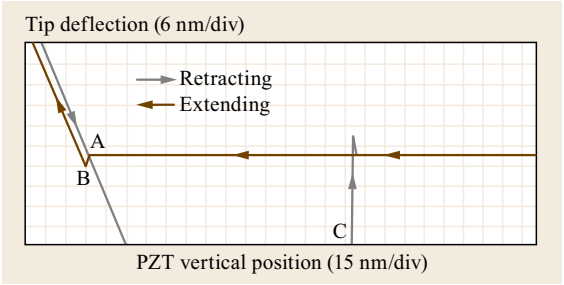

Fig. 27.6 Typical force–distance curve for contact between an Si_3N_4 tip and single-crystal silicon surface in measurements made in the ambient environment. Snap-in occurs at point A; contact between the tip and silicon occurs at point B; tip breaks free of adhesive forces at point C as the sample moves away from the tip

example, scan rates in the fast and slow scan directions for an area of $10\,\mu m \times 10\,\mu m$ scanned at 0.5 Hz are $10\,\mu m/s$ and 20 nm/s, respectively.

27.1.2 Adhesion Measurements

Adhesive force measurements are performed in the so-called force calibration mode. In this mode, force-distance curves are obtained, for an example see Fig. 27.6. The horizontal axis gives the distance that the piezo (and hence the sample) travels, and the vertical axis gives the tip deflection. As the piezo extends, it approaches the tip, which is at this point in free air and hence shows no deflection. This is indicated by the flat portion of the curve. As the tip approaches the sample within a few nanometers (point A), an attractive force exists between the atoms of the tip surface and the atoms of the sample surface. The tip is pulled towards the sample and contact occurs at point B on the graph. From this point on, the tip is in contact with the surface and as the piezo further extends, the tip gets further deflected. This is represented by the sloped portion of the curve. As the piezo retracts, the tip goes beyond the zero deflection (flat) line because of attractive forces (van der Waals forces and long-range meniscus forces), into the adhesive regime. At point C in the graph, the tip snaps free of the adhesive forces and is again in free air. The horizontal distance between points B and C along the retrace line gives the distance moved by the tip in the adhesive regime. This distance multiplied by the stiffness of the cantilever gives the adhesive force. Incidentally, the horizontal shift between the loading and unloading curves results from the hysteresis in the PZT tube [27.2, 14].

27.1.3 Scratching, Wear, and Fabrication/Machining

For microscale scratching, microscale wear, nanofabrication/nanomachining, and nanoindentation hardness measurements, an extremely hard tip is required. A three-sided pyramidal single-crystal natural diamond tip with an apex angle of 80° and a radius of about 100 nm mounted on a stainless steel cantilever beam with normal stiffness of about 25 N/m is used at relatively higher loads (1–150 μN; Fig. 27.4a). For scratching and wear studies, the sample is generally scanned in a direction orthogonal to the long axis of the cantilever beam (typically at a rate of 0.5 Hz) so that friction can be measured during scratching and wear. The tip is mounted on the cantilever such that one of its edges is orthogonal to the long axis of the beam. Therefore, wear during scanning along the beam axis is higher (about 2–3×) than that during scanning orthogonal to the beam axis. For wear studies, an area on the order of $2\,\mu m \times 2\,\mu m$ is scanned at various normal loads (ranging from 1 to 100 μN) for a selected number of cycles [27.2, 14, 28].

Scratching can also be performed at ramped loads and the coefficient of friction can be measured during scratching [27.58]. A linear increase in the normal load approximated by a large number of normal load increments of small magnitude is applied using a software interface (lithography module in Nanoscope III) that allows the user to generate controlled movement of the tip with respect to the sample. The friction signal is tapped out of the AFM and is recorded on a computer. A scratch length on the order of 25 μm and a velocity on the order of $0.5\,\mu m/s$ are used and the number of loading steps is usually taken to be 50.

Nanofabrication/nanomachining is conducted by scratching the sample surface with a diamond tip at specified locations and scratching angles. The normal load used for scratching (writing) is on the order of 1–100 μN with a writing speed on the order of $0.1–200\,\mu m/s$ [27.2, 8, 14, 20, 28, 79].

27.1.4 Surface Potential Measurements

Various electrical measurements on the nanoscale can be made using a conducting tip. The conducting tip acts as a voltage electrode to provide stimuli and monitor surface electrical properties [27.80]. Various electrical techniques are used and include scanning Kelvin probe microscopy (SKPM), scanning capacitance microscopy (SCM), and scanning spreading resistance microscopy (SSRM) [27.53, 81, 82].

Kelvin probe microscopy can be used to detect wear precursors and to study the early stages of localized wear [27.81, 83, 84]. In this technique (also called *nano-Kelvin probe* technique), the potential difference is measured between the tip and the sample by applying a DC bias potential and an oscillating (AC (alternating current)) potential to a conducting tip over a grounded substrate. Mapping of the surface potential is carried out in the so-called *lift mode* (Fig. 27.7). These measurements are made simultaneously with the topography scan in the tapping mode, using an electrically conducting (nickel-coated single-crystal silicon) tip. After each line of the topography scan is completed, the feedback loop controlling the vertical piezo is turned off, and the tip is lifted from the surface and traced over the same topography at a constant distance of 100 nm. During the lift mode, a DC bias potential and an oscillating potential (3–7 V) is applied to the tip. The frequency of oscillation is chosen to be equal to the resonance frequency of the cantilever (≈ 80 kHz). When a DC bias potential equal to the negative value of surface potential of the sample (on the order of +2 V) is applied to the tip, it does not vibrate. During scanning, a difference between the DC bias potential applied to the tip and the potential of the surface will create DC electric fields that interact with the oscillating charges (as a result of the AC potential), causing the cantilever to oscillate at its resonance frequency, as in tapping mode. However, a feedback loop is used to adjust the DC bias on the tip to exactly nullify the electric field, and thus the vibrations of the cantilever. The required bias voltage follows the localized potential of the surface. The surface potential was obtained by reversing the sign of the bias potential provided by the electronics [27.81, 84].

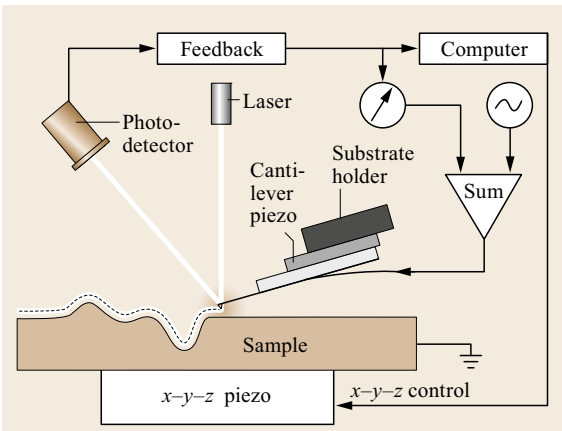

Fig. 27.7 Schematic of lift mode used to make surface potential measurement. The topography is collected in tapping mode in the primary scan. The cantilever piezo is de-activated. Using topography information of the primary scan, the cantilever is scanned across the surface at a constant height above the sample. An oscillating voltage at the resonant frequency is applied to the tip and a feedback loop adjusts the DC (direct current) bias of the tip to maintain the cantilever amplitude at zero. The output of the feedback loop is recorded by the computer and becomes the surface potential map

Surface and subsurface changes of structure and/or chemistry can cause changes in the measured potential of a surface. Thus, mapping of the surface potential after sliding can be used for detecting wear precursors and studying the early stages of localized wear [27.81, 83, 84].

27.1.5 In situ Characterization of Local Deformation Studies

In situ characterization of local deformation of materials can be carried out by performing tensile, bending, or compression experiments inside an AFM and by observing nanoscale changes during the deformation experiment [27.18]. In these experiments, small deformation stages are used to deform the samples inside an AFM. For tensile testing of the polymeric films carried out by *Bobji* and *Bhushan* [27.73, 74] and *Tambe* and *Bhushan* [27.75] and of the hair by *Seshadri* and *Bhushan* [27.85, 86], a tensile stage was used (Fig. 27.8). The stage with a left-right combination lead screw (which helps to move the slider in the opposite direction) was used to stretch the sample to minimize the movement of the scanning area, which was kept close to the center of the tensile specimen. One end of the sample was mounted on the slider via a force sensor to monitor the tensile load. The samples were stretched for various strains using a stepper motor and the same control area at different strains was imaged. In order to better locate the control area for imaging, a set of four markers was created at the corners of a 30 μm × 30 μm square at the center of the sample by scratching the sample with a sharp silicon tip. The scratching depth was controlled such that it did not affect the cracking behavior of the coating. A minimum displacement of 1.6 μm could be obtained. This corresponded to a strain

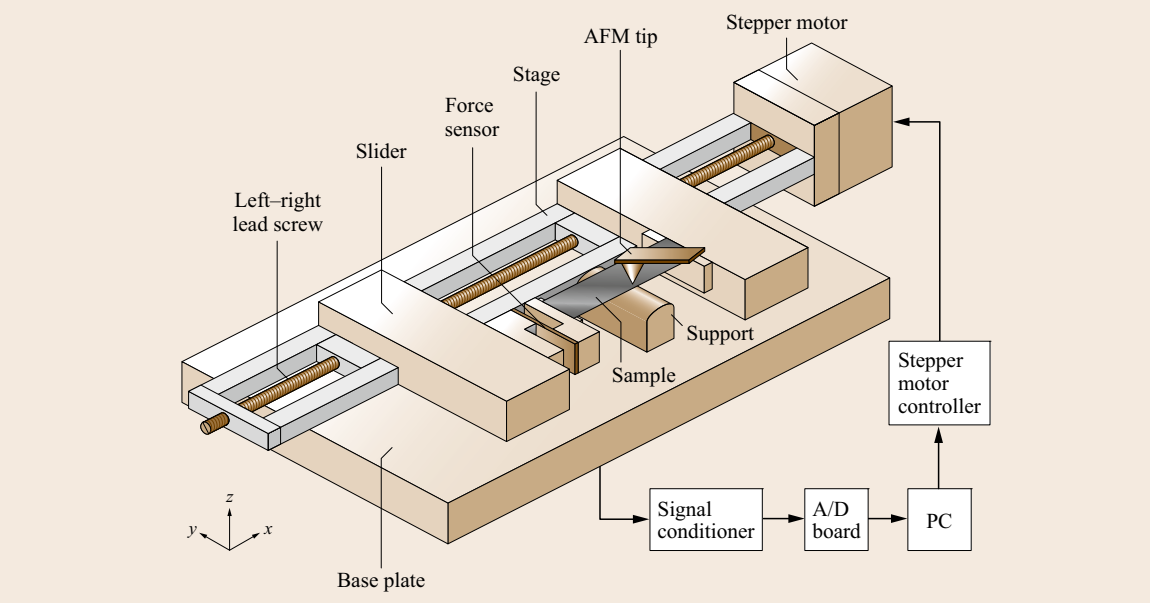

Fig. 27.8 Schematic of the tensile stage to conduct in situ tensile testing of the polymeric films in AFM

increment of 8×10^{-3}% for a sample length of 38 mm. The maximum travel distance was about 100 mm. The resolution of the force sensor was 10 mN with a capacity of 45 N. While stretching, a stress–strain curve was obtained during the experiment to study any correlation between the degree of plastic strain and the propensity of cracks.

27.1.6 Nanoindentation Measurements

For nanoindentation hardness measurements the scan size is set to zero, and then a normal load is applied to make the indents using the diamond tip. During this procedure, the tip is continuously pressed against the sample surface for about two seconds at various indentation loads. The sample surface is scanned before and after the scratching, wear, or indentation to obtain the initial and the final surface topography, at a low normal load of about 0.3 μN using the same diamond tip. An area larger than the indentation region is scanned to observe the indentation marks. Nanohardness is calculated by dividing the indentation load by the projected residual area of the indents [27.61].

Direct imaging of the indent allows one to quantify piling up of ductile material around the indenter. However, it becomes difficult to identify the boundary of the indentation mark with great accuracy. This makes the direct measurement of contact area somewhat inaccurate. A technique with the dual capability of depth-sensing as well as in situ imaging, which is most appropriate in nanomechanical property studies, is used for accurate measurement of hardness with shallow depths [27.2, 14, 60]. This nano/picoindentation system is used for the load–displacement measurement process and for subsequent in situ imaging of the indent, if required. The indentation system, shown in Fig. 27.9, consists of a three-plate transducer with electrostatic actuation hardware used for the direct application of a normal load and a capacitive sensor used for the measurement of vertical displacement. The AFM head is replaced with this transducer assembly while the specimen is mounted on the PZT scanner, which remains stationary during indentation experiments. The transducer consists of a three (Be-Cu)-plate capacitive structure, and the tip is mounted on the center plate. The upper and lower plates serve as drive electrodes, and the load is applied by applying appropriate voltage to the drive

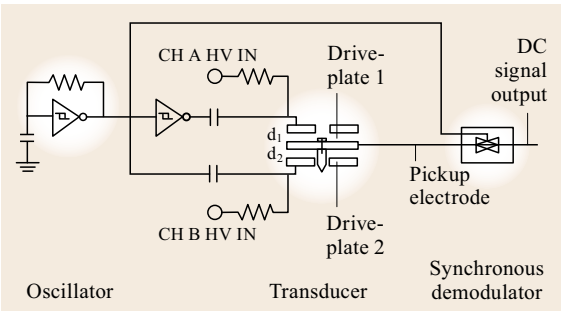

Fig. 27.9 Schematic of a nano/picoindentation system with three-plate transducer with electrostatic actuation hardware and capacitance sensor (after [27.60])

electrodes. Vertical displacement of the tip (indentation depth) is measured by measuring the displacement of the center plate relative to the two outer electrodes using the capacitance technique. Indent area and consequently hardness value can be obtained from the load–displacement data. The Young's modulus of elasticity is obtained from the slope of the unloading curve.

27.1.7 Localized Surface Elasticity and Viscoelasticity Mapping

Localized Surface Elasticity

Indentation experiments provide a single-point measurement of the Young's modulus of elasticity calculated from the slope of the indentation curve during unloading. Localized surface elasticity maps can be obtained using dynamic force microscopy, in which an oscillating tip is scanned over the sample surface in contact under steady and oscillating load. Lower frequency operation modes in the kHz range, such as force modulation mode [27.64, 66] or pulsed force mode [27.87], are well suited for soft samples such as polymers. However, if the tip-sample contact stiffness becomes significantly higher than the cantilever stiffness, the sensitivity of these techniques strongly decreases. In this case, sensitivity of the measurement of stiff materials can be improved by using high-frequency operation modes in the MHz range with a lateral motion, such as acoustic (ultrasonic) force microscopy, referred to as atomic force acoustic microscopy (AFAM), or contact resonance spectroscopy [27.68, 88, 89]. Inclusion of vibration frequencies other than only the first cantilever flexural or torsional resonance frequency also allows additional information to be obtained.

In the negative lift mode force modulation technique, during primary scanning height data is recorded in tapping mode as described earlier. During interleave scanning, the entire cantilever/tip assembly is moved up and down at the force modulation holder's bimorph resonance frequency (about 24 kHz) at some amplitude, here referred to as the force modulation amplitude, and the z-direction feedback control for the sample x–y–z piezo is deactivated (Fig. 27.10a) [27.64, 66, 69]. During this scanning process, height information from the primary scan is used to maintain a constant lift scan height. This eliminates the influence of height on the measured signals during the interleave scan. Lift scan height is the mean tip-to-sample distance between the tip and sample during the interleave scan. The lift scan height is set such that the tip is in constant contact with the sample, i. e., a constant static load is applied. (A higher lift scan height gives a closer mean tip-to-sample distance.) In addition, the tip motion caused by the bimorph vibration results in a modulating periodic force. The sample surface resists the oscillations of the tip to a greater or lesser extent depending upon the sample's stiffness. The computer records amplitude (which is a function of elastic stiffness of the material). Contact analyses can be used to obtain a quantitative measure of localized elasticity of soft surfaces [27.66]. Etched single-crystal silicon cantilevers with integrated tips (Bruker force modulation etched Si probe or FESP) with a radius of 25−50 nm, a stiffness of 1−5 N/m, and a natural frequency of 60−100 kHz, are commonly used for the measurements. Scanning is normally set to a rate of 0.5 Hz along the fast axis.

In the AFAM technique [27.68, 88, 89], the cantilever/tip assembly is moved either in the normal or lateral mode, and the contact stiffness is evaluated by comparing the resonance frequency of the cantilever in contact with the sample surface to those of the free vibrations of the cantilever. Several free resonance frequencies are measured. On the basis of the shift of the measured frequencies, the contact stiffness is determined by solving the characteristic equation for the tip vibrating in contact with the sample surface. The elastic modulus is calculated from contact stiffness using Hertz analysis for a spherical tip indenting a plane. Contact stiffness is equal to 8 × contact radius × reduced shear modulus in shear mode.

In the lateral mode using the AFAM technique, the sample is glued on cylindrical pieces of aluminum which serves as ultrasonic delay lines coupled to an ultrasonic shear wave transducer (Fig. 27.10b) [27.34, 68, 89]. The transducer is driven with frequency sweeps to generate in-plane lateral sample surface vibrations. These couple to the cantilever via the tip–sample contact. To measure torsional vibrations of the cantilever at frequencies up to 3 MHz, the original electronic circuit of the lateral channel of the AFM (using a lowpass filter with limited bandwidth to a few hundred kHz) was replaced by a high-speed scheme which bypasses the lowpass filter. The high-frequency signal was fed to a lock-in amplifier, digitized using a fast analog/digital (A/D) card, and fed into a broadband amplifier, followed by an root mean square (RMS)-to-DC converter and read by a computer. Etched single-crystal silicon cantilevers (normal stiffness of 3.8−40 N/m) with integrated tips are used.

Viscoelastic Mapping

Another form of dynamic force microscopy, phase contrast microscopy, is used to detect the contrast in viscoelastic (viscous energy dissipation) properties of different materials across the surface [27.48, 65, 69, 70, 72, 90, 91]. In these techniques, both deflection amplitude and phase angle contrasts are measured, which are measures of the relative stiffness and viscoelastic

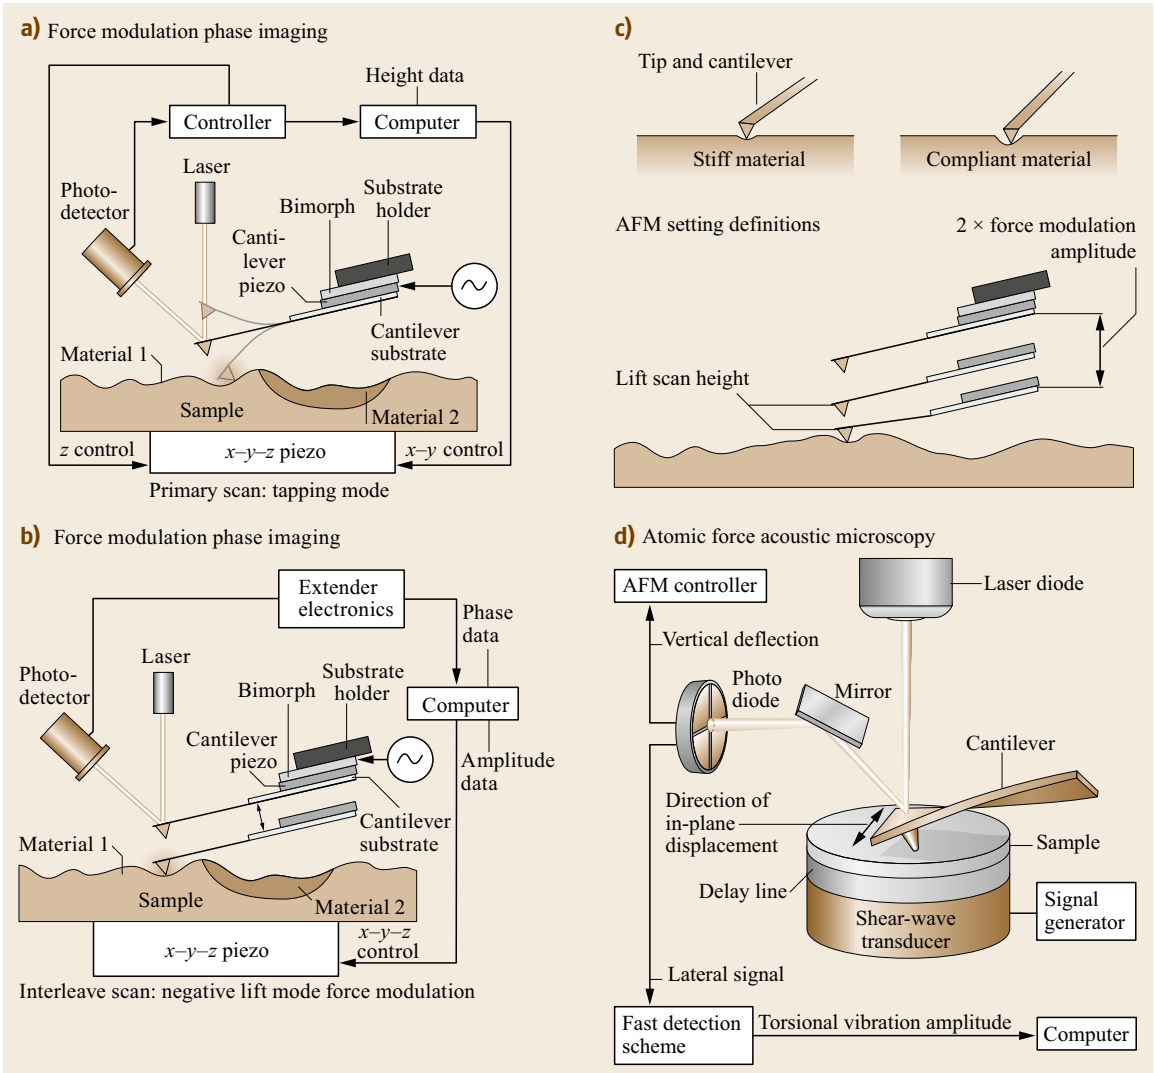

Fig. 27.10 **(a–c)** Schematic of force modulation mode used to obtain amplitude (stiffness) and definitions of force modulation amplitude and lift scan height. During primary scanning, height data is recorded in tapping mode. During interleave scanning, the entire cantilever/tip assembly is vibrated at the bimorph's resonance frequency and the z-direction feedback control for the sample x–y–z piezo is deactivated. During this scanning, height information from the primary scan is used to maintain a constant lift scan height. The computer records amplitude (which is a function of material stiffness) during the interleave scan. **(d)** Schematic of an AFM incorporating shear wave transducer which generates in-plane lateral sample surface vibrations. Because of the forces between the tip and the surface, torsional vibrations of the cantilever are excited (after [27.34]). The shift in contact resonance frequency is a measure of contact stiffness

properties, respectively. Two phase measurement techniques – tapping mode and torsional resonance (TR) mode – have been developed. We describe them next.

In the tapping mode (TM) technique, as described earlier, the cantilever/tip assembly is sinusoidally vibrated at its resonant frequency, and the sample x–y–z piezo is adjusted using feedback control in the z-direction to maintain a constant setpoint (Fig. 27.3) [27.69, 70]. The feedback signal to the z-direction sample piezo (to keep the setpoint constant) is a measure of surface roughness. The extender electronics is used to measure the phase angle lag between the cantilever piezo drive signal and the cantilever response during sample engagement. As illustrated in Fig. 27.3, the phase angle lag (at least partially) is a function of the viscoelastic properties of the sample material.

A range of tapping amplitudes and setpoints can be used for measurements. A commercially etched single-crystal silicon tip (DI TESP), with a radius of 5–10 nm, a stiffness of 20–100 N/m, and a natural frequency of 350–400 kHz, is normally used for tapping mode. Scanning is normally set to a rate of 1 Hz along the fast axis.

In the torsional mode (TR mode), a tip is vibrated at high frequency at the resonance frequency of the cantilever beam. An etched single-crystal silicon cantilever with integrated tip (DI FESP) with a radius of about 5–10 nm, normal stiffness of 1–5 N/m, torsional stiffness of about 30 times normal stiffness, and torsional natural frequency of 800 kHz is normally used. A major difference between the TM and TR modes is the directionality of the applied oscillation – a normal (compressive) amplitude exerted for the TM and a torsional amplitude for the TR mode. The TR mode is expected to provide good contrast in the tribological and mechanical properties of the near-surface region as compared to the TM. Two of the reasons are as follows. (1) In the TM, the interaction is dominated by the vertical properties of the sample, so the tip spends a small fraction of its time in near-field interaction with the sample. Furthermore, the distance between the tip and the sample changes during the measurements, which changes interaction time and forces, and affects measured data. In the TR mode, the distance remains nearly constant. (2) The lateral stiffness of a cantilever is typically about two orders of magnitude larger than the normal (flexural) stiffness. Therefore, in the TM, if the sample is relatively rigid, much of the deformation occurs in the cantilever beam, whereas in the TR mode, much of the deformation occurs in the sample. A few comments on the special applications of the TR mode are made next. Since most of the deformation occurs in the sample, the TR mode can be used to measure stiff and hard samples. Furthermore, properties of thin films can be measured more readily with the TR mode. For both the TM and TR modes, if the cantilever is driven to vibrate at frequencies above resonance, it would have less motion (high apparent stiffness), leading to higher sample deformation and better contrast. It should be further noted that the TM exerts a compressive force, whereas the TR mode exerts torsional force, therefore normal and shear properties are measured in the TM and TR modes, respectively.

In the TR mode, the torsional vibration of the cantilever beam is achieved using a specially designed cantilever holder. It is equipped with a piezo system mounted in a cantilever holder, in which two piezos vibrate out-of-phase with respect to each other. A tuning process prior to scanning is used to select the torsional vibration frequency. The piezo system excites torsional vibration at the cantilever's resonance frequency. The torsional vibration amplitude of the tip (TR amplitude) is detected by the lateral segments of the split-diode photodetector (Fig. 27.11) [27.71]. The TR mode measures surface roughness and phase angle as follows. During the measurement, the cantilever/tip assembly is

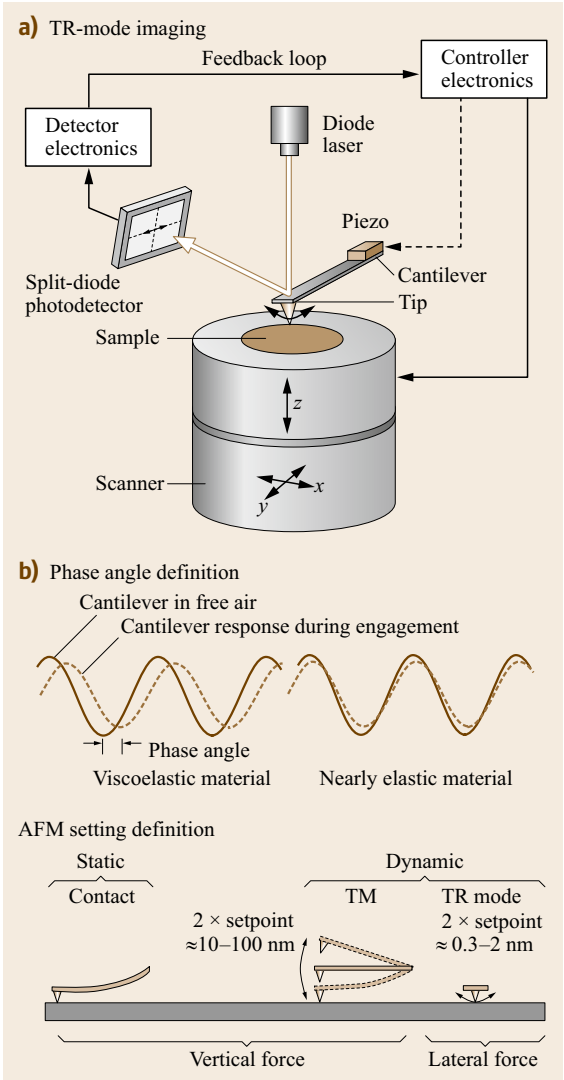

Fig. 27.11a,b Schematic of torsional resonance mode shown *at the top* (**a**). Two examples of the phase angle response are shown *in the middle* (**b**). One is for materials exhibiting viscoelastic and the other nearly elastic properties. Three AFM settings are compared *at the bottom*: contact, tapping mode (TM), and TR modes. The TR mode is a dynamic approach with a laterally vibrating cantilever tip that can interact with the surface more intensively than other modes. Therefore, more detailed near-surface information is available

first vibrated at its resonance at some amplitude dependent upon the excitation voltage, before the tip engages the sample. Next, the tip engages the sample at some setpoint. A feedback system coupled to a piezo stage is used to keep a constant TR amplitude during scanning. This is done by controlling the vertical position of the sample using a piezo moving in the z-direction, which changes the degree of tip interaction. The displacement of the sample z piezo gives a roughness image of the sample. A phase angle image can be obtained by measuring the phase lag of the cantilever vibration response in the torsional mode during engagement with respect to the cantilever vibration response in free air before engagement. The control feedback of the TR mode is similar to that of tapping, except that the torsional resonance amplitude replaces flexural resonance amplitude [27.71].

Chen and *Bhushan* [27.72] used a variation to the approach just described (referred to as mode I here). They performed measurements at constant normal cantilever deflection (constant load; mode II) instead of using the constant setpoint in the *Kasai* et al. [27.71] approach. Their approach overcomes the meniscus adhesion problem present in mode I and reveals true surface properties.

Song and *Bhushan* [27.92] presented a forced torsional vibration model for a tip-cantilever assembly under viscoelastic tip–sample interaction. This model provides a relationship of torsional amplitude and phase shift with lateral contact stiffness and viscosity which can be used to extract in-plane interfacial mechanical properties.

Various operating modes of AFM used for surface roughness, localized surface elasticity, and viscoelastic mapping and friction force measurements (to be discussed later) are summarized in Table 27.2.

27.1.8 Boundary Lubrication Measurements

To study nanoscale boundary lubrication properties, adhesive forces are measured in the force calibration mode, as previously described. The adhesive forces are also calculated from the horizontal intercept of friction versus normal load curves at a zero value of friction force. For friction measurements, the samples are typically scanned using an Si tip over an area of $2 \times 2\,\mu m^2$ at the normal load ranging from 5 to 130 nN. The samples are generally scanned with a scan rate of 0.5 Hz resulting in a scanning speed of $2\,\mu m/s$. Velocity effects on friction are studied by changing the scan frequency from 0.1 to 60 Hz, while the scan size is maintained at $2 \times 2\,\mu m^2$, which allows velocity to vary from 0.4 to $240\,\mu m/s$. To study the durability properties, the friction force and coefficient of friction are monitored during scanning at a normal load of 70 nN and a scanning speed of $0.8\,\mu m/s$, for a desired number of cycles [27.42, 43, 47].

27.1.9 AFM Tip Wear

AFM tips wear during use. Wear can result in an increase in tip radius and adhesion between the tip and the sample, thus reducing the image resolution and introducing artifacts. The tip geometry can be measured by AFM imaging using an ultrasharp geometry (sharper than the AFM tip), known as a tip characterizer, and analyzing the data for tip reconstruction using a tip de-

Table 27.2 Summary of various operating modes of AFM for surface roughness, stiffness, phase angle, and friction

Operating mode	Direction of cantilever vibration	Vibration frequency of cantilever (kHz)	Vibration amplitude (nm)	Feedback control	Data obtained
Contact	N/A			Constant normal load	Surface height, friction
Tapping	Vertical	350–400	10–100	Setpoint (constant tip amplitude)	Surface height, phase angle (normal viscoelasticity)
Force modulation	Vertical	10–20 (bimorph)	10–100	Constant normal load	Surface height, amplitude (normal stiffness)
Lateral	Lateral (AFAM)	100–3000 (sample)	≈ 5 (sample)	Constant normal load	Shift in contact resonance (normal stiffness, friction)
TR mode I	Torsional	≈ 800	0.3–2	Setpoint (constant tip amplitude)	Surface height, phase angle (lateral viscoelasticity)
TR mode II	Torsional	≈ 800	0.3–2	Constant normal load	Surface height, amplitude and phase angle (lateral stiffness and lateral viscoelasticity)
TR mode III	Torsional	> 800 in contact	0.3–2	Constant normal load	Shift in contact resonance (friction)

convolution algorithm [27.93]. A grating sample with an array of sharp tips with a radius less than 10 nm is commonly used.

Tao and *Bhushan* [27.93] developed fluoropolymer coatings deposited on the silicon probe to reduce their tip wear.

27.2 Surface Imaging, Friction, and Adhesion

27.2.1 Atomic-Scale Imaging and Friction

Surface height imaging down to atomic resolution of electrically conducing surfaces can be carried out using an STM. An AFM can also be used for surface height imaging and roughness characterization down to the nanoscale. Figure 27.12 shows a sequence of STM images at various scan sizes of solvent-deposited C_{60} film on 200 nm thick gold-coated freshly cleaved mica [27.94]. The film consists of clusters of C_{60} molecules 8 nm in diameter. The C_{60} molecules within a cluster appear to pack into a hexagonal array with a spacing of about 1 nm, however, they do not follow any long-range order. The measured cage diameter of the C_{60} molecule is about 0.7 nm, very close to the projected diameter of 0.71 nm.

In an AFM measurement during surface imaging, the tip comes into intimate contact with the sample surface and leads to surface deformations with finite tip–sample contact area (typically few atoms). The finite size of the contact area prevents the imaging of individual point defects, and only the periodicity of the atomic lattice can be imaged. Figure 27.13a shows the topography image of a freshly cleaved surface of highly oriented pyrolytic graphite (HOPG) [27.26]. The periodicity of the graphite is clearly observed.

To study the friction mechanisms on an atomic scale, a freshly cleaved HOPG was studied by *Mate* et al. [27.23] and *Ruan* and *Bhushan* [27.26]. Figure 27.14a shows the atomic-scale friction force map (raw data) and Fig. 27.13a shows the friction force maps (after two-dimensional (2-D) spectrum filtering with high-frequency noise truncated) [27.26]. Figure 27.14a also shows a line plot of friction force profiles along some crystallographic direction. The actual shape of the friction profile depends upon the spatial location of the axis of tip motion. Note that a portion of atomic-scale lateral force is conservative. *Mate* et al. [27.23] and *Ruan* and *Bhushan* [27.26] reported that the average friction force linearly increased with normal load and was reversible with load. Friction profiles were similar during the sliding of the tip in either direction.

During scanning, the tip moves discontinuously over the sample surface and jumps with discrete steps from one potential minimum (well) to the next. This leads to a saw-tooth-like pattern for the lateral motion (force) with a periodicity of the lattice constant. This motion is called the stick-slip movement of the tip [27.2, 23, 26]. The observed friction force includes two components – conservative and periodic, and non-

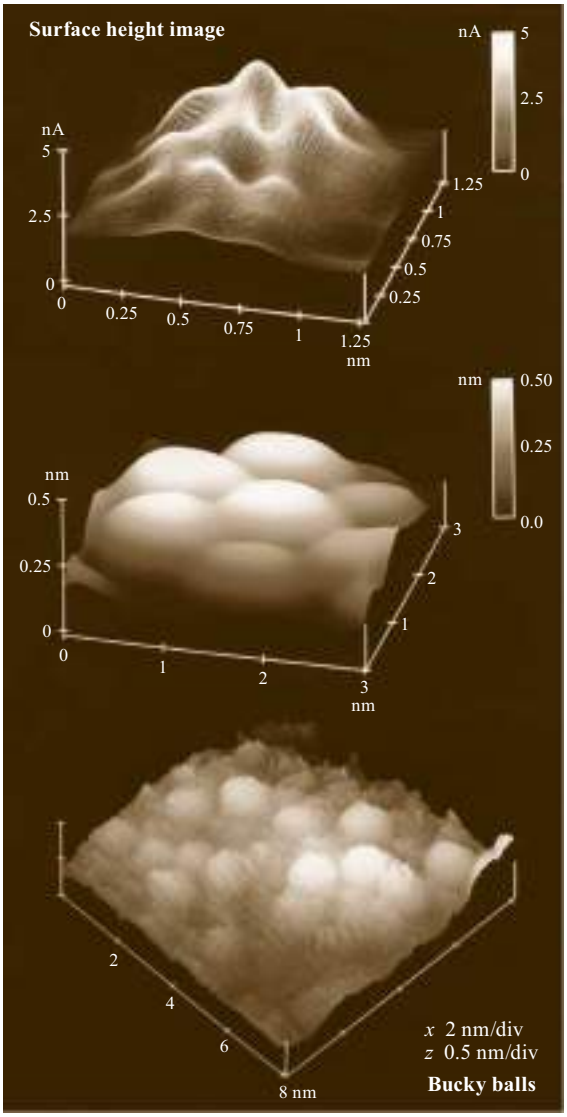

Fig. 27.12 STM images of solvent-deposited C_{60} film on a gold-coated freshly cleaved mica at various scan sizes (after [27.95])

conservative and constant. If the relative motion of the sample and tip were simply that of two rigid collections of atoms, the effective force would be a conservative force oscillating about zero. Slow reversible elastic deformation would also contribute to conservative force. The origin of the nonconservative direction-dependent force component would be phonon generation, viscous dissipation, or plastic deformation.

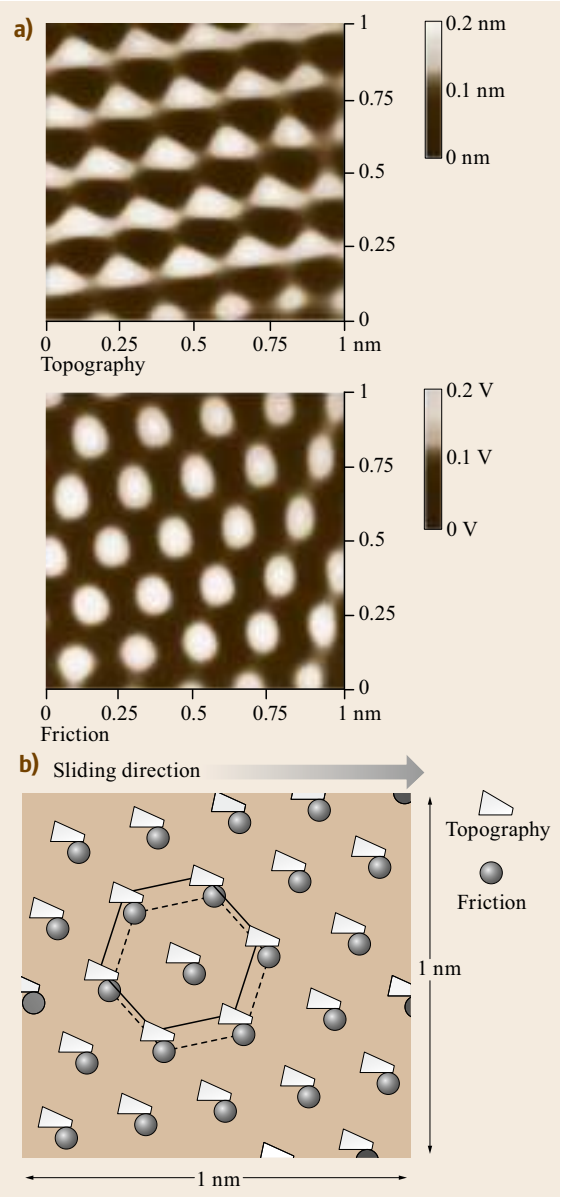

Fig. 27.13 **(a)** Gray-scale plots of surface topography and friction force maps (2-D spectrum filtered), measured simultaneously, of a $1\,\text{nm} \times 1\,\text{nm}$ area of freshly cleaved HOPG, showing the atomic-scale variation of topography and friction, and **(b)** schematic of superimposed topography and friction maps from **(a)**; the *symbols* correspond to maxima. Note the spatial shift between the two plots (after [27.26])

Stick-slip on the atomic scale, discussed above, is the result of the energy barrier required to be overcome to jump over the atomic corrugations on the sample surface. It corresponds to the energy required for the jump of the tip from a stable equilibrium position on the surface to a neighboring position. The perfect atomic regularity of the surface guarantees the periodicity of the lateral force signal, independent of the actual atomic structure of the tip apex. A few atoms (based on the magnitude of the friction force, less than ten) on a tip sliding over an array of atoms on the sample are expected to undergo the stick-slip. For simplicity, Fig. 27.14b shows a simplified model for one atom on a tip with a one-dimensional spring mass system. As the sample surface slides against the AFM tip, the tip remains *stuck* initially until it can overcome the energy (potential) barrier, which is illustrated by a sinusoidal interaction potential as experienced by the tip. After some motion, there is enough energy stored in the spring which leads to *slip* into the neighboring stable equilibrium position. During the slip and before attaining stable equilibrium, stored energy is converted into vibrational energy of the surface atoms in the range of 10^{13} Hz (phonon generation) and decays within the range of 10^{-11} s into heat. (A wave of atoms vibrating in concert are termed a phonon). The stick-slip phenomenon, resulting from irreversible atomic jumps, can be theoretically modeled with classical mechanical models [27.96, 97]. The Tomanek-Zhong-Thomas model [27.97] is the starting point for determining friction force during atomic-scale stick-slip. The AFM model describes the total potential as the sum of the potential acting on the tip due to interaction with the sample and the elastic energy stored in the cantilever. Thermally activated stick-slip behavior can explain the velocity effects on friction, to be presented later.

Finally, based on Fig. 27.13a, the atomic-scale friction force of HOPG exhibited the same periodicity as that of the corresponding topography, but the peaks in friction and those in the topography are displaced relative to each other (Fig. 27.13b). A Fourier expansion of the interatomic potential was used by *Ruan* and *Bhushan* [27.26] to calculate the conservative interatomic forces between the atoms of the FFM tip and those of the graphite surface. Maxima in the interatomic forces in the normal and lateral directions do not occur at the same location, which explains the observed shift between the peaks in the lateral force and those in the corresponding topography.

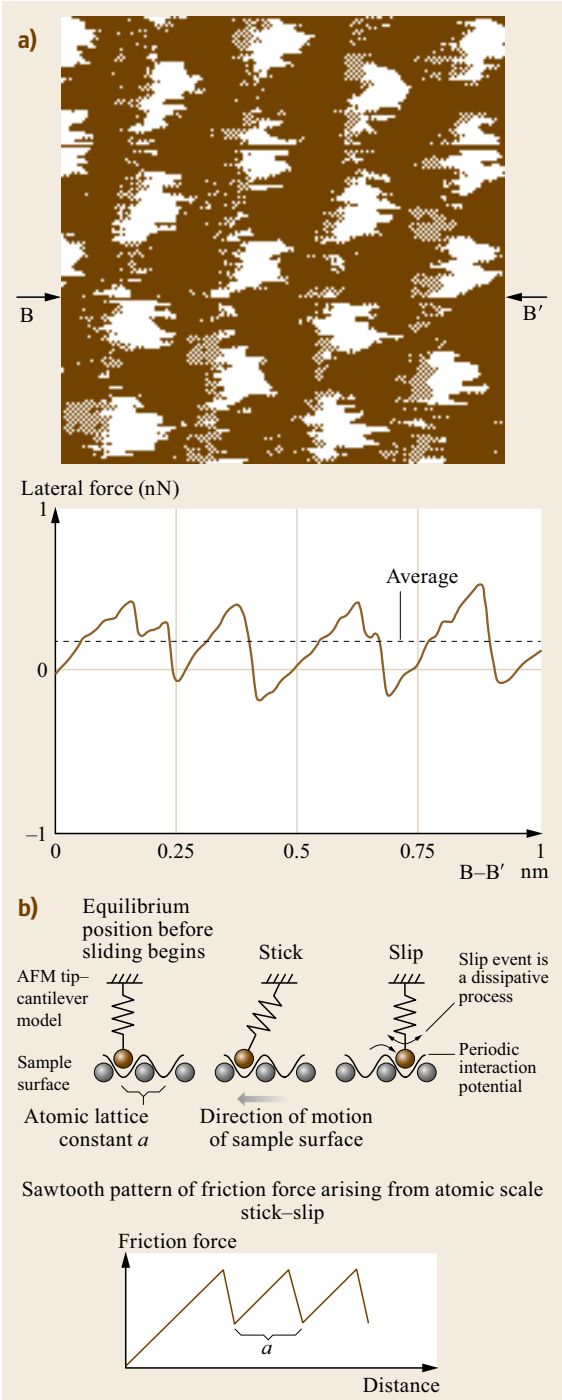

Fig. 27.14 **(a)** Gray-scale plot of a friction force map (raw data) of a $1 \times 1\,\mathrm{nm}^2$ area of freshly cleaved HOPG, showing atomic-scale variation of friction force. High points are shown by a *lighter color*. Also shown is a line plot of the friction force profile along the line indicated by the *arrows*. The normal load was 25 nN and the cantilever normal stiffness was 0.4 N/m (after [27.26]). **(b)** Schematic of a model for a tip atom sliding on an atomically flat periodic surface. The schematic shows the tip jumping from one potential minimum to another, resulting in stick-slip behavior ◄

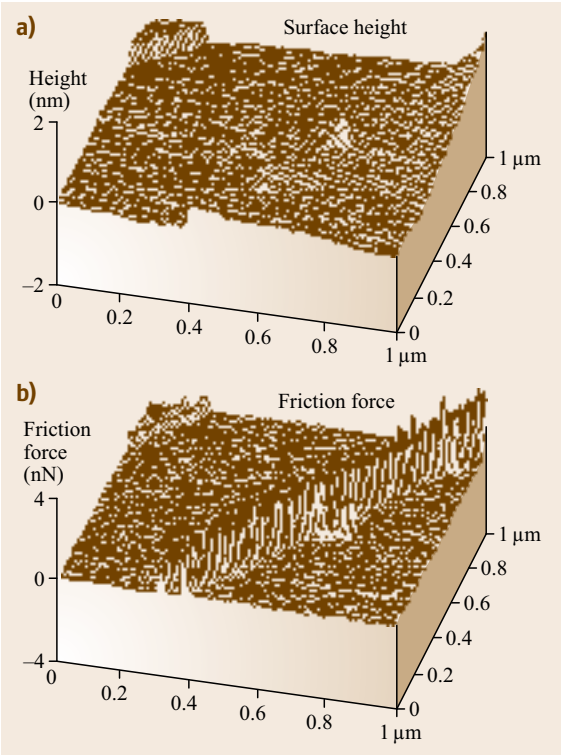

Fig. 27.15 **(a)** Surface roughness and **(b)** friction force maps at a normal load of 42 nN of a freshly cleaved HOPG surface against an Si_3N_4 FFM tip. Friction in the *line-shaped region* is over an order of magnitude larger than the smooth areas (after [27.26])

27.2.2 Microscale Friction

Local variations in the microscale friction of cleaved graphite are observed (Fig. 27.15). Microscale friction is defined as the friction measured with a scan size equal to or larger than $1\,\mu\mathrm{m} \times 1\,\mu\mathrm{m}$. These arise from structural changes that occur during the cleaving process [27.27]. The cleaved HOPG surface is largely atomically smooth but exhibits line-shaped regions in which the coefficient of friction is more than an order of magnitude larger. Transmission electron microscopy indicates that the line-shaped regions consist of graphite planes of different orientation, as well as of amorphous carbon. Differences in friction have also been observed for multiphase ceramic materials [27.56]. Figure 27.16 shows the surface roughness and friction

force maps of Al_2O_3-TiC (70–30 wt%). TiC grains have a Knoop hardness of about 2800 kg/mm^2 and Al_2O_3 has 2100 kg/mm^2, therefore, TiC grains do not polish as much and result in a slightly higher elevation (about 2–3 nm higher than that of Al_2O_3 grains). TiC grains exhibit higher friction force than Al_2O_3 grains. The coefficients of friction of TiC and Al_2O_3 grains are 0.034 and 0.026, respectively, and the coefficient of friction of Al_2O_3-TiC composite is 0.03. Local variation in friction force also arises from the scratches present on the Al_2O_3-TiC surface. *Meyer* et al. [27.98] also used FFM to measure structural variations of organic mono- and multilayer films. All of these measurements suggest that the FFM can be used for structural mapping of the surfaces. FFM measurements can also be used to map chemical variations, as indicated by the use of the FFM with a modified probe tip to map the spatial arrangement of chemical functional groups in mixed organic monolayer films [27.99]. Here, sample regions that had stronger interactions with the functionalized probe tip exhibited greater friction.

Local variations in the microscale friction of nominally rough, homogeneous material surfaces can be significant, and are seen to depend on the local surface slope rather than the surface height distribution (Fig. 27.17). This dependence was first reported by

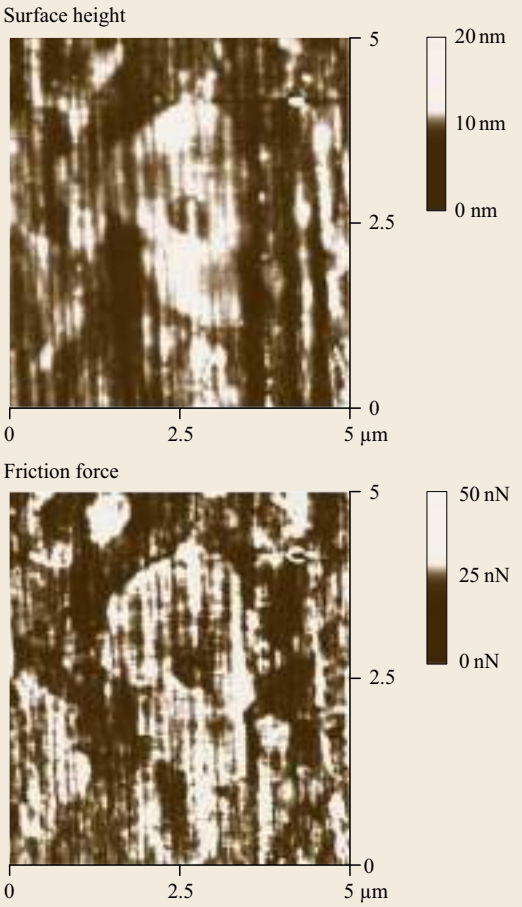

Fig. 27.16 Gray-scale surface roughness ($\sigma = 0.80$ nm) and friction force maps (mean = 7.0 nN, $\sigma = 0.90$ nN) for Al_2O_3-TiC (70–30 wt%) at a normal load of 138 nN (after [27.56])

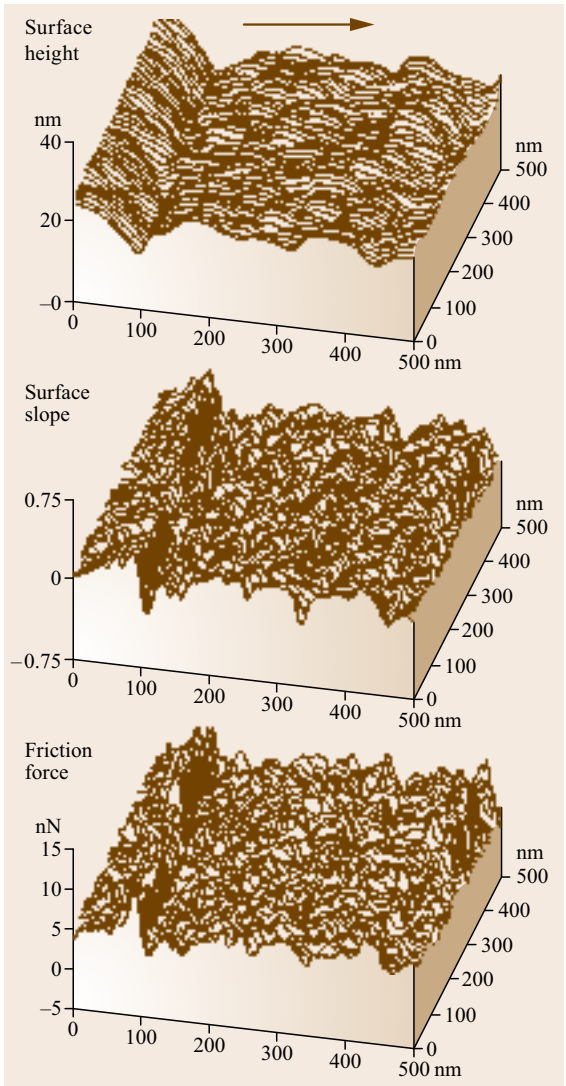

Fig. 27.17 Surface roughness map ($\sigma = 4.4$ nm), surface slope map taken in the sample-sliding direction (the *horizontal axis*; mean = 0.023, $\sigma = 0.197$), and friction force map (mean = 6.2 nN, $\sigma = 2.1$ nN) for a lubricated thin-film magnetic rigid disk for a normal load of 160 nN (after [27.28])

Bhushan and *Ruan* [27.24], *Bhushan* et al. [27.28] and *Bhushan* [27.79] and later discussed in more detail by *Koinkar* and *Bhushan* [27.100] and *Sundararajan* and *Bhushan* [27.101]. In order to elegantly show any correlation between local values of friction and surface roughness, surface roughness and friction force maps of a gold-coated ruler with somewhat rectangular grids and a silicon grid with square pits were obtained (Fig. 27.18). Figures 27.17 and 27.18 show the surface roughness map, the slopes of the roughness map taken along the sliding direction (surface slope map), and the friction force map for various samples. There is a strong correlation between the surface slopes and friction forces. For example, in Fig. 27.18, the friction force is high locally at the edge of the grids and pits with a positive slope and is low at the edges with a negative slope.

We now examine the mechanism of microscale friction, which may explain the resemblance between the slope of surface roughness maps and the corresponding friction force maps [27.2, 7, 13, 14, 24, 26–28, 101, 102]. There are three dominant mechanisms of friction; adhesive, ratchet, and plowing [27.103, 104]. As a first order, we may assume these to be additive. The adhesive mechanism cannot explain the local variation in friction. Next, we consider the ratchet mechanism. We consider a small tip sliding over an asperity making an angle θ with the horizontal plane (Fig. 27.19). The normal force W (normal to the general surface) applied by the tip to the sample surface is constant. The friction force F on the sample would be a constant for a smooth surface if the friction mechanism does not change. For the rough surface shown in Fig. 27.19, if the adhesive mechanism does not change during sliding, the local value of the coefficient of friction remains constant,

$$\mu_0 = \frac{S}{N} , \tag{27.1}$$

where S is the local friction force and N is the local normal force. However, the friction and normal forces are measured with respect to global horizontal and normal axes, respectively. The measured local coefficient of friction μ_1 in the ascending part is

$$\mu_1 = \frac{F}{W} = \frac{\mu_0 + \tan\theta}{1 - \mu_0 \tan\theta} \approx \mu_0 + \tan\theta, \quad \text{for small } \mu_0 \tan\theta \tag{27.2}$$

indicating that in the ascending part of the asperity one may simply add the friction force and the asperity slope to one another. Similarly, on the right-hand side (descending part) of the asperity,

$$\mu_2 = \frac{\mu_0 - \tan\theta}{1 + \mu_0 \tan\theta} \approx \mu_0 - \tan\theta, \quad \text{for small } \mu_0 \tan\theta . \tag{27.3}$$

For a symmetrical asperity, the average coefficient of friction experienced by the FFM tip traveling across the whole asperity is

$$\begin{aligned} \mu_{\text{ave}} &= \frac{\mu_1 + \mu_2}{2} \\ &= \mu_0 \frac{1 + \tan^2\theta}{1 - \mu_0^2 \tan^2\theta} \\ &\approx \mu_0 (1 + \tan^2\theta), \quad \text{for small } \mu_0 \tan\theta . \end{aligned} \tag{27.4}$$

Finally, we consider the plowing component of friction with the tip sliding in either direction, which is [27.14, 79]

$$\mu_{\text{p}} \approx \tan\theta . \tag{27.5}$$

Because in FFM measurements we notice little damage of the sample surface, the contribution from plowing is expected to be small, and the ratchet mechanism is believed to be the dominant mechanism for the local variations in the friction force map. With the tip sliding over the leading (ascending) edge of an asperity, the surface slope is positive; it is negative during sliding over the trailing (descending) edge of an asperity. Thus, measured friction is high at the leading edge of asperities and low at the trailing edge. In addition to the slope effect, the collision of the tip when encountering an asperity with a positive slope produces additional torsion of the cantilever beam leading to higher measured friction force. When encountering an asperity with the same negative slope, however, there is no collision effect and hence no effect on torsion. This effect also contributes to the difference in friction forces when the tip scans up and down on the same topography feature. The ratchet mechanism and the collision effects thus semiquantitatively explain the correlation between the slopes of the roughness maps and friction force maps observed in Figs. 27.17 and 27.18. We note that in the ratchet mechanism, the FFM tip is assumed to be small compared to the size of asperities. This is valid since the typical radius of curvature of the tips is about 10–50 nm. The radii of curvature of the asperities of the samples measured here (the asperities that produce most of the friction variation) are found to typically be about 100–200 nm, which is larger than that of the FFM tip [27.105]. It is important to note that the measured local values

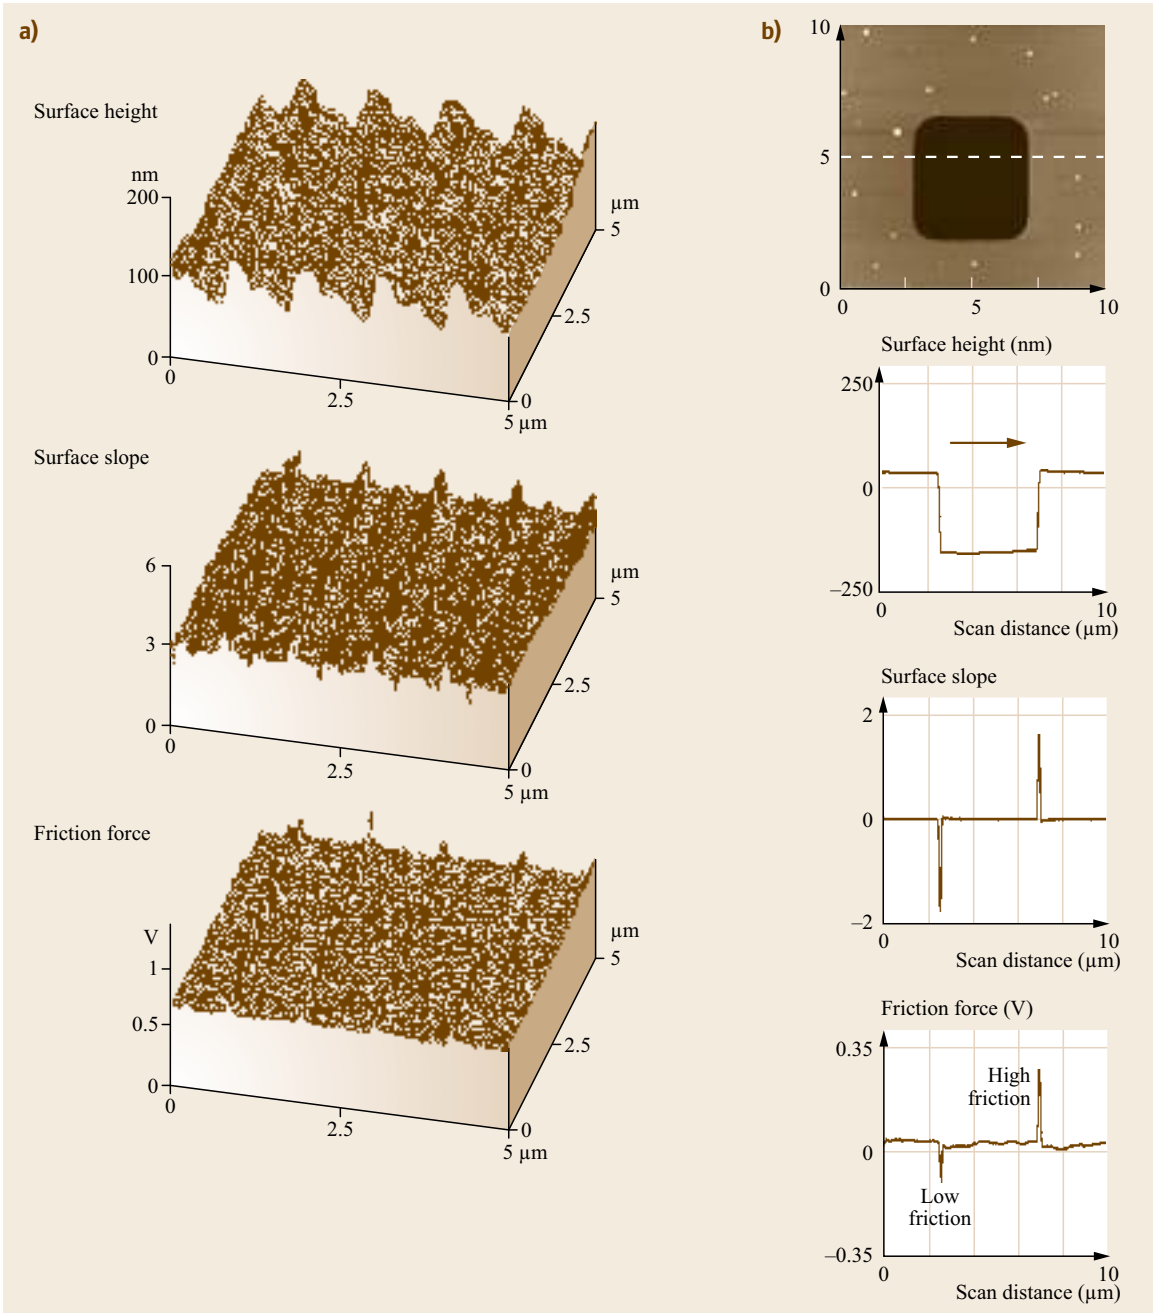

Fig. 27.18a,b Surface roughness map, surface slope map taken in the sample-sliding direction (*the horizontal axis*), and friction force map for **(a)** a gold-coated ruler (with somewhat rectangular grids with a pitch of 1 µm and a ruling step height of about 70 nm) at a normal load of 25 nN and **(b)** a silicon grid (with 5 µm square pits of depth 180 nm and a pitch of 10 µm) (after [27.101])

of friction and normal forces are measured with respect to global (and not local) horizontal and vertical axes, which are believed to be relevant in applications.

27.2.3 Directionality Effect on Microfriction

During friction measurements, the friction force data from both the forward (trace) and backward (re-

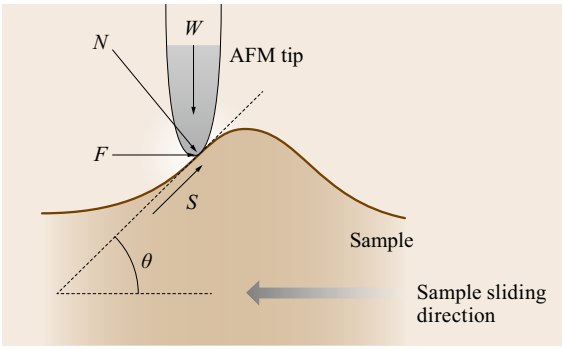

Fig. 27.19 Schematic illustration showing the effect of an asperity (making an angle θ with the horizontal plane) on the surface in contact with the tip on local friction in the presence of an adhesive friction mechanism. W and F are the normal and friction forces, respectively, and S and N are the force components along and perpendicular to the local surface of the sample at the contact point, respectively

trace) scans are useful in understanding the origins of the observed friction forces. Magnitudes of material-induced effects are independent of the scanning direction whereas topography-induced effects are different between forward and backward scanning directions. Since the sign of the friction force changes as the scanning direction is reversed (because of the reversal of torque applied to the end of the tip), addition of the friction force data of the forward and backward scan eliminates the material-induced effects while topography-induced effects still remain. Subtraction of the data between forward and backward scans does not eliminate either effect (Fig. 27.20) [27.101].

Owing to the reversal of the sign of the retrace (R) friction force with respect to the trace (T) data, the friction force variations due to topography are in the same direction (peaks in trace correspond to peaks in retrace). However, the magnitudes of the peaks in trace and retrace at a given location are different. An increase in the friction force experienced by the tip when scanning up a sharp change in topography is more than the decrease in the friction force experienced when scanning down the same topography change, partly because of collision effects discussed earlier. Asperities on engineering surfaces are asymmetrical, which also affect the magnitude of friction force in the two directions. Asymmetry in tip shape may also have an effect on the directionality effect of friction. We will note later that the magnitude of surface slopes are virtually identical, therefore, the tip shape asymmetry should not have much effect.

Figure 27.21 shows the surface height and friction force data for a gold ruler and a silicon grid in the trace and retrace directions. Subtraction of two friction data

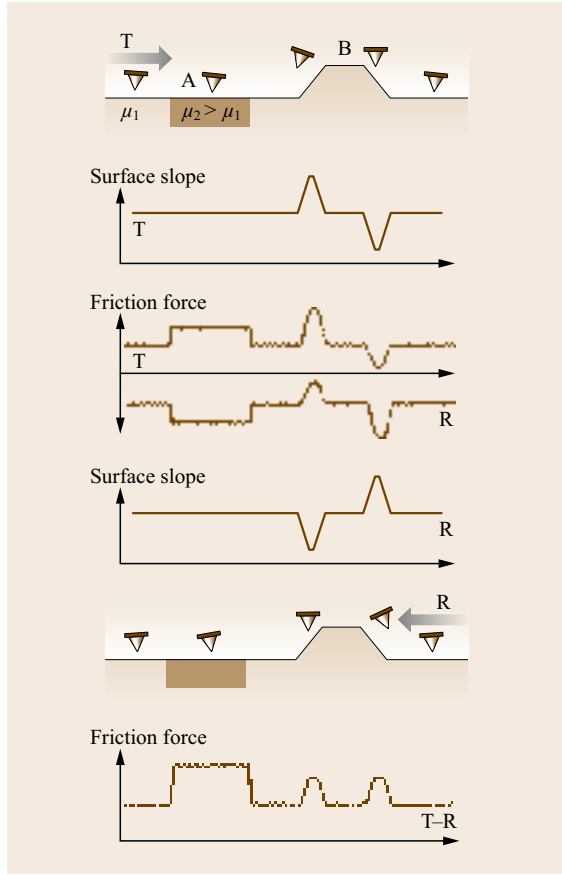

Fig. 27.20 Schematic of friction forces expected when a tip traverses a sample that is composed of different materials and sharp changes in topography. A schematic of surface slope is also shown

yields a residual peak because of the differences in the magnitudes of friction forces in the two directions. This effect is observed at all locations of significant changes in topography.

In order to facilitate comparison of the directionality effect on friction, it is important to take into account the sign change of the surface slope and friction force in the trace and retrace directions. Figure 27.22 shows surface height, surface slope, and friction force data for the two samples in the trace and retrace directions. The correlations between surface slope and friction forces are clear. The third column in the figures shows retrace slope and friction data with an inverted sign (-retrace). Now we can compare trace data with -retrace data. It is clear that the friction experienced by the tip is dependent upon the scanning direction because of surface topography. In addition to the effect of topographical changes discussed earlier, during surface-finishing processes, material can be transferred preferentially onto

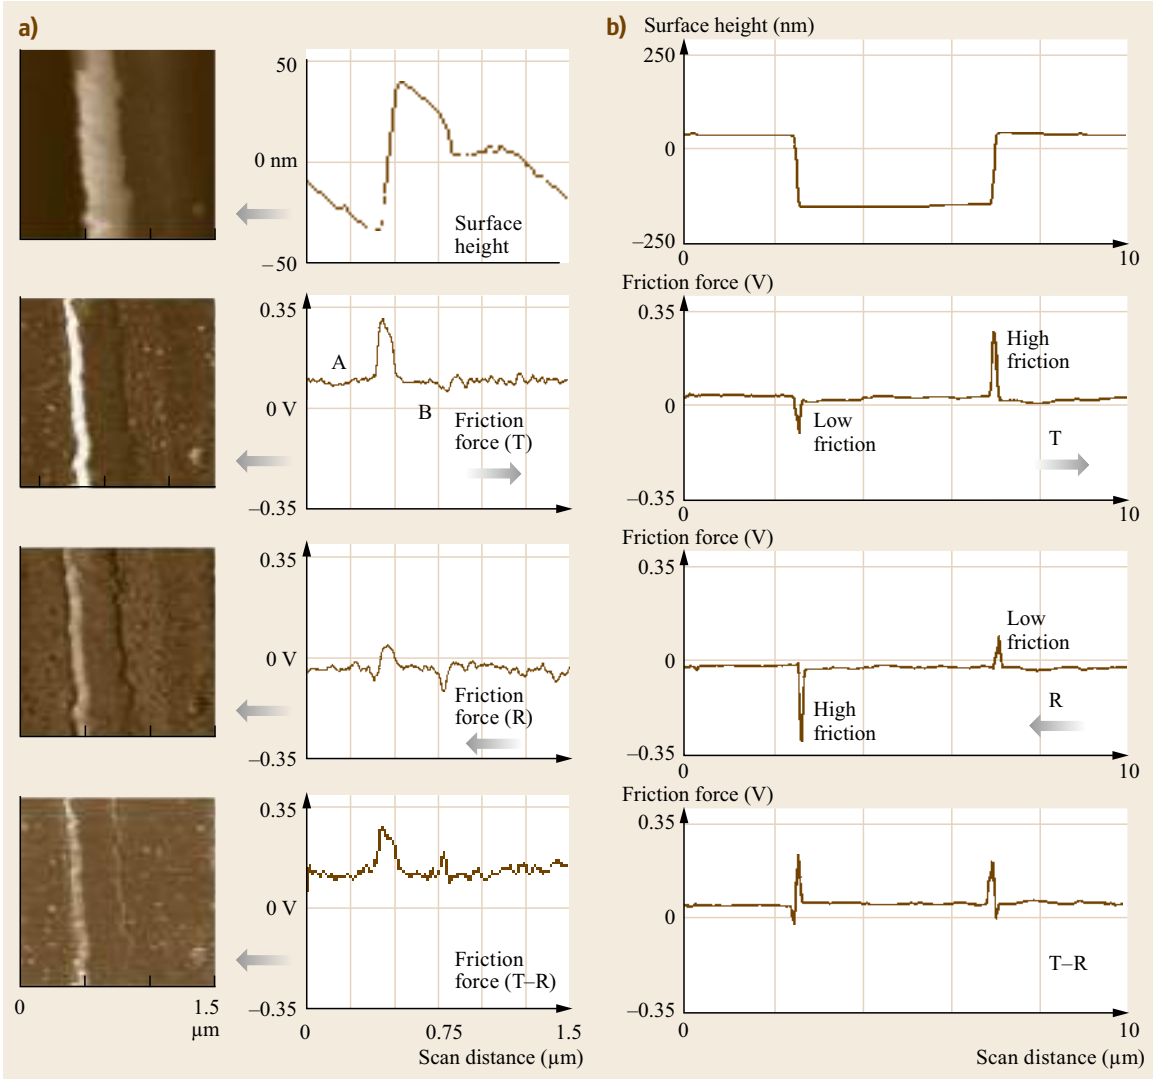

Fig. 27.21 **(a)** Gray-scale images and two-dimensional profiles of surface height and friction forces across a single ruling of the gold-coated ruling, and **(b)** two-dimensional profiles of surface height and friction forces across a silicon grid pit. Friction force data in trace and retrace directions, and subtracted force data are presented (after [27.101])

one side of the asperities, which also causes asymmetry and direction dependence. Reduction in local variations and in the directionality of friction properties requires careful optimization of surface roughness distributions and of surface-finishing processes.

The directionality as a result of a surface asperities effect will be also manifested in macroscopic friction data, i. e., the coefficient of friction may be different in one sliding direction than that in the other direction. The asymmetrical shape of the asperities accentuates this effect. The frictional directionality can also exist in materials with particles having a preferred orientation. The directionality effect in friction on a macroscale is observed in some magnetic tapes. In a macroscale test, a 12.7 mm wide polymeric magnetic tape was wrapped over an aluminum drum and slid in a reciprocating motion with a normal load of 0.5 N and a sliding speed of about 60 mm/s [27.79]. The coefficient of friction as a function of sliding distance in either direction is shown in Fig. 27.23. We note that the coefficient of friction on a macroscale for this tape is different in different directions. Directionality in friction is sometimes observed on the macroscale; on the microscale this is the norm [27.2, 16]. On the macroscale, the effect of surface asperities normally is averaged out over a large number of contacting asperities.

27.2.4 Surface Roughness–Independent Microscale Friction

As just reported, the friction contrast in conventional friction measurements is based on interactions dependent upon interfacial material properties superimposed by roughness-induced lateral forces, and the cantilever twist is dependent on the sliding direction because of the local surface slope. Hence it is difficult to separate the friction-induced from the roughness-induced cantilever twist in the image. To obtain the roughness-independent friction, lateral or torsional modulation techniques are used in which the tip is oscillated in-plane with a small amplitude at a constant normal load, and change in shape and magnitude of cantilever resonance is used as a measure of friction force [27.4, 34–37, 106, 107]. These techniques also allow measurements over a very small area (few nm to few μm).

Scherer et al. [27.33] and *Reinstaedtler* et al. [27.34, 35] used lateral mode for friction measurements (Fig. 27.10b). *Bhushan* and *Kasai* [27.37] used the TR mode for these measurements (Fig. 27.11). Before engagement, the cantilever is driven into torsional motion of the cantilever/tip assembly with a given normal vibration amplitude (vibration amplitude in free air). After engagement, the vibration amplitude decreases due to the interaction between the tip and the sample, the vibration frequency increases, and phase shift occurs. During scanning, the normal load is kept constant, and the vibration amplitude of the cantilever is measured at the contact frequency.

As mentioned earlier, the shift in contact resonance frequency both in lateral and in TR modes is a measure of contact stiffness as shown schematically in Fig. 27.24. At an excitation voltage above a certain value, as a result of microslip at the interface, a flattening of the resonance frequency spectra occurs

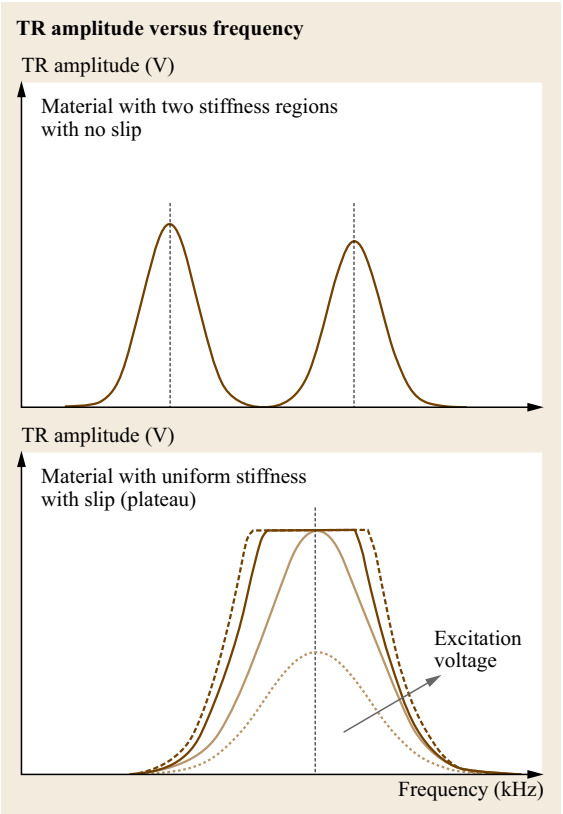

Fig. 27.24 Schematic showing frequency profiles of the TR amplitude for materials with two phases and a single phase. The maximum TR amplitude at the contact resonance frequency of the resonance curve with a flattened top, resulting from slip, can be used for friction force measurement

(Fig. 27.22). At lowest excitation voltage, the AFM tip sticks to the sample surface and follows the motion like an elastic contact with viscous damping, and the resonance curve is Lorentzian with a well-defined maximum. The excitation voltage should be high enough to initiate microslip. The maximum torsional amplitude at a given resonance frequency is a function of friction force and sample stiffness, so the technique is not valid for inhomogeneous samples. If the torsional stiffness of the cantilever is very high compared to the sample stiffness, the technique should work.

Reinstaedtler et al. [27.34] performed lateral mode experiments on bare Si and Si lubricated with 5 nm thick chemically bonded perfluoropolyether (Z-DOL) lubricant film. Figure 27.25a shows the amplitude of the cantilever torsional vibration as a function of frequency on a bare silicon sample. The frequency sweep was adjusted such that a contact resonance frequency was covered. The different curves correspond to dif-

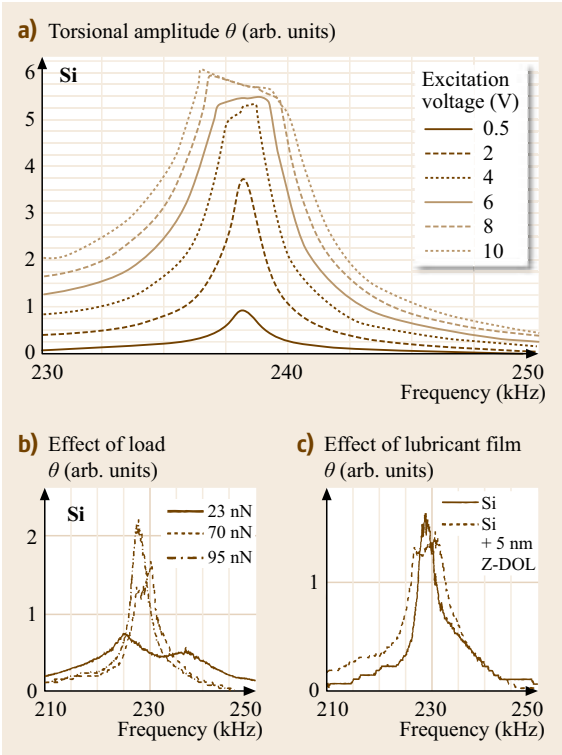

Fig. 27.25a–c Torsional vibration amplitude of the cantilever as a function of excitation frequency. **(a)** Measurement on bare silicon. The *different curves* correspond to increasing excitation voltages applied to the transducer and, hence, increasing surface amplitudes. **(b)** Measurement on silicon lubricated with a 5 nm thick Z-DOL layer. *Curves* for three different static loads are shown. The transducer was excited with 5 V of amplitude. **(c)** Measurement with a static load of 70 nN and 7 V excitation amplitude. The *two curves* correspond to bare silicon and lubricated silicon, respectively (after [27.34])

ferent excitation voltages applied to the shear wave transducer. At low amplitudes, the shape of the resonance curve is Lorentzian. Above a critical excitation amplitude of the transducer (excitation voltage = 4 V corresponding to ≈ 0.2 nm lateral surface amplitude as measured by interferometry), the resonance curve flattens out, and the frequency span of the flattened part increases further with the excitation amplitude. Here, the static force applied was 47 nN and the adhesion force was 15 nN. The resonance behavior of the tip-cantilever system in contact with the lubricated silicon sample (Fig. 27.25b) was similar to that of the bare silicon sample. By increasing the static load, the critical amplitude for the appearance of the flattening increases. The deviations from the Lorentzian resonance curve became visible at static loads lower than 95 nN. As shown in Fig. 27.25c, the resonance curve obtained at the same normal load of 70 nN and at the same excitation voltage (7 V) is more flattened on the lubricated sample than on the bare silicon which led us to conclude that the critical amplitude is lower on the lubricated sample than on the bare sample. These experiments clearly demonstrate that torsional vibration of an AFM cantilever at ultrasonic frequencies leads to stick-slip phenomena and sliding friction. Above a critical vibration amplitude, sliding friction sets in.

Bhushan and *Kasai* [27.37] performed friction measurements on a silicon ruler and demonstrated that friction data in TR mode is essentially independent of surface-roughness and sliding direction. Figure 27.26 shows surface height and friction force maps on a silicon ruler obtained using the TR mode and contact mode techniques. A comparison is made between the TR mode and contact mode friction force maps. For easy comparison, the line scan profiles near the central area are shown on top of the gray-scale maps. The vertical scales of the friction force profiles in the two graphs are selected to cover the same range of friction force so that direct comparison can be made, i. e., 0.25 V in full scale for the TR mode corresponds to 0.5 V for the contact mode in these measurements. As expected, for the trace scan, small downward peaks in the TR mode map and large upward and downward peaks in the contact mode map are observed. The positions of these peaks coincide with those of the surface slope. Therefore, the peaks in the friction signals are attributed to a topography-induced effect. For the retrace scan, the peak pattern for the TR mode remains similar, but for the contact mode, the pattern becomes reversed.

The subtraction image for the TR mode shows almost flat contrast, since the trace and retrace friction data profiles are almost identical. For the contact mode, the subtraction image shows that the topography-induced contribution still exists. As stated earlier, the addition image of the TR mode and the addition image of the contact mode enhance the topography-induced effect, which is observed in the figure.

A closer look at the silicon ruler images at one pitch was taken, and the associated images are shown in Fig. 27.27. The surface height profiles in the TR mode and contact mode are somewhat different. The TR mode shows sharper edges than those in contact mode. The ratios of the change in amplitude at the steps to the change in the mean amplitude in the TR mode and in the contact mode are a measure of topography effects. The ratio in the contact mode (≈ 85%) is about seven times larger than that of the TR mode (≈ 12%).

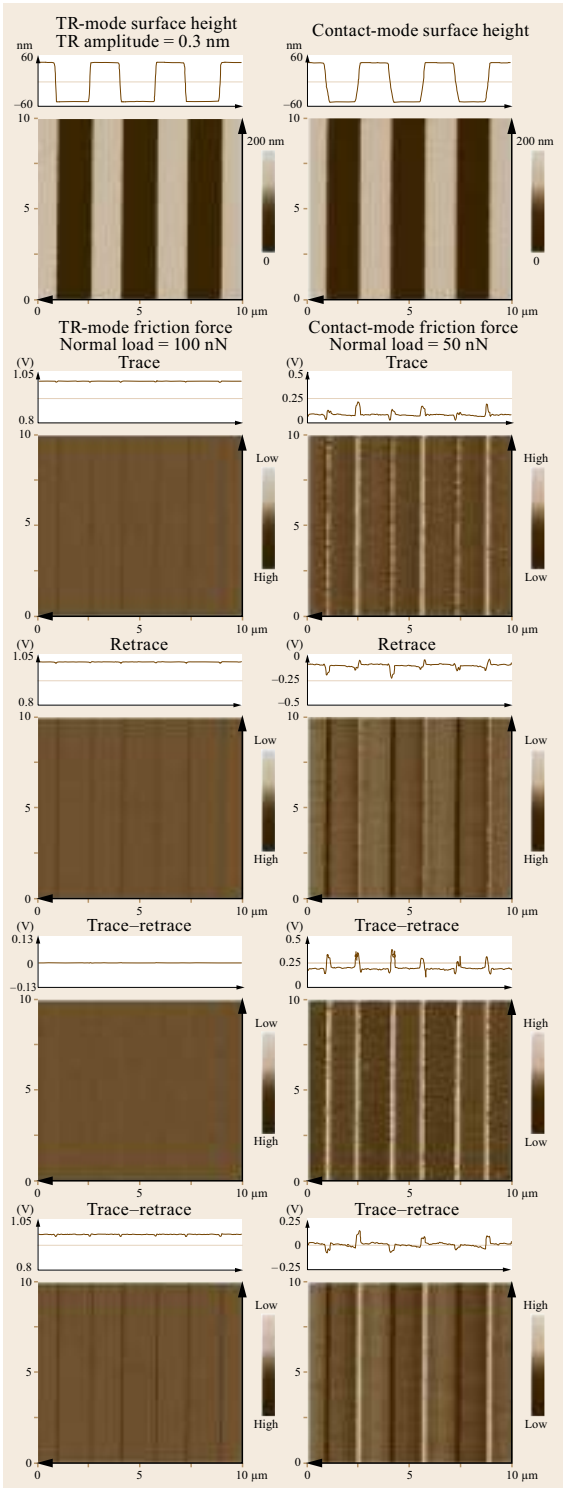

Fig. 27.26 A comparison between TR mode friction and contact mode friction maps together with line scans, on the silicon ruler. The TR mode surface height and contact mode surface height images are also shown (after [27.37])

27.2.5 Velocity Dependence on Micro/Nanoscale Friction

AFM/FFM experiments can be generally conducted at relative velocities as high as about 100–250 µm/s. To simulate applications, it is of interest to conduct friction experiments at higher velocities (up to 1 m/s). Furthermore, high-velocity experiments would be useful to study velocity dependence on friction and wear. One approach has been to mount samples on a shear wave transducer (ultrasonic transducer) and then drive it at very high frequencies (in the MHz range) as reported earlier (Fig. 27.10) [27.32–36, 106, 108]. The coefficient of friction on the nanoscale is estimated based on the contact resonance frequency and requires the solution of the characteristic equations for the tip vibrating in contact with the sample surface. The approach is complex and is dependent upon various assumptions.

An alternative approach is to utilize piezo stages with large amplitude ($\approx 10-100\,\mu m$) and relatively low resonance frequency (few kHz) and directly measure the friction force on microscale using the FFM signal without any analysis with assumptions used in the previous approaches using shear wave transducers. The commercial AFM setup modified with this approach can yield sliding velocities up to 200 mm/s [27.38, 109]. In the high-velocity piezo stage shown in Fig. 27.28b, the single axis piezo stage is oriented such that the scanning axis is perpendicular to the long axis of the AFM cantilever (which corresponds to the 90 °C scan angle mode of the commercial AFM). The displacement is monitored using an integrated capacitive feedback sensor, located diametrically opposite to the piezo crystal. The capacitive change, corresponding to the stage displacement, gives a measure of the amount of displacement and can be used as feedback to the piezo controller for better guiding and tracking accuracy during scanning. The closed loop position control of the piezoelectric driven stages using capacitive feedback sensors provides linearity of motion better than 0.01% with nanometer resolution and a stable drift-free motion [27.38]. In the ultrahigh-velocity piezo stage shown in Fig. 27.28a, a rectangular monolithic piezoceramic plate (the stator) with two excitation electrodes is resonated using a 12 V power supply. Depending on the desired direction of the motion, the left or right electrode is excited to produce high-frequency eigenmode oscillations up to 200 kHz. Simultaneous eigenmodes result in quasielliptical motion. An alumina friction tip (pusher) attached to the plate pushes a slider with a glued friction bar which rests on a set of bearings. Through its contact with the friction bar, the piezoceramic plate provides microimpulses and drives the slider forward or backward.

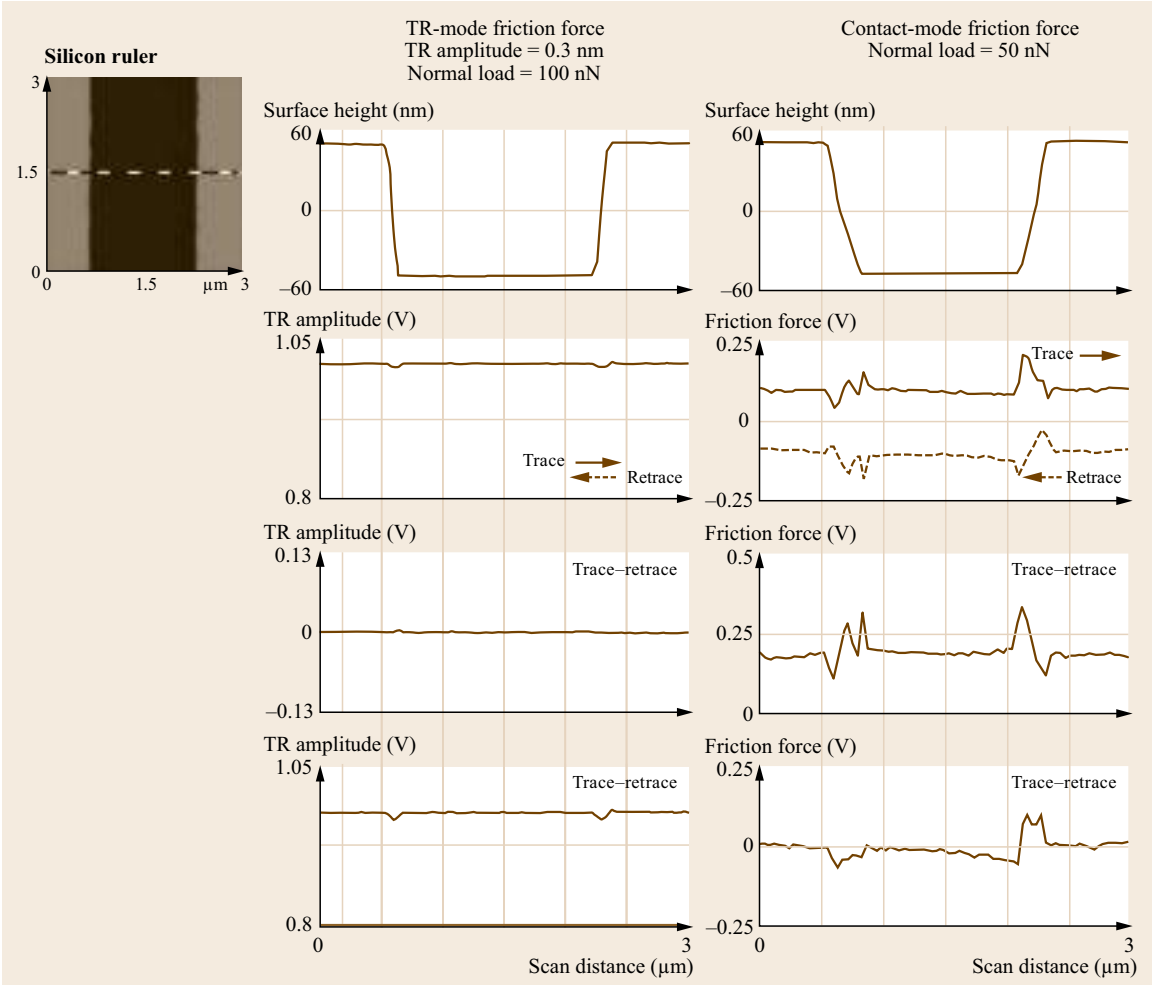

Fig. 27.27 A comparison of the line scans of TR mode friction and contact mode friction on a selected pitch of the silicon ruler (after [27.37])

While the longitudinal oscillation component provides energy as the driving force, the transverse component serves to change the pressure of the friction tip against the friction bar. The transverse oscillation energy determines the maximum frictional force and hence the holding and driving force of the stage. An optical position reference photosensor is located approximately in the middle of the travel range and is used to reference the absolute position of the stage within 1 μm repeatability. During motion, the increments of the linear scale from a home (reference) position point are converted to determine the position using a linear optical encoder.

The block diagram of the high-speed data collection and processing system used for the friction force measurement is shown in Fig. 27.28c. During the experiments, the AFM cantilever is held stationary by maintaining a scan size of zero. The mounted sample is scanned below the AFM tip by moving stages, and the normal and torsional deflections of the tip are recorded by a photodiode detector. The raw deflection signals from the optical detection system are directly routed to a high speed data acquisition A/D board. Raw friction data is acquired at a high sampling rate up to 80 kilosample/s.

Velocity dependence on friction for Si(100), diamond-like carbon (DLC), self-assembled monolayer, and perfluoropolyether lubricant films were studied by *Tambe* and *Bhushan* [27.38, 110–113] and *Tao* and *Bhushan* [27.109, 114]. The friction force as a function of velocity for Si(100) and DLC (deposited by filtered cathodic arc) is shown in Fig. 27.29 on a logarithm velocity scale (middle column). The solid lines in the figure represent the results for a scan length of 1000 μm

with velocity ranging from 1000 to $2\times10^5\,\mu m/s$ using the ultrahigh-velocity stage. The dotted lines represent results for a 25 μm scan length with velocity ranging from 5 to 500 μm/s using the high-velocity stage. To clearly show the friction force dependence on velocity in the lower range, the test results with velocity varying from 5 to 500 μm/s for 25 μm are shown on a magnified scale in the left column of Fig. 27.29.

For the Si(100) sample, the friction force decreased with velocity at low velocities ($v < 10\,\mu m/s$) and then increased linearly with $\log(v)$ for a 25 μm scan length. For the 1000 μm scan length, the friction force increased linearly with $\log(v)$ when velocity was lower than $2\times10^4\,\mu m/s$. When velocities were higher than $2\times10^4\,\mu m/s$, the friction force increased linearly with velocity. For DLC, the friction force increased linearly with $\log(v)$ from 5 to 500 μm/s for the 25 μm scan length. For the 1000 μm scan length, the friction force increases with velocity until about $2\times10^4\,\mu m/s$ where the friction force reaches a maximum, then the friction force decreased with velocity.

For different samples, the change in the friction force with velocity involves different mechanisms in relation to sample surface conditions. The silicon surface is hydrophilic, while the DLC surface is nearly hydrophobic. Under the ambient condition, a thin layer of water film is condensed on a hydrophilic sample surface. On a hydrophobic surface with high contact angle, the water film would be difficult to form on the sample surface, and the effect of the water film on the adhesive force and friction force could be neglected.

On the silicon surface, when the velocity is lower than 10 μm/s, the friction force decreased with velocity. This can be explained as follows. The water meniscus bridges develop as a function of time around the tip until reaching the equilibrium condition and are the dominant contributor to the friction force [27.2, 14, 103, 104]. The motion of the tip results in continuous breaking and reforming of the meniscus bridges. As the tip sliding velocity exceeds a critical velocity (10 μm/s), the menisci cannot reform due to insufficient time, and the meniscus force no longer plays a dominant role. Between 10 and $2\times10^4\,\mu m/s$, the friction increases linearly with $\log(v)$ for both 25 and 1000 μm scan lengths. This logarithmic dependence can be explained by the atomic-scale stick-slip phenomenon [27.111, 114]. At a velocity larger than $2\times10^4\,\mu m/s$, the friction increases linearly with velocity, and this trend can be explained by viscous shear; see the friction force plotted as a function of velocity on a linear scale at a magnified scale in the right column of Fig. 27.29.

To explain the atomic-scale stick-slip mechanism of friction, the motion for the tip is expressed by a spring

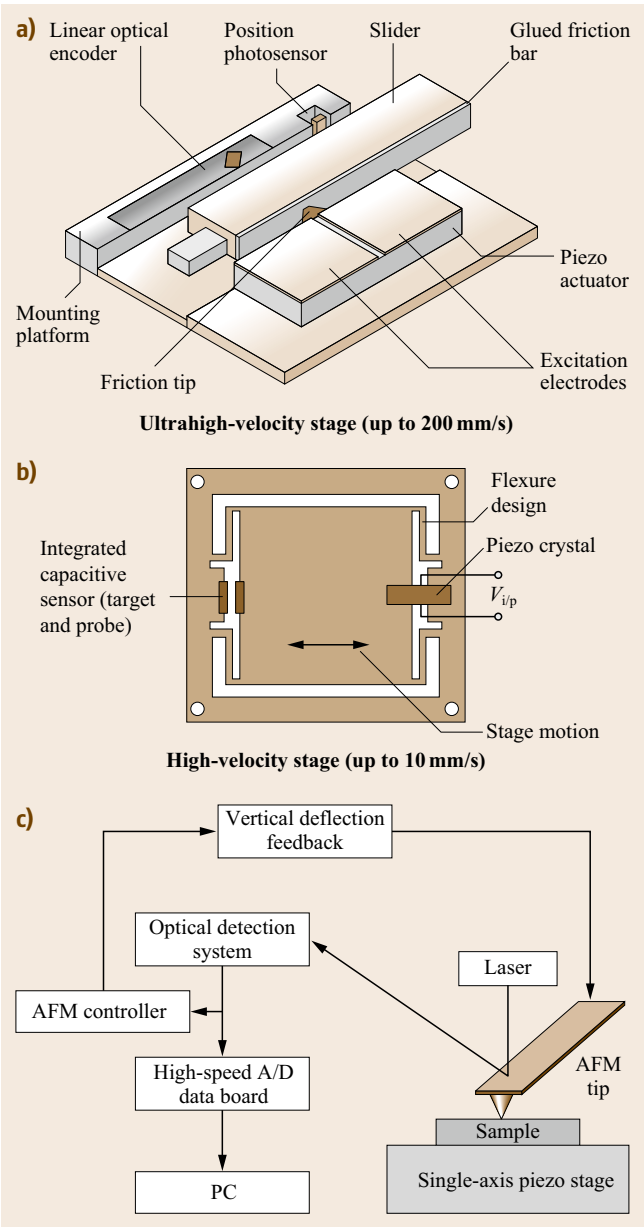

Fig. 27.28a–c Schematics of (a) an ultrahigh-velocity piezo stage, (b) high-velocity piezo stage, and (c) a block diagram of the high-speed data collection and processing system used for friction force measurement (after [27.38, 109])

mass model [27.115] as follows

$$m\ddot{x}_t = -\eta\dot{x}_t - k(x_M - x_t) - F\,, \qquad (27.6)$$

where m is the effective mass of the system, η the viscous damping coefficient, k the spring constant of the cantilever, $x_M = v_M t$ the equilibrium position of the

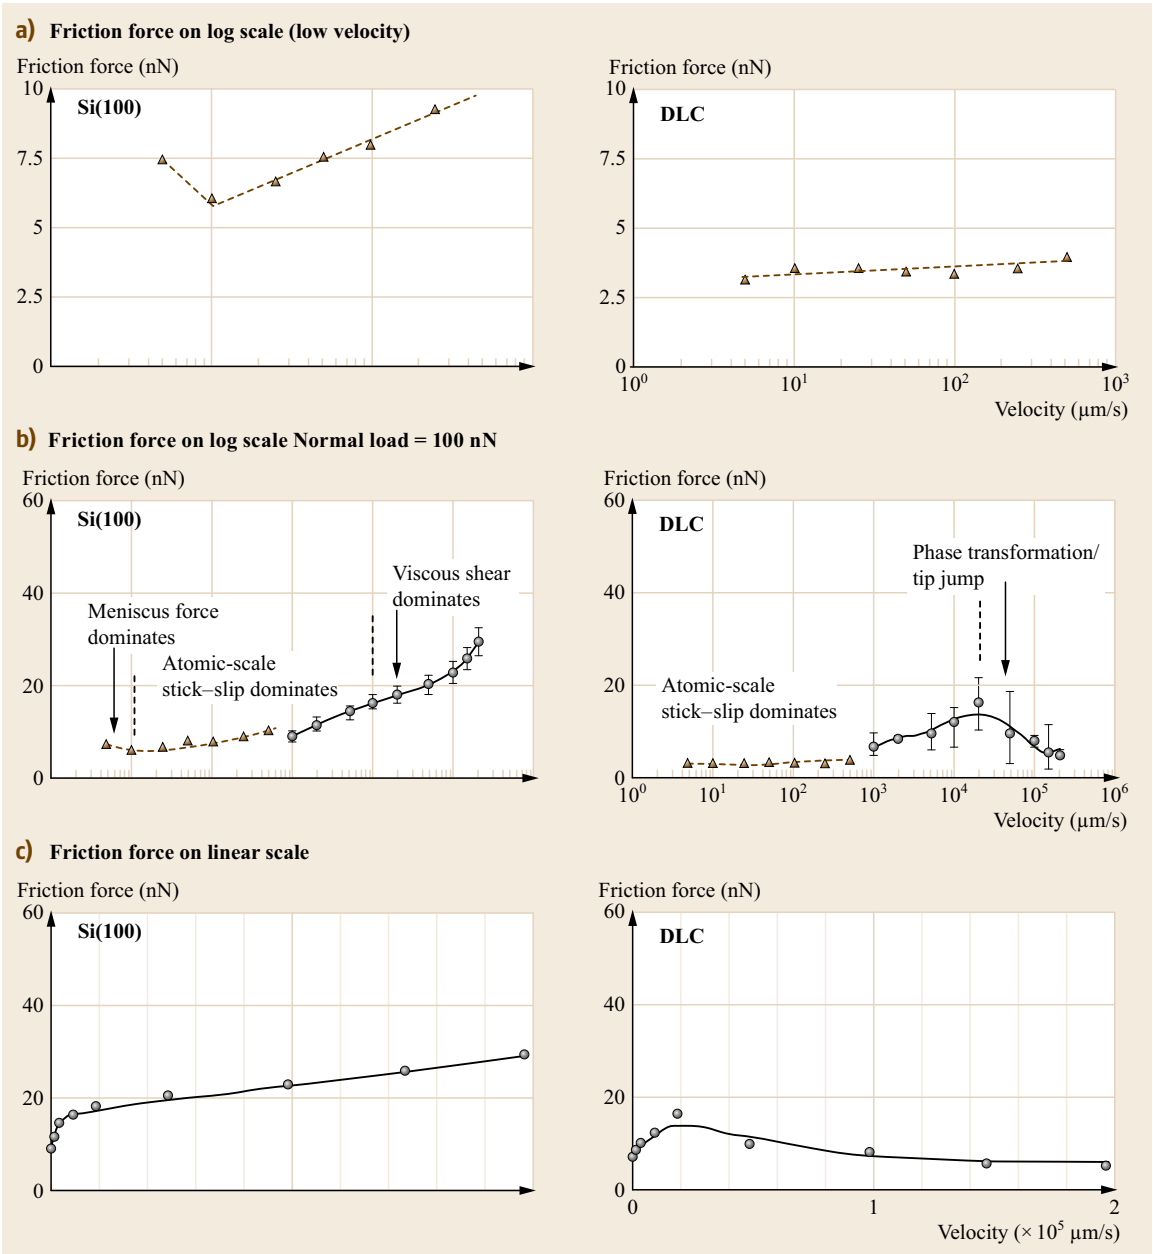

Fig. 27.29a–c Friction force as a function of sliding velocity obtained for a 25 μm scan length using a high-velocity stage (*dotted line*) and a 1000 μm scan length using an ultrahigh-velocity stage (*solid line*). In the *top two rows* (**a**,**b**), velocity is plotted on a log scale. (**a**) shows a lower velocity range – between 1 and 500 μm/s. (**c**) shows the data at a higher range of velocity on the linear scale (after [27.114])

cantilever, x_t the position of the tip, and F the external force. The lateral force is expressed as $F_l = k(x_M - x_t)$, and the friction force F_{fric} is the lateral force averaged over time.

For velocities lower than 2×10^4 μm/s, the damping part ($\eta\dot{x}_t$) in (27.6) is comparatively low, and atomic-scale stick-slip dominates. To investigate the stick-slip, *Tomlinson* [27.96] assumed a periodic surface with potential

$$V(x) = V_0\left[1-\cos\left(\frac{2\pi x}{a}\right)\right], \qquad (27.7)$$

where V_0 is surface barrier potential height, and a is the lattice constant of the surface. Then the force (F) in (27.6) is expressed as

$$F = V'(x) = \frac{2\pi V_0}{a} \sin\left(\frac{2\pi x}{a}\right) . \tag{27.8}$$

On the basis of the Tomlinson model, and taking into account the effect of thermal activation, or the elastic energy stored in the cantilever during sliding, *Gnecco* et al. [27.116] derived the relationship between the friction force and velocity, which is expressed as

$$F_{\text{stick-slip}} = F_0 + c \ln v , \tag{27.9}$$

where F_0 and c are constants.

When the tip slides on a solid surface covered by a viscous film such as a water film at high velocities, the friction force (F_{fric}) is related to the velocity and viscosity of the film given by [27.103, 104]

$$F_{\text{fric}} = \mu N + \eta \dot{\gamma} A \approx \mu N + \frac{\eta v A}{d} , \tag{27.10}$$

where μ is the coefficient of friction between the dry sliding bodies, N is the applied load, τ is the shear stress, A is the real contact area, η is the viscosity of the film, $\dot{\gamma}$ is the velocity gradient, v is the sliding velocity, and d is the thickness of the film. From (27.10), the relationship between the friction force and the sliding velocity is linear when sliding on a viscous coating. The relationship is consistent with the conclusion by *Helman* et al. [27.117] about the linear relationship between the friction force and the sliding velocity ($F_{\text{fric}} \approx \eta v_{\text{M}}$) at high sliding velocities for a spring mass model in (27.6) which simulates the AFM tip sliding on a viscous liquid.

The sliding of the tip on a hydrophilic surface with water films at low velocities, middle velocities, and high velocities is schematically illustrated in Fig. 27.30a [27.114]. It should be noted that the stick-slip mechanism considered by *Gnecco* et al. [27.116] was based on investigations on a dry surface. In this study, although the water was condensed on the Si(100) surface, the water film on the surface would not have significant effect on the energy dissipation due to the surface variation at relatively low velocities. Thus, the linear relationship between friction and $\log(v)$ could be maintained. When the velocity increases above a certain value, the tip would lose direct contact with the sample surface and shear the water film. At velocities higher than $2\times10^4\,\mu\text{m/s}$, the asperity deformation from the high velocity impact could be another mechanism as proposed by *Tambe* and *Bhushan* [27.111].

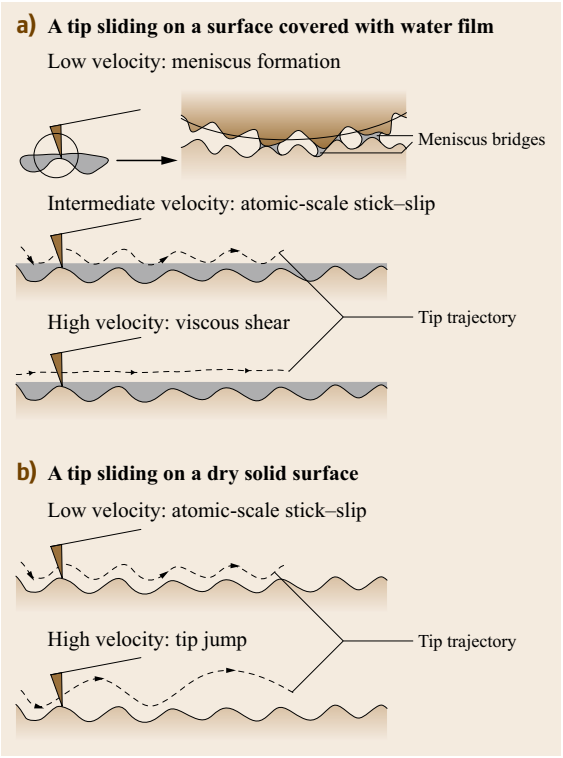

Fig. 27.30a,b Schematics of a tip sliding at different velocities on **(a)** a water-covered surface, and **(b)** a dry surface (after [27.114])

For the DLC film, since the surface is nearly hydrophobic, a uniform water film would not form on the surface. When sliding at a velocity lower than $1000\,\mu\text{m/s}$, the friction force increased linearly with $\log(v)$, which could also be explained by atomic-scale stick-slip. At velocities higher than $1000\,\mu\text{m/s}$, the friction force increased with velocity until the local maximum at the velocity of $2\times10^4\,\mu\text{m/s}$, then decreased with velocity. The decreasing trend in friction at higher velocities could be due to tip jump during sliding. The tip jump is illustrated in Fig. 27.30b. The tip jump results in the reduction of lateral force during sliding. Variation of the friction force with distance, indicative of the tip jump, was observed from the lateral force signal (not shown). When damping is low and velocity is high, the tip could jump several periodical cycles or several peaks [27.118]. At a given low damping coefficient, the slip results in a low transient lateral force, as discussed by *Fusco* and *Fasolino* [27.118]. Thus, the average lateral force (friction force) over the scan length is low. The tip jump could also cause high velocity impact of asperities on the DLC surface, resulting in the phase transformation of DLC from sp^3 to sp^2, as explained by *Tambe* and *Bhushan* [27.111]. The

sp^2-phase layer can act as a lubricant and reduce the interfacial friction.

27.2.6 Nanoscale Friction and Wear Mapping

Contrary to the classical friction laws postulated by Amontons and Coulomb centuries ago, a nanoscale friction force is found to be strongly dependent on the normal load and sliding velocity. Many materials, coatings, and lubricants that have wide applications show reversals in friction behavior corresponding to transitions between different friction mechanisms [27.14, 38, 110, 111, 119]. Most of the analytical models developed to explain nanoscale friction behavior have remained limited in their focus and have left investigators at a loss when trying to explain friction behavior scaling multiple regimes. Nanoscale friction maps provide fundamental insights into friction behavior. They help identify and classify the dominant friction mechanisms, as well as determine the critical operating parameters that influence transitions between different mechanisms [27.111, 112]. Figure 27.31 shows a nanoscale friction map for DLC with the friction mapped as a function of the normal load and the sliding velocity [27.120]. The contours represent constant friction force lines. The friction force is seen to increase with the normal load as well as velocity. The increase in friction force with velocity is the result of atomic-scale stick-slip. This is a result of thermal activation of the irreversible jumps of the AFM tip that arise from overcoming of the energy barrier between the adjacent atomic positions, as described earlier. The concentric contour lines corresponding to the constant friction force predicts a peak point, a point where the friction force reaches maxima and beyond which point any further increase in the normal load or the sliding velocity results in a decrease in friction force. This characteristic behavior for DLC is the result of phase transformation of DLC into a graphite-like phase by sp^3 to sp^2 phase transition, as described earlier. During the AFM experiments, the Si_3N_4 tip gives rise to contact pressures in the range of 1.8–4.4 GPa for DLC for normal loads of 10–150 nN [27.121]. A combination of the high contact pressures that are encountered on the nanoscale and the high frictional energy dissipation arising from the asperity impacts at the tip–sample interface due to the high sliding velocities accelerates a phase transition process whereby a low shear strength graphite-like layer is formed at the sliding interface.

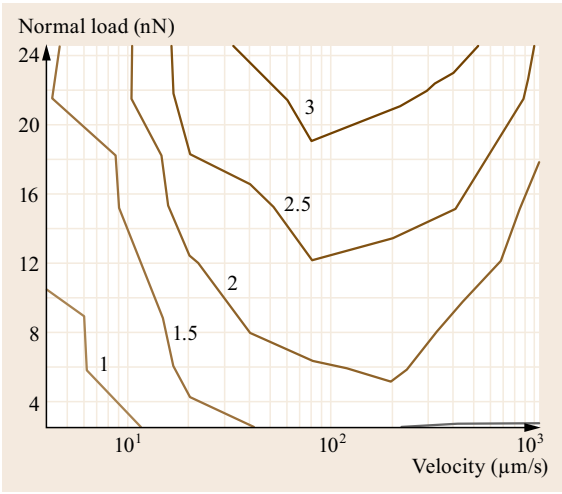

Fig. 27.31 Contour map showing friction force dependence on normal load and sliding velocity for DLC (after [27.97])

Similar to friction mapping, one way of exploring the broader wear patterns is to construct wear mechanism maps that summarize data and models for wear, thereby showing mechanisms for any given set of conditions to be identified [27.119, 122–124]. Wear of sliding surfaces can occur through one or more wear mechanisms, including adhesive, abrasive, fatigue, impact, corrosive, and fretting [27.103, 104]. *Tambe* and *Bhushan* [27.121, 124] performed AFM experiments to develop nanoscale wear maps. Figure 27.32 shows a nanowear map generated for a DLC sample by simultaneously varying the normal load and the sliding velocity over the entire scan area. The wear map was generated for a normal load range of 0–1000 nN and sliding velocity range of 0–2.5 mm/s. Wear debris, believed to result from phase transformation of DLC by sp^3 to sp^2 phase transition, was seen to form only for a high value of sliding velocities times normal loads, i. e., only beyond a certain threshold of friction energy dissipation [27.121, 124]. Hence the wear region exhibits a transition line indicating that for low velocities and low normal loads there is no phase transformation. For clarity, the wear mark corners are indicated by white dots in the AFM image (top) and the two zones of interest over the entire wear mark are schematically illustrated in Fig. 27.32 (top).

Nanoscale friction and wear mapping are novel techniques for investigating friction and wear behavior on the nanoscale over a range of operating parameters. By simultaneously varying the sliding velocity and normal load over a large range of values, nanoscale friction and wear behavior can be mapped, and the transitions between different wear mechanisms can be investigated. These maps help identify and demarcate critical operating parameters for different wear mechanisms and are very important tools in the process of design and selection of materials/coatings.

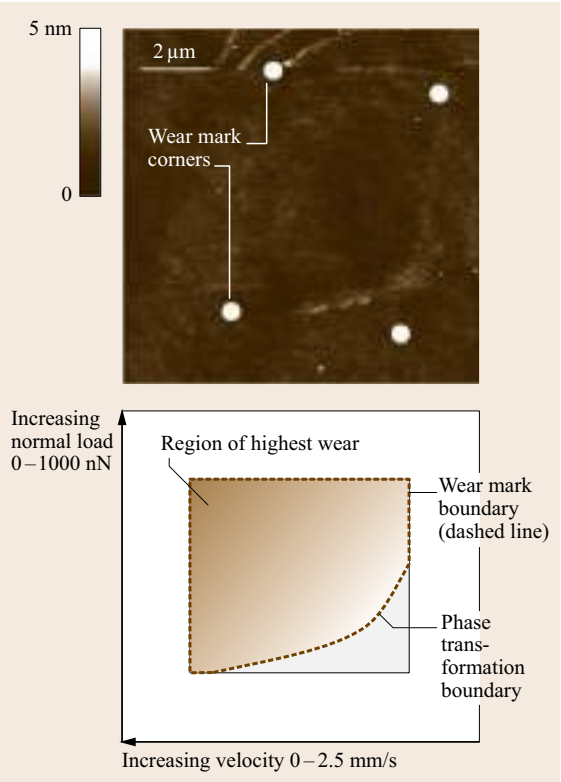

Fig. 27.32 Nanowear map (AFM image and schematic) illustrating the effect of sliding velocity and normal load on the wear of DLC resulting from phase transformation. The *curved area* shows debris lining and is indicative of the minimum frictional energy needed for phase transformation. For clarity, the wear mark corners are indicated by *white dots* in the AFM image and the various zones of interest over the entire wear mark are schematically illustrated (after [27.124])

27.2.7 Adhesion and Friction in Wet Environments

Experimental Observations

Relative humidity affects adhesion and friction for dry and lubricated surfaces [27.19, 31, 125]. Figure 27.33 shows the variation of single point adhesive force measurements as a function of tip radius on an Si(100) sample for several humidities. The adhesive force data are also plotted as a function of relative humidity for several tip radii. The general trend at humidities up to the ambient is that a 50 nm radius Si_3N_4 tip exhibits a lower adhesive force as compared to the other microtips of larger radii. However, in the latter case, values are similar. Thus, for the microtips there is no appreciable variation in adhesive force with tip radius at a given humidity up to the ambient. The adhesive force increases as relative humidity increases for all tips.

The sources of adhesive force between a tip and a sample surface are van der Waals attraction and meniscus formation [27.19, 103, 104]. The relative magnitudes of the forces from the two sources are dependent upon various factors including the distance between the tip and the sample surface, their surface roughness, their hydrophobicity, and the relative humidity [27.126]. For most rough surfaces, the meniscus contribution dominates at moderate to high humidities which arise from the capillary condensation of water vapor from the environment. If enough liquid is present to form a meniscus bridge, the meniscus force should increase with an increase in tip radius (proportional to tip radius for a spherical tip). In addition, an increase in the tip radius results in an increased contact area leading to higher values of van der Waals forces. However, if nanoasperities on the tip and the sample are considered then the number of contacting and near-contacting asperities forming meniscus bridges increases with an increase of humidity leading to an increase in meniscus forces. These explain the trends observed in Fig. 27.33. From the data, the tip radius has little effect on the adhesive forces at low humidities but increases with tip radius at high humidity. Adhesive force also increases with an increase in humidity for all tips. This observation suggests that thickness of the liquid film at low humidities is insufficient to form continuous meniscus bridges to affect adhesive forces in the case of all tips.

Figure 27.33 also shows the variation in the coefficient of friction as a function of the tip radius at a given humidity, and as a function of the relative humidity for a given tip radius for Si(100). It can be observed that for 0% RH (relative humidity), the coefficient of friction is about the same for the tip radii except for the largest tip, which shows a higher value. At all other humidities, the trend consistently shows that the coefficient of friction increases with the tip radius. An increase in friction with tip radius at low to moderate humidities arises from the increased contact area (due to higher van der Waals forces) and higher values of the shear forces required for a larger contact area. At high humidities, similar to adhesive force data, an increase with tip radius occurs because of both contact area and meniscus effects. Although the AFM/FFM measurements are able to measure the combined effect of the contribution of van der Waals and meniscus forces towards the friction force or adhesive force, it is difficult to measure their individual contributions separately. It can be seen that for all tips, the coefficient of friction increases with humidity to about ambient, beyond which it starts to decrease. The initial increase in the coefficient of friction with humidity arises from the fact that the thickness of

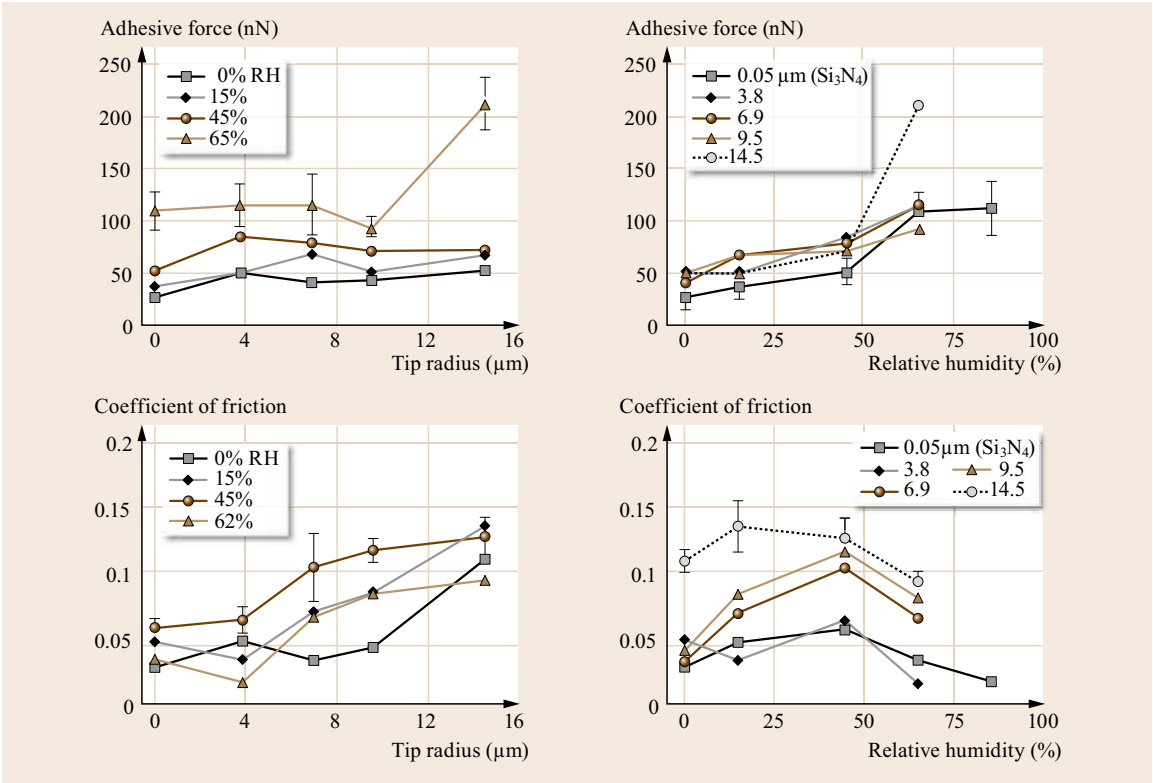

Fig. 27.33 Adhesive force and coefficient of friction as a function of tip radius at several humidities and as a function of relative humidity at several tip radii on Si(100) (after [27.31])

the water film increases with an increase in the humidity, which results in a larger number of nanoasperities forming meniscus bridges and leads to higher friction (larger shear force). The same trend is expected with the microtips beyond 65% RH. This is attributed to the fact that at higher humidities, the adsorbed water film on the surface acts as a lubricant between the two surfaces. Thus, the interface is changed at higher humidities, resulting in lower shear strength and hence lower friction force and coefficient of friction.

Adhesion and Friction Force Expressions for a Single-Asperity Contact

We now obtain the expressions for the adhesive force and coefficient of friction for a single-asperity contact with a meniscus formed at the interface (Fig. 27.34). For a spherical asperity of radius R in contact with a flat and smooth surface with the composite modulus of elasticity E^* and in the presence of liquid with a concave meniscus, the attractive meniscus force (adhesive force), designated as F_m or W_{ad}, is given as [27.19, 103, 104]

$$W_{ad} = 2\pi R\gamma(\cos\theta_1 + \cos\theta_2)\,, \tag{27.11}$$

where γ is the surface tension of the liquid, and θ_1 and θ_2 are the contact angles of the liquid with surfaces 1 and 2, respectively. For an elastic contact for both extrinsic (W) and intrinsic (W_{ad}) normal load, the friction force is given as,

$$F_e = \pi\tau\left[\frac{3(W + W_{ad})R}{4E^*}\right]^{2/3}, \tag{27.12}$$

where W is the external load, and τ is the average shear strength of the contacts. (The surface energy effects are not considered here.) Note that adhesive force increases linearly with an increase in the tip radius, and the friction force increases with an increase in the tip radius as $R^{2/3}$ and with normal load as $(W + W_{ad})^{2/3}$. The experimental data in support of $W^{2/3}$ dependence on the friction force can be found in various references [27.67]. The coefficient of friction μ_e is obtained from (27.12) as

$$\mu_e = \frac{F_e}{(W + W_{ad})} = \pi\tau\left(\frac{3R}{4E^*}\right)^{2/3}\frac{1}{(W + W_{ad})^{1/3}}\,. \tag{27.13}$$

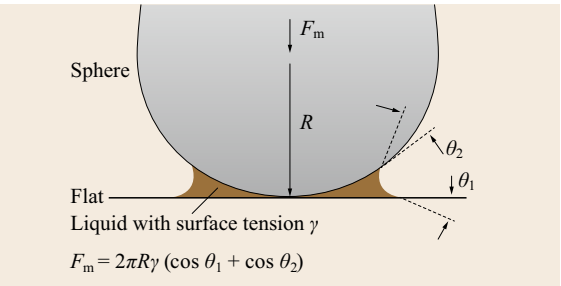

Fig. 27.34 Meniscus formation from a liquid condensate at the interface for a sphere in contact with a plane surface

In the plastic contact regime [27.103, 104], the coefficient of friction μ_p is obtained as

$$\mu_p = \frac{F_p}{W + W_{ad}} = \frac{\tau}{H_s}\,, \tag{27.14}$$

where H_s is the hardness of the softer material. Note that in the plastic contact regime, the coefficient of friction is independent of external load, adhesive contributions, and surface geometry.

For comparisons, for multiple-asperity contacts in the elastic contact regime the total adhesive force W_{ad} is the summation of adhesive forces at n individual contacts,

$$W_{ad} = \sum_{i=1}^{n} (W_{ad})_i \tag{27.15}$$

and

$$\mu_e \approx \frac{3.2\tau}{E^*(\sigma_p/R_p)^{1/2} + (W_{ad}/W)}\,,$$

where σ_p and R_p are the standard deviation of summit heights and average summit radius, respectively. Note that the coefficient of friction depends upon the surface roughness. In the plastic contact regime, the expression for μ_p in (27.14) does not change.

The source of the adhesive force in a wet contact in the AFM experiments being performed in an ambient environment includes mainly attractive meniscus force due to capillary condensation of water vapor from the environment. The meniscus force for a single contact increases with an increase in the tip radius. A sharp AFM tip in contact with a smooth surface at low loads (on the order of a few nN) for most materials can be simulated as a single-asperity contact. At higher loads, for rough and soft surfaces, multiple contacts would occur. Furthermore, at low loads (nN range) for most materials, the local deformation would be primarily elastic. Assuming that the shear strength of contacts does not change, the adhesive force for smooth and hard surfaces at low normal load (on the order of a few nN) (for a single-asperity contact in the elastic contact regime) would increase with an increase in tip radius, and the coefficient of friction would decrease with an increase in total normal load as $(W + W_{ad})^{-1/3}$ and would increase with an increase of tip radius as $R^{2/3}$. In this case, Amontons' law of friction which states that the coefficient of friction is independent of the normal load and is independent of the apparent area of contact does not hold. For a single-asperity plastic contact and multiple-asperity plastic contacts, neither the normal load nor tip radius comes into play in the calculation of the coefficient of friction. In the case of multiple-asperity contacts, the number of contacts increase with an increase of normal load, therefore the adhesive force increases with an increase in load.

In the data presented earlier in this section, the effect of tip radius and humidity on the adhesive forces and the coefficient of friction is investigated for experiments with the Si(100) surface at loads in the range of 10–100 nN. The multiple-asperity elastic-contact regime is relevant for this study involving large tip radii. An increase in humidity generally results in an increase in the number of meniscus bridges, which would increase the adhesive force. As was suggested earlier, that increase in humidity also may decrease the shear strength of contacts. A combination of an increase in adhesive force and a decrease in shear strength would affect the coefficient of friction. An increase in the tip radius would increase the meniscus force (adhesive force). A substantial increase in the tip radius may also increase interatomic forces. These effects influence the coefficient of friction with an increase in the tip radius.

27.2.8 Separation Distance Dependence of Meniscus and van der Waals Forces

When two surfaces are in close proximity, sources of adhesive forces are weak van der Waals attraction and meniscus formation. Relative magnitudes of the forces from the two sources are dependent upon various factors including the interplanar separation, their surface roughness, their hydrophobicity, and relative humidity (liquid volume) [27.126]. Meniscus contribution dominates at moderate to high humidities, and van der Waals forces dominate at asperities a few nm apart. In some micro/nanocomponents, it is important to know the relative contribution of two sources as a function of given interplanar separation so as to design an interface for low adhesion. For example, if two ultrasmooth surfaces come in close proximity with interplanar separation on

the order of a nm, van der Waals forces may dominate, and their magnitude may be reduced by creating bumps on one of the interfaces. This analysis is also of interest in AFM studies to understand distance dependence of adhesive forces as the tip goes in and out of contact.

Stifter et al. [27.126] modeled the contact of a parabolic-shaped tip and a flat, smooth sample surface. The tip may represent a surface asperity on an interface or an AFM tip in an AFM experiment. They calculated van der Waals and meniscus forces as a function of different parameters, namely, tip geometry, tip–sample starting distance, relative humidity, surface tension, and contact angles. They compared the meniscus forces with van der Waals forces to understand their relative importance in various operating conditions.

The interacting force between tip and sample in dry conditions is the Lennard-Jones force derived from the Lennard-Jones potential. The Lennard-Jones potential is composed of two interactions – the van der Waals attraction and the Pauli repulsion. Van der Waals forces are significant because they are always present. For a parabolic tip above a half-plane with a distance D between tip and plane, the Lennard-Jones potential is obtained by integrating the atomic potential over the volume of the tip and sample. It is given as [27.126]

$$V(D) = \frac{c}{12}\left(-\frac{A}{D} + \frac{B}{210D^7}\right), \qquad (27.16)$$

where c is the width of the parabolic tip (= diameter in the case of a spherical tip), and A and B are two potential parameters, where A is the Hamaker constant. This equation provides expressions for attractive and repulsive parts. The calculations were made for Lennard-Jones force (total) and van der Waals force (attractive part) for two Hamaker constants: 0.04×10^{-19} J (representative of polymers) and 3×10^{-19} J (representative of ceramics), and meniscus force for a water film ($\gamma_\ell = 72.5\,\mathrm{N/m}$). Figure 27.35 shows various forces as a function of separation distance. The effect of two relative humidities and three tip radii was also studied as to their effect on meniscus forces. The two dashed curves indicate the spread of possible van der Waals forces for two Hamaker constants. The figure shows that meniscus forces exhibit weaker distance dependence. The meniscus forces can be stronger or weaker than van der Waals forces for distances smaller than about 0.5 nm. For longer distances, the meniscus forces are stronger than the van der Waals forces. Van der Waals forces must be considered for a tip–sample distance up to a few nm ($D < 5$ nm). The meniscus forces operate up to the break of the meniscus in the range from 5 to 20 nm [27.126].

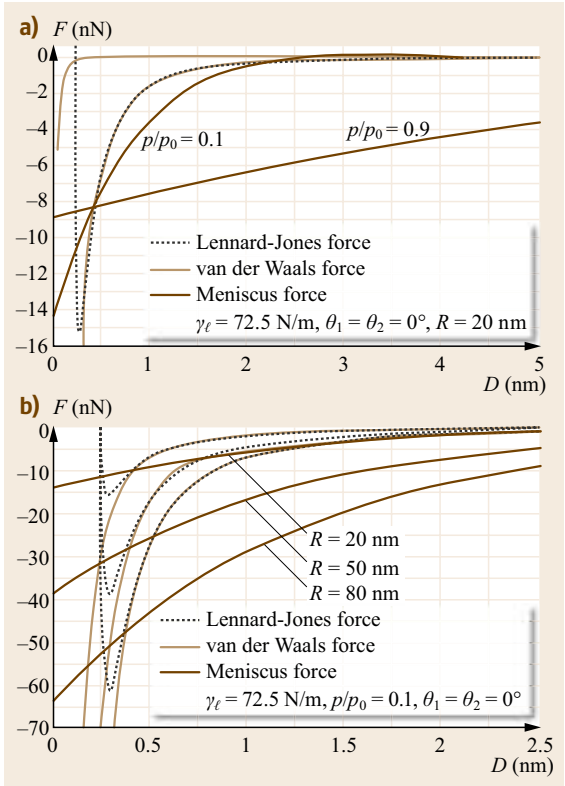

Fig. 27.35a,b Relative contribution of meniscus, van der Waals and Lennard-Jones forces (F) as a function of separation distance (D) and at **(a)** two values of relative humidity (p/p_o) for tip radius of 20 nm and Hamaker constants of 0.04×10^{-19} and 3.0×10^{-19} J, and **(b)** three tip radii (R) and a Hamaker constant of 3.0×10^{-19} J (after [27.126])

27.2.9 Scale Dependence in Friction

Table 27.3 presents the adhesive force and the coefficient of friction data obtained on the nanoscale and microscale [27.25, 110, 127, 128]. Adhesive force and coefficient of friction values on the nanoscale are about half to one order of magnitude lower than that on the microscale. Scale dependence is clearly observed in this data. As a further evidence of scale dependence, Table 27.4 shows the coefficient of friction measured for Si(100), HOPG, natural diamond, and DLC on the nanoscale and microscales. It is clearly observed that friction values are scale-dependent.

To estimate the scale length, the apparent contact radius at test loads is calculated and presented in Table 27.3. Mean apparent pressures are also calculated and presented. For nanoscale AFM experiments, it is assumed that an AFM tip coming in contact with a flat surface represents a single-asperity and elastic contact,

Table 27.3 Micro- and nanoscale values of adhesive force and coefficient of friction in micro- and nanoscale measurements (after [27.127])

Sample	Adhesive force		Coefficient of friction

and Hertz analysis was used for the calculations. In the microscale experiments, a ball coming in contact with a flat surface represents multiple-asperity contacts due to the roughness, and the contact pressure of the asperity contacts is higher than the apparent pressure. For calculation of a characteristic scale length for multiple asperity contacts, which is equal to the apparent length of contact, Hertz analysis was also used. This analysis provides an upper limit on apparent radius and lower limit on the mean contact pressure.

There are several factors responsible for the differences in the coefficients of friction at the micro- and nanoscale. Among them are the contributions from wear and contaminant particles, transition from elasticity to plasticity, and the meniscus effect [27.134–137]. The contribution of wear and contaminant particles is more significant at the macro/microscale because of the larger number of trapped particles, referred to as third-body contribution. It can be argued that for the nanoscale AFM experiments the asperity contacts are predominantly elastic (with average real pressure being less than the hardness of the softer material), and adhesion is the main contribution to the friction, whereas for the microscale experiments the asperity contacts are predominantly plastic, and deformation is an important factor. It will be shown later that hardness has a scale effect; it increases with decreasing scale and is responsible for less deformation on a smaller scale. The meniscus effect results in an increase of friction with increasing tip radius (Fig. 27.33). Therefore, third-

body contribution, scale-dependent hardness, and other properties transition from elastic contacts in nanoscale contacts to plastic deformation in microscale contacts, and meniscus contribution plays an important role.

Friction is a complex phenomenon, which involves asperity interactions involving adhesion and deformation (plowing). Adhesion and plastic deformation imply energy dissipation, which is responsible for friction (Fig. 27.36) [27.103, 104]. A contact between two bodies takes place on high asperities, and the real area of contact (A_r) is a small fraction of the apparent area of contact. During contact of two asperities, a lateral force may be required for asperities of a given slope to climb against each other. This mechanism is known as the ratchet mechanism, and it also contributes to the friction. Wear and contaminant particles present at the interface, referred as the *third body*, also contribute to the friction (Fig. 27.36). In addition, during contact even at low humidity, a meniscus is formed (Fig. 27.34). Generally, any liquid that wets or has a small contact angle on surfaces will condense from vapor into cracks and pores on surfaces as bulk liquid and in the form of annular-shaped capillary condensate in the contact zone. A quantitative theory of scale effects in friction should consider the scale effect on physical properties relevant to various contributions.

According to the adhesion and deformation model of friction, the coefficient of dry friction μ is a sum of the adhesion component μ_a and the deformation (plowing) component μ_d. The latter, in the presence of particles, is a sum of the asperity summits deformation component μ_{ds} and particles deformation component μ_{dp}, so that the total coefficient of friction is [27.136]

$$\begin{aligned}\mu &= \mu_a + \mu_{ds} + \mu_{dp} \\ &= \frac{F_a + F_{ds} + F_{dp}}{W} \\ &= \frac{A_{ra}\tau_a + A_{ds}\tau_{ds} + A_{dp}\tau_{dp}}{W} ,\end{aligned} \tag{27.17}$$

where W is the normal load, F is the friction force, A_{ra}, A_{ds}, A_{dp} are the real areas of contact during adhesion, two-body deformation and with particles, respectively, and τ is the shear strength. The subscripts a, ds, and dp correspond to adhesion, summit deformation, and particle deformation, respectively.

The adhesional component of friction depends on the real area of contact and adhesion shear strength. The real area of contact is scale-dependent due to the scale dependence of the surface roughness (for elastic and plastic contact) and due to the scale dependence of hardness (for plastic contact) [27.136]. We limit the analysis here to the multiple-asperity contact. For this case, scale L is defined as apparent size of contact between two bodies. (For completeness, for a single-asperity contact, scale is defined as the contact diameter.) It is suggested by *Bhushan* and *Nosonovsky* [27.135] that for many materials, dislocation-assisted sliding (microslip) is the main mechanism responsible for shear strength. They considered dislocation-assisted sliding based on the assumption that contributing dislocations are located in a subsurface volume. The thickness of this volume is limited by the distance which dislocations can climb ℓ_s (material parameter) and by the radius of contact a. They showed that τ_a is scale-dependent. Based on this, the adhesional components of the coefficient of friction in the case of elastic contact μ_{ae} and in the case of plastic contact μ_{ap} are given as [27.135]

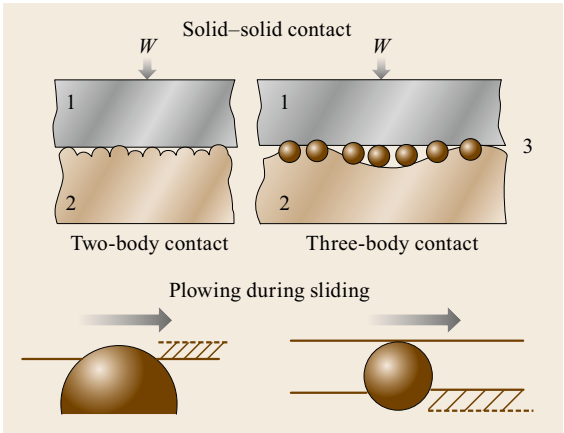

Fig. 27.36 Schematic of two- and three-body dry rough surface contacts

$$\mu_{ae} = \frac{\mu_{ae0}}{\sqrt{\ell + (\ell_s\sqrt{a_0})}} \left(\frac{L}{L_{\ell c}}\right)^{m-n} \sqrt{1 + \left(\frac{L_s}{L}\right)^m}, \quad L < L_{\ell c} \tag{27.18}$$

$$\mu_{ap} = \mu_{ap0} \sqrt{\frac{1 + (\ell_d\sqrt{a_0})}{1 + (\ell_s\sqrt{a_0})}} \sqrt{\frac{1 + (L_s/L)^m}{1 + (L_d/L)^m}}, \quad L < L_{\ell c} , \tag{27.19}$$

where μ_{ae0} and μ_{ap0} are values of the coefficient of friction at the macroscale ($L \geq L_{\ell c}$), m and n are indices which characterize the scale dependence of surface parameters, $\bar{a}_0$ is the macroscale value of mean contact radius, $L_{\ell c}$ is the long wavelength limit for scale dependence of the contact parameters, ℓ_s and ℓ_d are material-specific characteristic length parameters, and L_s and L_d are length parameters related to ℓ_s and ℓ_d. Scale dependence of the adhesional component of the

coefficient of friction is presented in Fig. 27.37, based on (27.18) and (27.19).

On the basis of the assumption that multiple asperities of two rough surfaces in contact have a conical shape, the two-body deformation component of friction can be determined as [27.103, 104]

$$\mu_{ds} = \frac{2\tan\theta_r}{\pi}\,, \tag{27.20}$$

where θ_r is the roughness angle (or attack angle) of a conical asperity. Mechanical properties affect the real area of contact and shear strength, and these cancel out in (27.16) [27.136]. On the basis of a statistical analysis of a random Gaussian surface [27.136]

$$\mu_{ds} = \frac{2\sigma_0}{\pi\beta_0 *}\left(\frac{L}{L_{\ell c}}\right)^{n-m} = \mu_{ds0}\left(\frac{L}{L_{\ell c}}\right)^{n-m}, \quad L < L_{\ell c}\,, \tag{27.21}$$

where μ_{ds0} is the value of the coefficient of summits deformation component of the coefficient of friction at macroscale ($L \geq L_{\ell c}$), and σ_0 and β_0^* are macroscale values of standard deviation of surface heights and correlation length, respectively, for a Gaussian surface. The scale dependence for the two-body deformation component of the coefficient of friction is presented in Fig. 27.38 (top curve) for $m = 0.5$, $n = 0.2$, based on (27.21). The coefficient of friction increases with decreasing scale, according to (27.21). This effect is a consequence of increasing average slope or roughness angle.

For the three-body deformation, it is assumed that wear and contaminant particles at the borders of the contact region are likely to leave the contact region, while the particles in the center are likely to stay (Fig. 27.39). The plowing three-body deformation is plastic and, assuming that particles are harder than the bodies, the shear strength τ_{dp} is equal to the shear yield strength of the softer body τ_Y, the three-body deformation component of the coefficient of friction is given by [27.137]

$$\mu_{dp} = \mu_{dp0} n_{tr} \frac{\overline{d}^2}{\overline{d}_0^2} \frac{\sqrt{1+2\ell_d\sqrt{\overline{d}}}}{\sqrt{1+2\ell_d\sqrt{\overline{d}_0}}}\,, \tag{27.22}$$

where $\overline{d}$ is the mean particle diameter, $\overline{d}_0$ is the macroscale value of mean particle diameter, n_{tr} is the number of trapped particles divided by total number of particles, and μ_{dp0} is the macroscale ($L \to \infty$, $n_{tr} \to 1$)

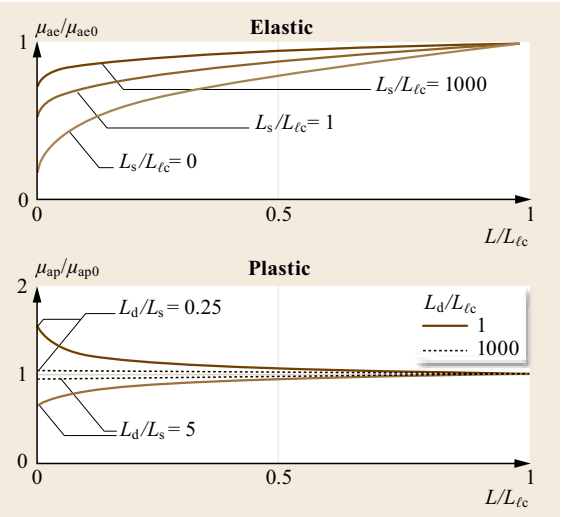

Fig. 27.37 Normalized results for the adhesional component of coefficient of friction, as a function of $L/L_{\ell c}$ for the multiple-asperity contact. Data are presented for $m = 0.5$, $n = 0.2$. For the multiple-asperity plastic contact, data are presented for two values of $L_d/L_{\ell c}$ (after [27.136])

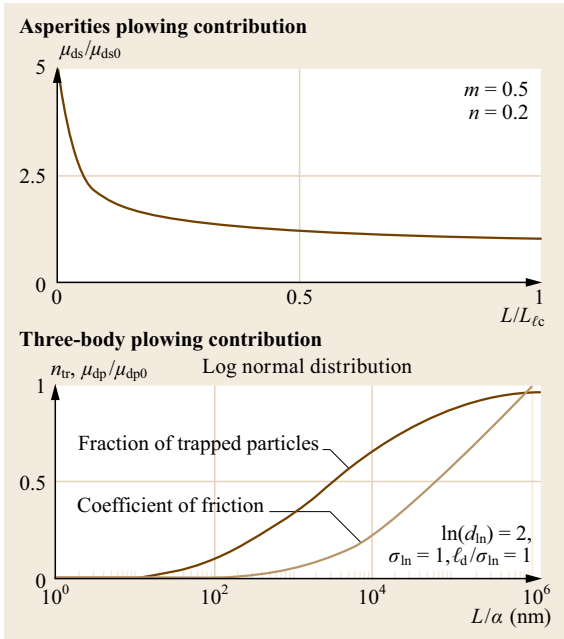

Fig. 27.38 Normalized results for the two-body deformation component of the coefficient of friction, and the number of trapped particles divided by the total number of particles and three-body deformation component of the coefficient of friction, normalized by the macroscale value for log-normal distribution of debris size, where α is the probability of a particle in the border zone to leave the contact region. Various constants given in the figure correspond to log-normal distribution (after [27.136])

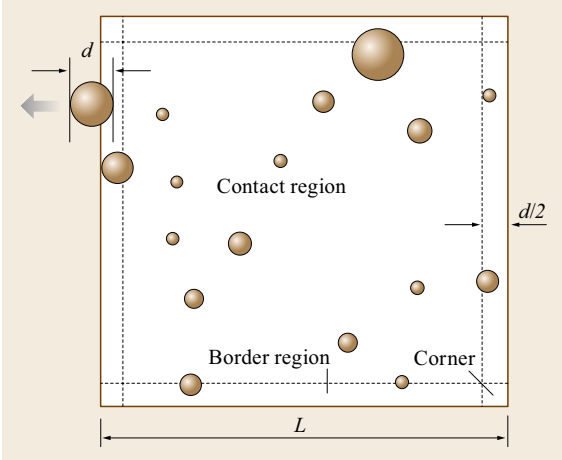

Fig. 27.39 Schematics of debris at the contact zone and at its border region. A particle of diameter d in the border region of $d/2$ is likely to leave the contact zone (after [27.136])

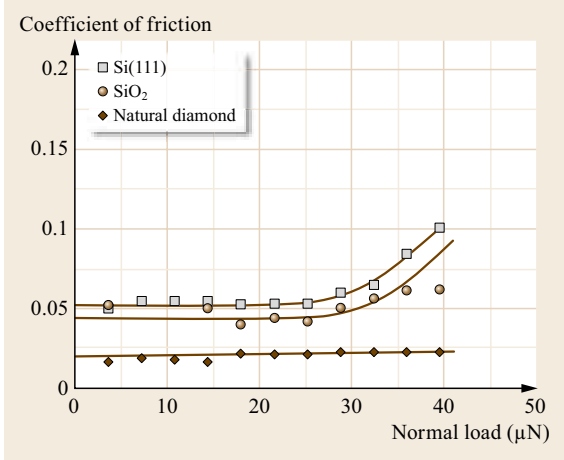

Fig. 27.40 Coefficient of friction as a function of normal load and for Si(111), SiO_2 coating and natural diamond. Inflections in the *curves* for Si and SiO_2 correspond to the contact stresses equal to the hardnesses of these materials (after [27.60])

value of the third-body deformation component of the coefficient of friction. Scale dependence of μ_{dp} is shown in Fig. 27.38 (bottom curve) based on (27.22). Based on the scale effect predictions presented in Figs. 27.37 and 27.38, trends in the experimental results in Table 27.3 can be explained.

Scale dependence of meniscus effects in friction, wear, and interface temperature can be analyzed in a similar way [27.137].

To demonstrate the load dependence of friction at the nano/microscale, the coefficient of friction as a function of normal load is presented in Fig. 27.40. The coefficient of friction was measured by *Bhushan* and *Kulkarni* [27.60] for a Si_3N_4 tip versus Si, SiO_2, and natural diamond using an AFM. They reported that for low loads, the coefficient of friction is independent of load and increases with increasing load after a certain load. It is noted that the critical value of loads for Si and SiO_2 corresponds to stresses equal to their hardness values, which suggests that the transition to plasticity plays a role in this effect. The friction values at higher loads for Si and SiO_2 approach that of macroscale values.

27.3 Micro/Nanoscale Wear and Scratching, Local Deformation, and Nanofabrication/Nanomachining

27.3.1 Nanoscale Wear

Bhushan and *Ruan* [27.24] conducted nanoscale wear tests on polymeric magnetic tapes using conventional silicon nitride tips at two different loads of 10 and 100 nN (Fig. 27.41). For a low normal load of 10 nN, measurements were made twice. There was no discernible difference between consecutive measurements for this load. However, as the load was increased from 10 to 100 nN, topographical changes were observed during subsequent scanning at a normal load of 10 nN; material was pushed in the sliding direction of the AFM tip relative to the sample. The material movement is believed to occur as a result of plastic deformation of the tape surface. Thus, deformation and movement of the soft materials on a nanoscale can be observed.

27.3.2 Microscale Scratching

The AFM can be used to investigate how surface materials can be moved or removed on micro- to nanoscales, for example, in scratching and wear [27.2, 7] (where these things are undesirable) and nanofabrication/nanomachining (where they are desirable). Figure 27.42a shows microscratches made on Si(111) at various loads and a scanning velocity of 2 μm/s after ten cycles [27.28]. As expected, the scratch depth increases linearly with load. Such microscratching measurements can be used to study failure mechanisms on

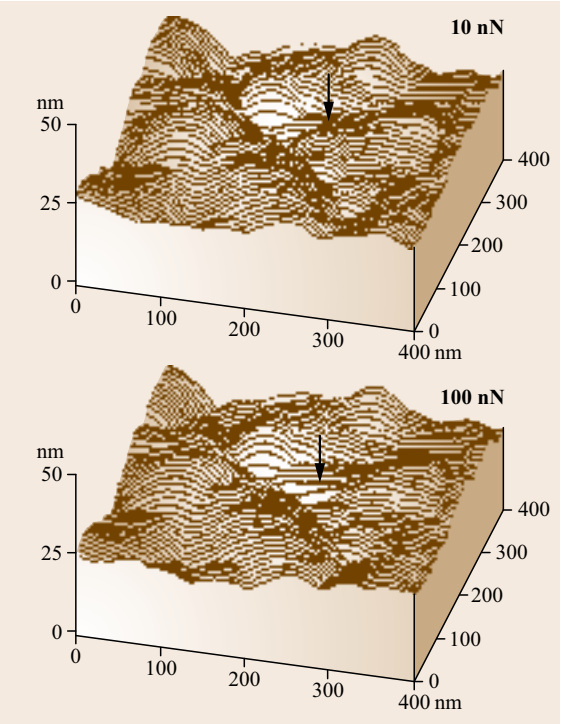

Fig. 27.41 Surface roughness maps of a polymeric magnetic tape at the applied normal load of 10 and 100 nN. Location of the change in surface topography as a result of nanowear is indicated by *arrows* (after [27.24])

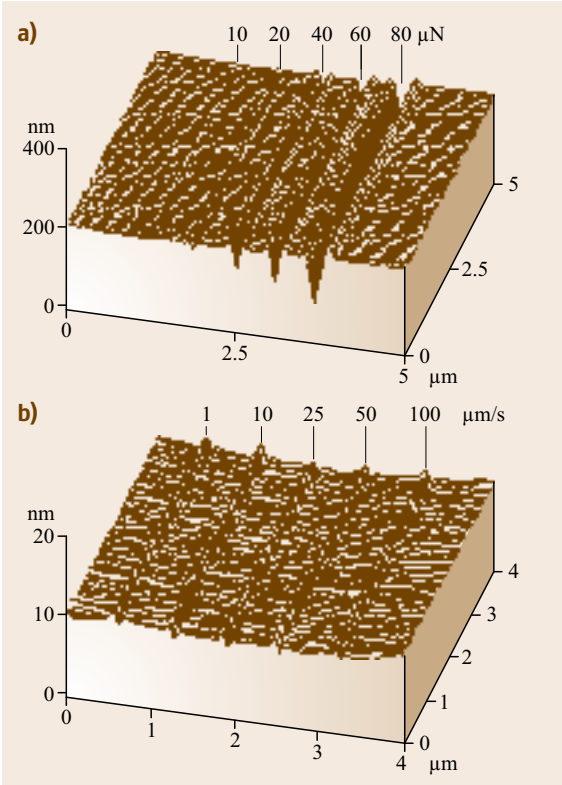

Fig. 27.42a,b Surface plots of **(a)** Si(111) scratched for ten cycles at various loads and a scanning velocity of 2 μm/s (after [27.28]). Note that *x*- and *y*-axes are in μm and the *z*-axis is in nm, and **(b)** Si(100) scratched in one unidirectional scan cycle at a normal force of 80 μN and different scanning velocities (after [27.31])

the microscale and to evaluate the mechanical integrity (scratch resistance) of ultrathin films at low loads.

To study the effect of scanning velocity, unidirectional scratches 5 μm in length were generated at scanning velocities ranging from 1 to 100 μm/s at various normal loads ranging from 40 to 140 μN [27.31]. There is no effect of scanning velocity obtained at a given normal load. Representative scratch profiles at 80 μN are shown in Fig. 27.42b. This may be because of a small effect of frictional heating with the change in scanning velocity used here. Furthermore, for a small change in interface temperature, there is a large underlying volume to dissipate the heat generated during scratching.

Scratching can be performed under ramped loading to determine the scratch resistance of materials and coatings [27.58]. The coefficient of friction is measured during scratching, and the load at which the coefficient of friction increases rapidly is known as the *critical load*, which is a measure of scratch resistance. In addition, postscratch imaging can be performed in situ with the AFM in tapping mode to study failure mechanisms. Figure 27.43 shows data from a scratch test on Si(100) with a scratch length of 25 μm and a scratching velocity of 0.5 μm/s. At the beginning of the scratch, the coefficient of friction is 0.04, which indicates a typical value for silicon. At about 35 μN (indicated by the arrow in the figure), there is a sharp increase in the coefficient of friction, which indicates the critical load. Beyond the critical load, the coefficient of friction continues to increase steadily. In the postscratch image, we note that at the critical load, a clear groove starts to form. This implies that Si(100) was damaged by plowing at the critical load, associated with the plastic flow of the material. At and after the critical load, small and uniform debris is observed, and the amount of debris increases with increasing normal load. *Sundararajan* and *Bhushan* [27.58] have also used this technique to measure the scratch resistance of diamond-like carbon coatings ranging in thickness from 3.5–20 nm.

27.3.3 Microscale Wear

By scanning the sample in two dimensions with the AFM, wear scars are generated on the surface. Fig-

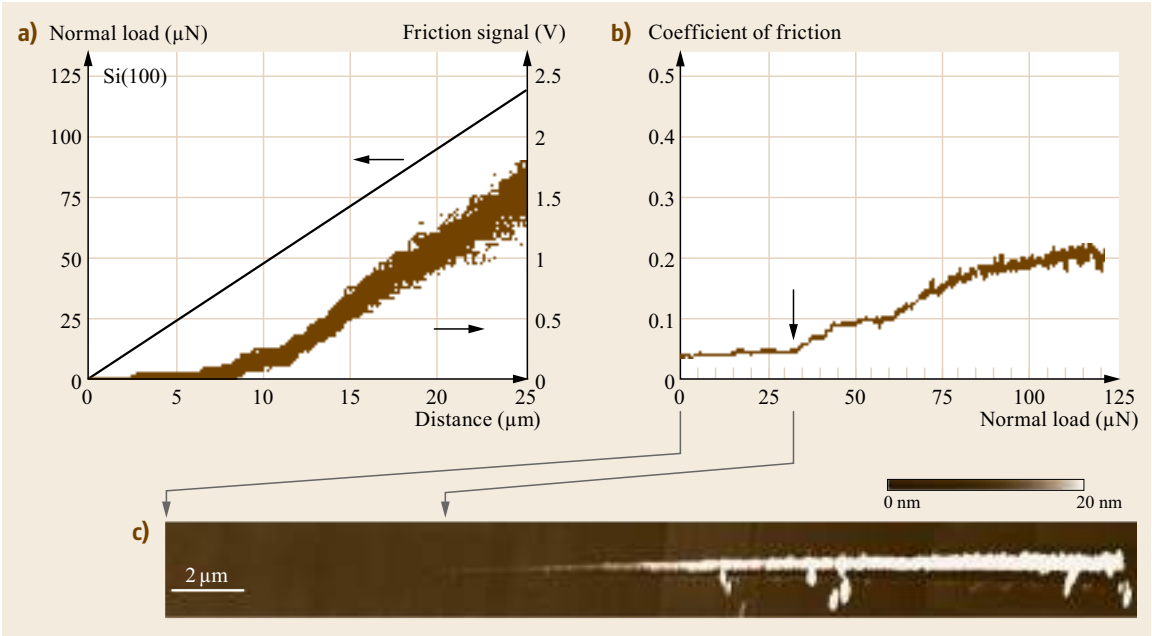

Fig. 27.43 **(a)** Applied normal load and friction signal measured during the microscratch experiment on Si(100) as a function of scratch distance, **(b)** friction data plotted in the form of coefficient of friction as a function of normal load, and **(c)** AFM surface height image of scratch obtained in tapping mode (after [27.58])

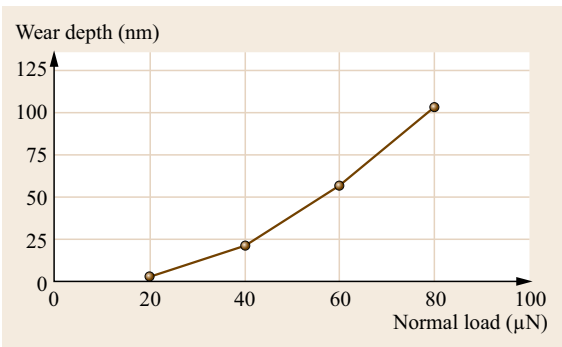

Fig. 27.44 Wear depth as a function of normal load for Si(100) after one cycle (after [27.138])

ure 27.44 shows the effect of normal load on wear depth on Si(100). We note that wear depth is very small below 20 μN of normal load [27.100, 138]. A normal load of 20 μN corresponds to contact stresses comparable to the hardness of silicon. Primarily, elastic deformation at loads below 20 μN is responsible for low wear [27.29, 30].

A typical wear mark of the size 2 μm × 2 μm generated at a normal load of 40 μN for one scan cycle and imaged using AFM with a scan size of 4 μm × 4 μm at 300 nN load is shown in Fig. 27.45a. The inverted map of wear marks shown in Fig. 27.45b indicates the uniform material removal at the bottom of the wear mark [27.100]. An AFM image of the wear mark shows debris at the edges, probably swiped during AFM scanning. This indicates that the debris is loose (not sticky) and can be removed during AFM scanning.

Next the mechanism of material removal on the microscale in AFM wear experiments is examined [27.31, 100, 138]. Figure 27.46 shows a secondary electron image of the wear mark and associated wear particles. The specimen used for the scanning electron microscope (SEM) was not scanned with the AFM after initial wear, in order to retain wear debris in the wear region. Wear debris is clearly observed. In the SEM micrographs, the wear debris appear to be agglomerated because of the high surface energy of the fine particles. Particles appear to be a mixture of rounded and so-called cutting type (feather-like or ribbon-like material). *Zhao* and *Bhushan* [27.138] reported an increase in the number and size of cutting-type particles with the normal load. The presence of cutting-type particles indicates that the material is removed primarily by plastic deformation.

To better understand the material removal mechanisms, *Zhao* and *Bhushan* [27.138] used transmission electron microscopy (TEM). The TEM micrograph of the worn region and associated diffraction pattern are shown in Fig. 27.47a,b. The bend contours are observed to pass through the wear mark in the micrograph. The bend contours around and inside the wear mark are indicative of a strain field, which in the absence of ap-

plied stresses can be interpreted as plastic deformation and/or elastic residual stresses. Often, localized plastic deformation during loading would lead to residual

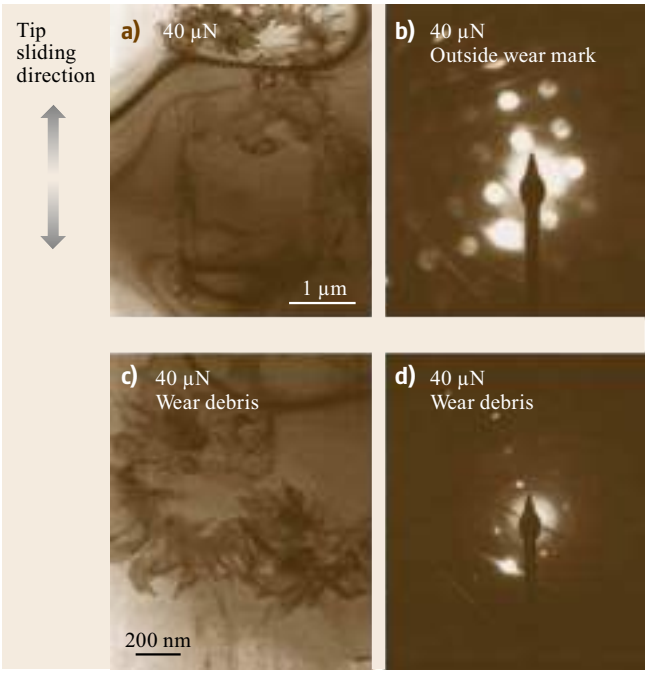

Fig. 27.47a–d Bright-field TEM micrographs **(a)** and diffraction patterns **(b)** of wear mark **(a,b)** and wear debris **(c,d)** in Si(100) produced at a normal load of 40 µN and one scan cycle. Bend contours around and inside wear mark are observed (after [27.138])

stresses during unloading; therefore, bend contours reflect a mix of elastic and plastic strains. The wear debris is observed outside the wear mark. The enlarged view of the wear debris in Fig. 27.47c shows that much of the debris is ribbon like, indicating that material is removed by a cutting process via plastic deformation, which is consistent with the SEM observations. The diffraction pattern from inside the wear mark was reported to be similar to that of virgin silicon, indicating no evidence of any phase transformation (amorphization) during wear. A selected area diffraction pattern of the wear debris shows some diffuse rings, which indicates the existence of amorphous material in the wear debris, confirmed as silicon oxide products from chemical analysis. It is known that plastic deformation occurs by generation and propagation of dislocations. No dislocation activity or cracking was observed at 40 µN. However, dislocation arrays could be observed at 80 µN. Figure 27.48 shows the TEM micrographs of the worn region at 80 µN; for better observation of the worn surface, wear debris was moved out of the wear mark by using AFM with a large area scan at 300 nN after the wear test. The existence of dislocation arrays confirms that material removal occurs by plastic deformation. This corroborates the observations made in scratch tests at ramped load in the previous section. It

is concluded that the material on the microscale at high loads is removed by plastic deformation with a small contribution from elastic fracture [27.138].

To understand wear mechanisms, evolution of wear can be studied using AFM. Figure 27.49 shows the evolution of wear marks of a DLC-coated disk sample. The data illustrate how the microwear profile for a load of 20 μN develops as a function of the number of scanning cycles [27.28]. Wear is not uniform, but is initiated at the nanoscratches. Surface defects (with high surface energy) present at the nanoscratches act as initiation sites for wear. Coating deposition also may not be uniform on and near nanoscratches which may lead to coating delamination. Thus, scratch-free surfaces will be relatively resistant to wear.

Wear precursors (precursors to measurable wear) can be studied by making surface potential measurements [27.81, 83, 84]. The contact potential difference, or simply the surface potential between two surfaces depends on a variety of parameters such as electronic work function, adsorption, and oxide layers. The surface potential map of an interface gives a measure of changes in the work function which is sensitive to both physical and chemical conditions of the surfaces including structural and chemical changes. Before material is actually removed in a wear process, the surface experiences stresses that result in surface and subsurface changes of structure and/or chemistry. These can cause changes in the measured potential of a surface. An AFM tip allows the mapping of the surface potential with nanoscale resolution. Surface height and change in surface potential maps of a polished single-crystal aluminum (100) sample, abraded using a diamond tip at loads of 1 and 9 μN, are shown in Fig. 27.50a. It is evident that both abraded regions show a large potential contrast (≈ 0.17 V), with respect to the nonabraded area. The black region in the lower right-hand part of the

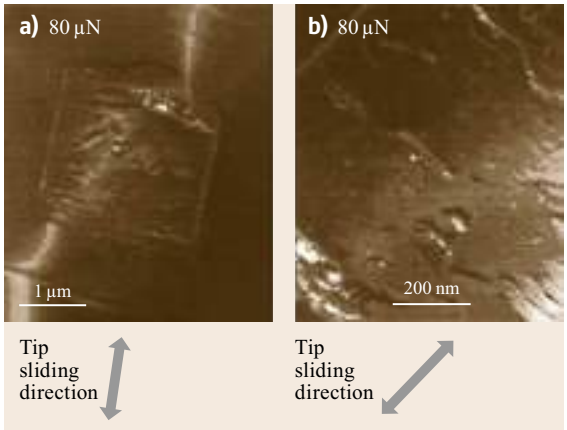

Fig. 27.48 (a) Bright-field and (b) weak-beam TEM micrographs of wear mark in Si(100) produced at a normal load of 80 μN and one scan cycle showing bend contours and dislocations (after [27.138])

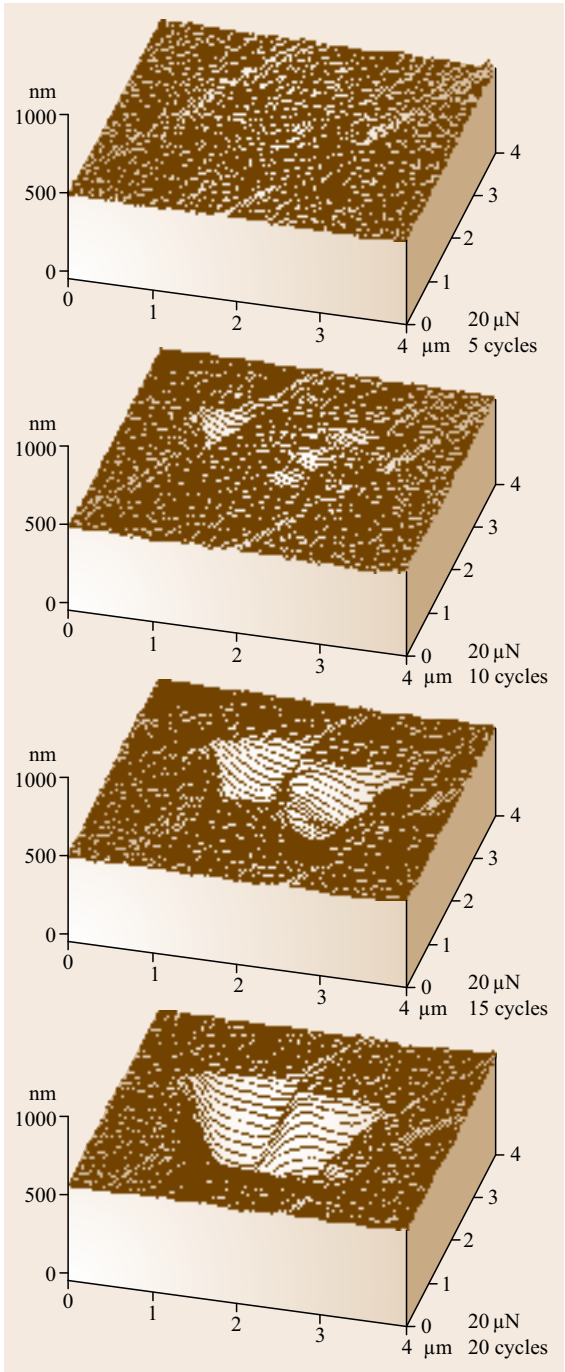

Fig. 27.49 Surface plots of a diamond-like carbon-coated thin-film disk showing the worn region; the normal load and number of test cycles are indicated (after [27.28])

topography scan shows a step that was created during the polishing phase. There is no potential contrast between the high region and the low region of the sample, indicating that the technique is independent of surface height. Figure 27.50b shows a close-up scan of the upper (low load) wear region in Fig. 27.50a. Notice that while there is no detectable change in the surface topography, there is nonetheless, a large change in the potential of the surface in the worn region. Indeed, the wear mark of Fig. 27.50b might not be visible at all in the topography map were it not for the noted absence of wear debris generated nearby and then swept off during the low load scan. Thus, even in the case of zero wear (no measurable deformation of the surface using AFM), there can be a significant change in the surface potential inside the wear mark which is useful for the study of wear precursors. It is believed that the removal of the thin contaminant layer including the natural oxide layer gives rise to the initial change in surface potential. The structural changes, which precede the generation of wear debris and/or measurable wear scars, occur under ultralow loads in the top few nanometers of the sample, and are primarily responsible for the subsequent changes in surface potential.

Surface potential measurements using the nano-Kelvin probe technique have been used to study wear and degradation for various applications such as for human skin [27.139], human hair [27.107, 140], Li-ion batteries [27.141] and MEMS switches [27.142].

27.3.4 In situ Characterization of Local Deformation

In situ surface characterization of local deformation of materials and thin films is carried out using a tensile stage inside an AFM [27.73–75, 85, 86]. As an example, failure mechanisms of coated polymeric thin films under tensile load were studied by *Bobji* and *Bhushan* [27.73, 74]. The specimens were strained at a rate of 4×10^{-3}%/s, and AFM images were captured at different strains up to about 10% to monitor generation and propagation of cracks and deformation bands. *Bobji* and *Bhushan* [27.73, 74] studied three magnetic tapes of thickness ranging from 7 to 8.5 μm. One of these had an acicular-shaped metal particle (MP) coating while the other two had metal-evaporated (ME) coatings with and without a thin diamond-like carbon (DLC) overcoat both on a polymeric substrate; all had a particulate back coating [27.16]. They also studied a polyethylene terephthalate (PET) substrate with 6 μm thickness. They reported that cracking of the coatings started at about 1% strain for all tapes much before the substrate starts to yield at about 2% strain. Figure 27.51 shows the topographical images of the MP tape at different strains. At 0.83% strain, a crack can be seen, originating at the marked point. As the tape is further stretched along the direction, as shown in Fig. 27.51, the crack propagates along the shorter boundary of the ellipsoidal particle. However, the general direction of crack propagation remains perpendicular to the direction of stretching. The length, width, and depth of the cracks increase with strain, and at the same time newer cracks keep nucleating and propagating with reduced crack spacing. At 3.75% strain, another crack can be seen nucleating. This crack continues to grow parallel to the first one. When the tape is unloaded after stretching up to a strain of about 2%, i. e., within the elastic limit of the substrate, the cracks close perfectly, and it is impossible to determine the difference from the unstrained tape.

Figure 27.52 shows topographical images of the three magnetic tapes and the PET substrate after being strained to 3.75%, which is well beyond the elastic

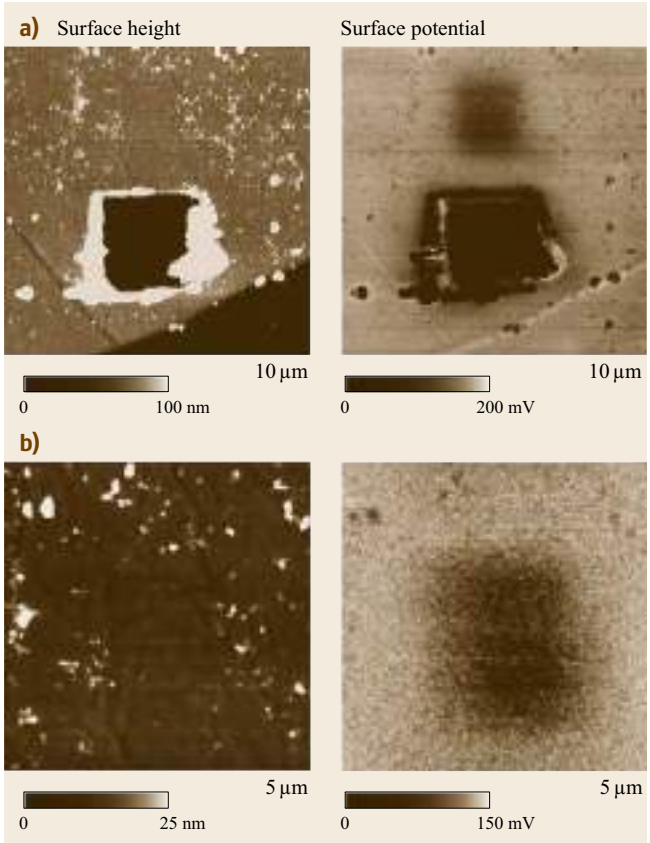

Fig. 27.50 (a) Surface height and change in surface potential maps of wear regions generated at 1 μN (*left*) and 9 μN (*right*) on a single-crystal aluminum sample showing bright contrast in the surface potential map on the worn regions. (b) Close up of upper (low load) wear region (after [27.83])

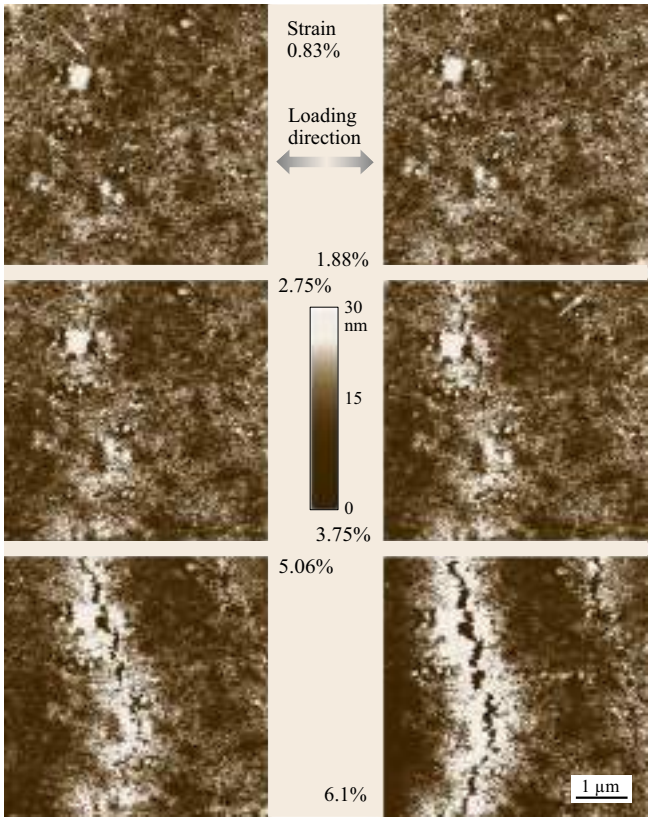

Fig. 27.51 Topographical images of the MP magnetic tape at different strains (after [27.73])

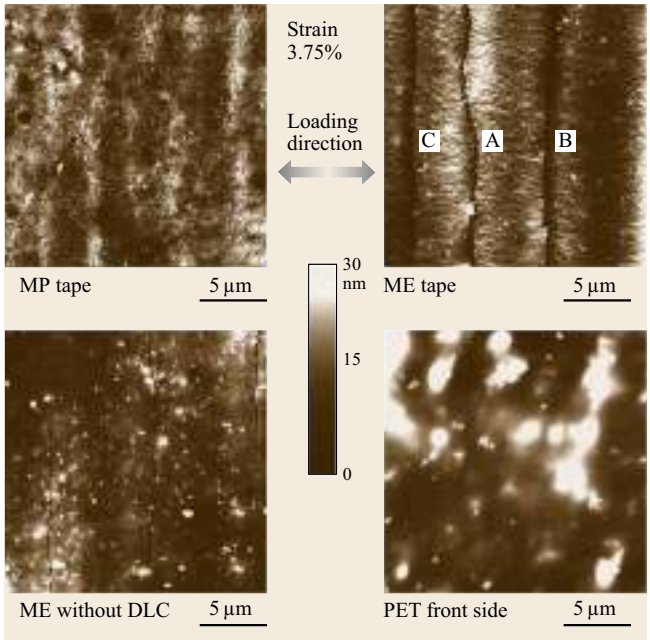

Fig. 27.52 Comparison of crack morphologies at 3.75% strain in three magnetic tapes and for a PET substrate. Cracks B and C, nucleated at higher strains, are more linear than crack A (after [27.74])

limit of the substrate. The MP tape develops short and numerous cracks perpendicular to the direction of loading. In tapes with metallic coating, the cracks extend throughout the tape width. In the ME tape with the DLC coating, there is a bulge in the coating around the primary cracks that are initiated when the substrate is still elastic, like crack A in the figure. The white band on the right-hand side of the figure is the bulge of another crack. The secondary cracks like B and C are generated at higher strains and are straighter compared to the primary cracks. In the ME tape which has a Co-O film on a PET substrate, with a thickness ratio of 0.03, both with and without DLC coating, no difference is observed in the rate of growth between primary and secondary cracks. The failure is cohesive with no bulging of the coating. This seems to suggest that the DLC coating has residual stresses that relax when the coating cracks, causing delamination. Since the stresses are already relaxed, the secondary crack does not result in delamination. The presence of the residual stress is confirmed by the fact that a free-standing ME tape curls up (in a cylindrical form with its axis perpendicular to the tape length) with a radius of curvature of about 6 mm, and the ME tape without the DLC does not curl. The magnetic coating side of the PET substrate is much smoother at smaller scan lengths. However, in the 20 μm scans it has a lot of bulging out, which appears as white spots in the figure. These spots change shape even when the samples are scanned in tapping mode at very low contact forces.

The variation of average crack width and average crack spacing with strain is plotted in Fig. 27.53. The crack width is measured at a spot along a given crack over a distance of 1 μm in the 5 μm scan image at different strains. The crack spacing is obtained by averaging the intercrack distance measured in five separate 50 μm scans at each strain. It can be seen that the cracks nucleate at a strain of about 0.7%–1.0%, well within the elastic limit of the substrate. There is a definite change in the slope of the load–displacement curve at the strain where cracks nucleate, and the slope after that is closer to the slope of the elastic portion of the substrate. This would mean that most of the load is supported by the substrate once the coating fails by cracking.

Fatigue experiments can be performed by applying a cyclic stress amplitude with a certain mean stress [27.75]. Fatigue life was determined by the first occurrence of cracks. Experiments were performed at various constant mean stresses and with a range of cyclic stress amplitudes for each mean stress value for various magnetic tapes. Number of cycles to failure was plotted as a function of stress state to obtain a so-called *S–N* (stress–life) diagram. As the stress is decreased,

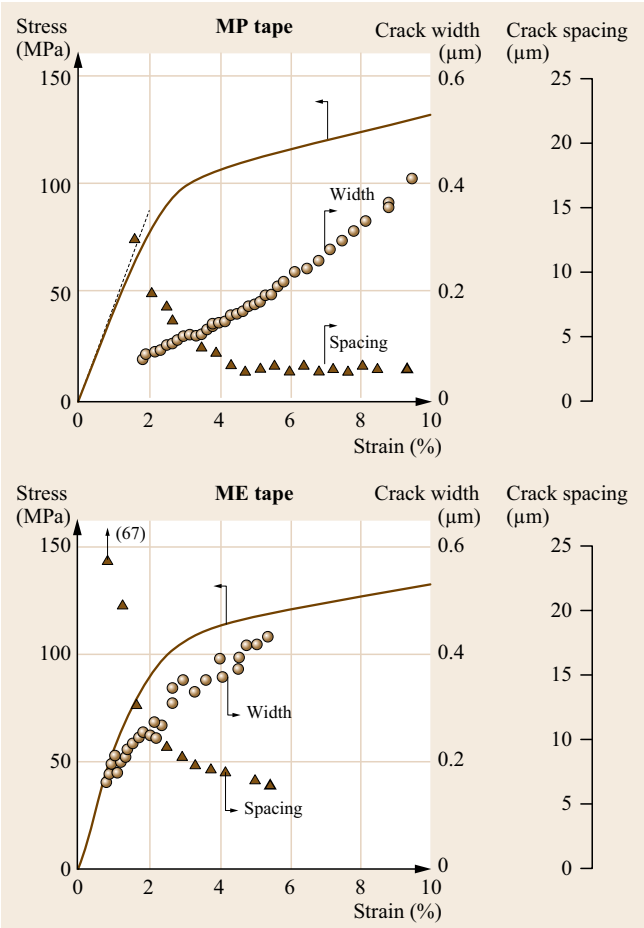

Fig. 27.53 Variation of stress, crack width, and crack spacing with strain in two magnetic tapes (after [27.73])

there is a stress value for which no failure occurs. This stress is termed the endurance limit or simply fatigue limit. Figure 27.54 shows the *S–N* curve for an ME tape and an ME tape without DLC. For the ME tape, the endurance limit is seen to go down with a decrease in mean stress. This is consistent with the literature, and is because at a lower mean stress the corresponding stress amplitude is relatively high and this causes failure. The endurance limit is found to be almost the same for all three mean stresses. In the case of the ME tape without DLC, the critical number of cycles is found to also be in the same range.

In situ surface characterization of unstretched and stretched films has been used to measure Poisson's ratio of polymeric thin films by *Bhushan* et al. [27.95]. Uniaxial tension is applied by the tensile stage. Surface height profiles obtained from the AFM images of unstretched and stretched samples are used to monitor the changes in displacements of the polymer films

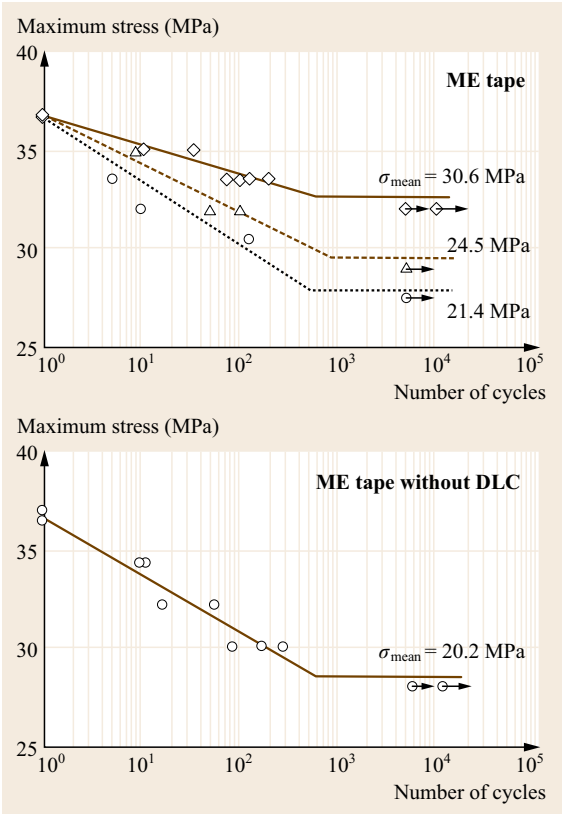

Fig. 27.54 *S–N* curve for two magnetic tapes with maximum stress plotted on the *ordinate* and number of cycles to failure on the *abscissa*. The data points marked with *arrows* indicate tests for which no failure (cracking) was observed in the scan area, even after a large number of cycles (10 000) (after [27.75])

in the longitudinal and lateral directions simultaneously.

27.3.5 Nanofabrication/Nanomachining

An AFM can be used for nanofabrication/nanomachining by extending the microscale scratching operation [27.2, 20, 28, 79]. Figure 27.55 shows two examples of nanofabrication. The patterns were created on a single-crystal silicon (100) wafer by scratching the sample surface with a diamond tip at specified locations and scratching angles. Each line is inscribed manually at a normal load of 15 μN and a writing speed of 0.5 μm/s. The separation between lines is about 50 nm, and the variation in line width is due to the tip asymmetry. Nanofabrication parameters – normal load, scanning speed, and tip geometry – can be controlled precisely to control the depth and length of the devices.

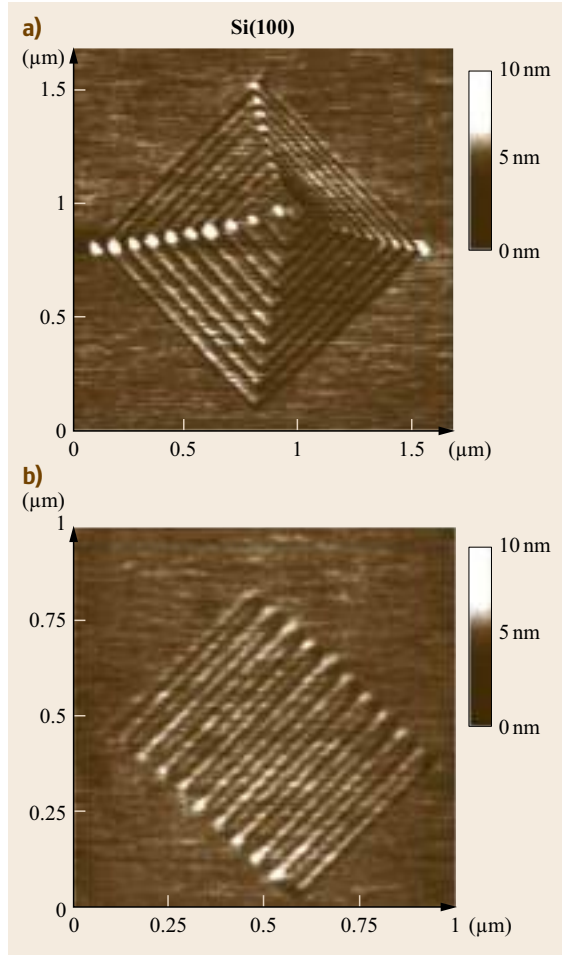

Fig. 27.55 **(a)** Trim and **(b)** spiral patterns generated by scratching an Si(100) surface using a diamond tip at a normal load of 15 μN and writing speed of 0.5 μm/s (after [27.2, 7])

Nanofabrication using mechanical scratching has several advantages over other techniques. Better control over the applied normal load, scan size, and scanning speed can be used for the nanofabrication of devices. Using the technique, nanofabrication can be performed on any engineering surface. Chemical etching or reactions is not required, and this dry nanofabrication process can be employed where the use of chemicals and electric field is prohibited. One disadvantage of this technique is the formation of debris during scratching. At light loads, debris formation is not a problem compared to high-load scratching. However, debris can be removed easily from the scan area at light loads during scanning.

27.4 Indentation

Mechanical properties on the relevant scales are needed for the analysis of friction and wear mechanisms. Mechanical properties, such as hardness and Young's modulus of elasticity, can be determined on the micro- to picoscales using the AFM [27.24, 28, 55, 61] and a depth-sensing indentation system used in conjunction with an AFM [27.60, 143–145].

27.4.1 Picoindentation

Indentability on the scale of subnanometers of soft samples can be studied in the force calibration mode (Fig. 27.7) by monitoring the slope of cantilever deflection as a function of the sample traveling distance after the tip is engaged and the sample is pushed against the tip. For a rigid sample, the cantilever deflection equals the sample traveling distance, but the former quantity is smaller if the tip indents the sample. In an example for a polymeric magnetic tape shown in Fig. 27.56, the line in the left portion of the figure is curved with a slope of less than 1 shortly after the sample touches the tip, which suggests that the tip has indented the sample [27.24]. Later, the slope is equal to 1, suggesting that the tip no longer indents the sample. This observation indicates that the tape surface is soft locally (polymer rich) but hard (as a result of magnetic particles) underneath. Since the curves in extending and retracting modes are identical, the indentation is elastic up to a maximum load of about 22 nN used in the measurements.

Detection of the transfer of material on a nanoscale is possible with the AFM. Indentation of C_{60}-rich fullerene films with an AFM tip has been shown [27.59] to result in the transfer of fullerene molecules to the AFM tip, as indicated by discontinuities in the cantilever deflection as a function of the sample traveling distance in subsequent indentation studies.

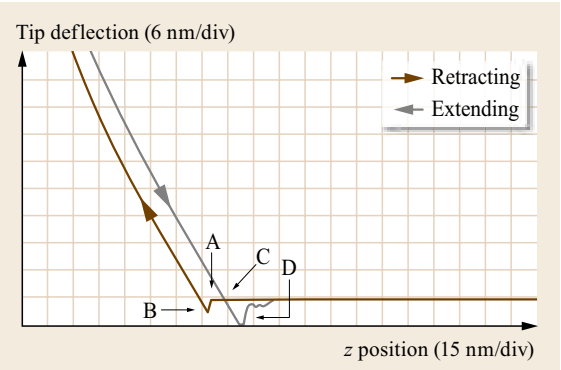

Fig. 27.56 Tip deflection (normal load) as a function of the z (separation distance) curve for a polymeric magnetic tape (after [27.24])

27.4.2 Nanoindentation

The indentation hardness of surface films with an indentation depth of as small as about 1 nm can be measured using an AFM [27.1, 16, 61]. Figure 27.57 shows the gray-scale plots of indentation marks made on Si(111) at normal loads of 60, 65, 70, and 100 μN. Triangular indents can be clearly observed with very shallow depths. At a normal load of 60 μN, indents are observed, and the depth of penetration is about 1 nm. As the normal load is increased, the indents become clearer, and indentation depth increases. For the case of hardness measurements at shallow depths on the same order as variations in surface roughness, it is desirable to subtract the original (unindented) map from the indent map for an accurate measurement of the indentation size and depth [27.28].

To make accurate measurements of hardness at shallow depths, a depth-sensing nano/picoindentation system (Fig. 27.9) is used [27.60]. Figure 27.58 shows the load–displacement curves at different peak loads for Si(100). Loading/unloading curves often exhibit sharp discontinuities, particularly at high loads. Discontinuities, also referred to as pop-ins, occurring during the initial loading part of the curve mark a sharp transition from pure elastic loading to a plastic deformation of the specimen surface, thus corresponding to an initial yield point. The sharp discontinuities in the unloading part of the curves are believed to be due to the formation of lateral cracks which form at the base of the median crack, which results in the surface of the specimen being thrust upward. Load–displacement data at residual depths as low as about 1 nm can be obtained. The indentation hardness of surface films has been measured for various materials at a range of loads including Si(100) up to a peak load of 500 μN and Al(100) up to a peak load of 2000 μN by *Bhushan* et al. [27.60] and *Kulkarni* and *Bhushan* [27.3, 16]. The hardnesses of single-crystal silicon and single-crystal aluminum at shallow depths on the order of a few nm (on a nanoscale) are found to be higher than at depths on the order of a few hundred nm (on a microscale) (Fig. 27.59). Microhardness has also been reported to be higher than that on the millimeter scale by several investigators. The data reported to date show that hardness exhibits a scale (size) effect.

During loading, the generation and propagation of dislocations are responsible for plastic deformation. A strain-gradient plasticity theory has been devel-

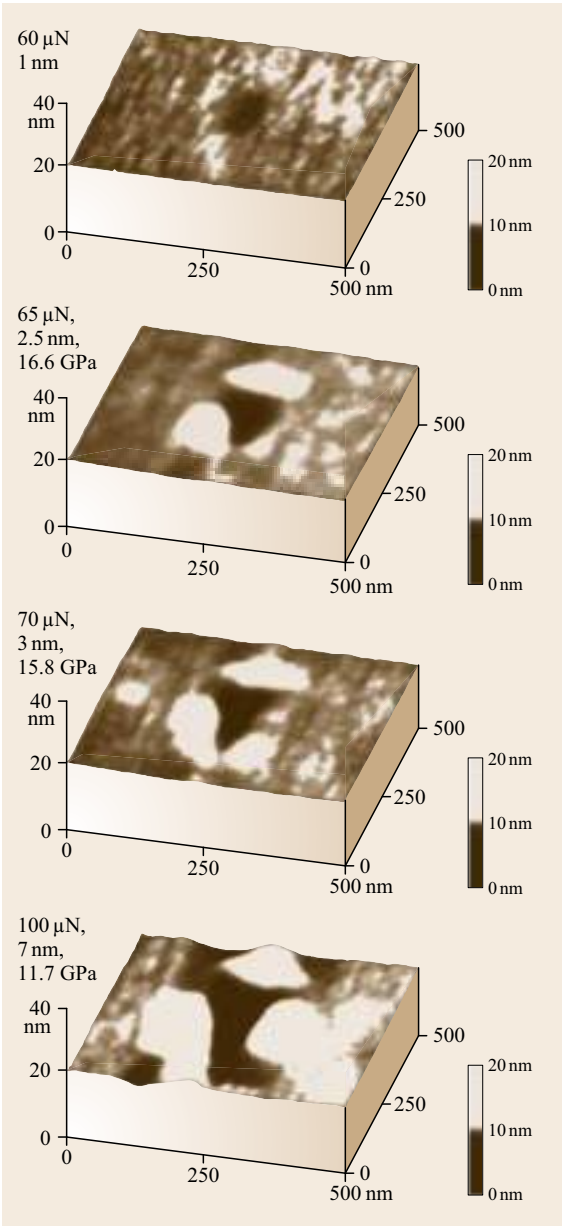

Fig. 27.57 Gray-scale plots of indentation marks on the Si(111) sample at various indentation loads. Loads, indentation depths and hardness values are listed in the figure (after [27.61])

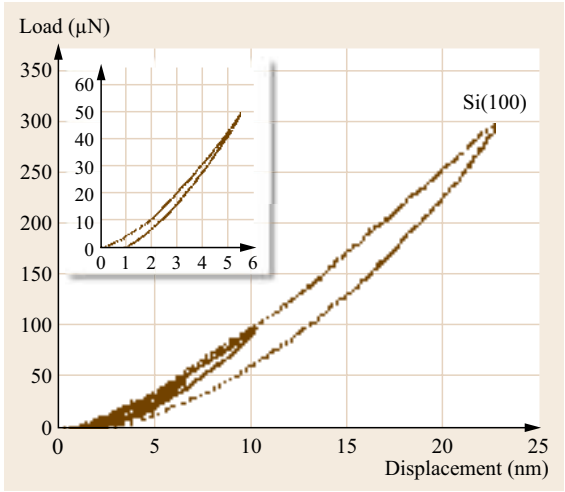

Fig. 27.58 Load–displacement curves at various peak loads for Si(100); *inset* shows the magnified curve for a peak load of 50 μN (after [27.60])

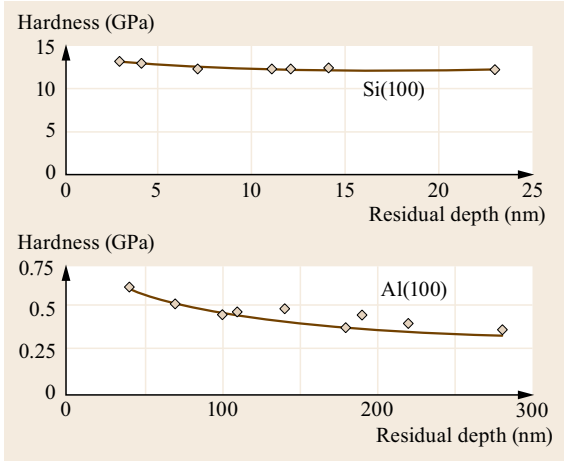

Fig. 27.59 Indentation hardness as a function of residual indentation depth for Si(100) (after [27.60]), and Al(100) (after [27.143])

oped for micro/nanoscale deformations, and is based on randomly created statistically stored and geometrically necessary dislocations [27.146, 147]. Large strain gradients inherent in small indentations lead to the accumulation of geometrically necessary dislocations, located in a certain sub-surface volume, for strain compatibility reasons. The large strain gradients in small indentations require these dislocations to account for the large slope at the indented surface. These dislocations become obstacles to other dislocations that cause enhanced hardening. These are a function of strain gradient, whereas statistically, stored dislocations are a function of strain. Based on this theory, scale-dependent hardness is given as

$$H = H_0 \sqrt{1 + \frac{\ell_d}{a}} \,, \tag{27.23}$$

where H_0 is the hardness in the absence of strain gradient or macrohardness, ℓ_d is the material-specific

characteristic length parameter, and a is the contact radius. In addition to the role of the strain-gradient plasticity theory, an increase in hardness with a decrease in indentation depth can possibly be rationalized on the basis that as the volume of deformed material decreases, there is a lower probability of encountering material defects.

Bhushan and *Koinkar* [27.55] used AFM measurements to show that ion implantation of silicon surfaces increases their hardness and thus their wear resistance. Formation of surface alloy films with improved mechanical properties by ion implantation is of growing technological importance as a means of improving the mechanical properties of materials. Hardness of 20 nm thick DLC films have been measured by *Kulkarni* and *Bhushan* [27.145].

To measure variations in mechanical properties of layered materials and nonhomogeneous composites, a so-called continuous stiffness technique is used [27.62]. The technique offers a direct measurement of dynamic contact stiffness during the loading portion of an indentation test. This allows the measurement of contact stiffness, elastic modulus, hardness, and fatigue properties. For example, the technique has been used in layered and nonhomogeneous magnetic tapes.

The creep and strain rate effects (viscoelastic effects) of ceramics can be studied using a depth-sensing indentation system. *Bhushan* et al. [27.60] and *Kulkarni* and *Bhushan* [27.143–145] have reported that ceramics (single-crystal silicon and diamond-like carbon) exhibit significant plasticity and creep on a nanoscale. Figure 27.60a shows the load–displacement curves for single-crystal silicon at various peak loads held at 180 s. To demonstrate the creep effects, the load–displacement curves for a 500 μN peak load held at 0 and 30 s are also shown as an inset. Note that significant creep occurs at room temperature. Nanoindenter experiments conducted by *Li* et al. [27.148] exhibited significant creep only at high temperatures (greater than or equal to 0.25 times the melting point of silicon). The mechanism of dislocation glide plasticity is believed to dominate the indentation creep process on the macroscale. To study the strain rate sensitivity of silicon, data at two different (constant) rates of loading are presented in Fig. 27.60b. Note that a change in the loading rate by a factor of about five results in a significant change in the load–displacement data. The viscoelastic effects observed here for silicon at ambient temperature could arise from the size effects mentioned earlier. Most likely, creep and strain rate experiments are being conducted on the hydrated films present on the silicon surface in an ambient environment, and these films are expected to be viscoelastic.

27.4.3 Localized Surface Elasticity and Viscoelasticity Mapping

The Young's modulus of elasticity can be calculated from the slope of the indentation curve during unloading. However, these measurements provide a single-point measurement. By using the force modulation technique, it is possible to obtain localized elasticity maps of soft and compliant materials of near-surface regions with nanoscale lateral resolution. This technique has been successfully used for polymeric magnetic tapes, which consist of magnetic and nonmagnetic ce-

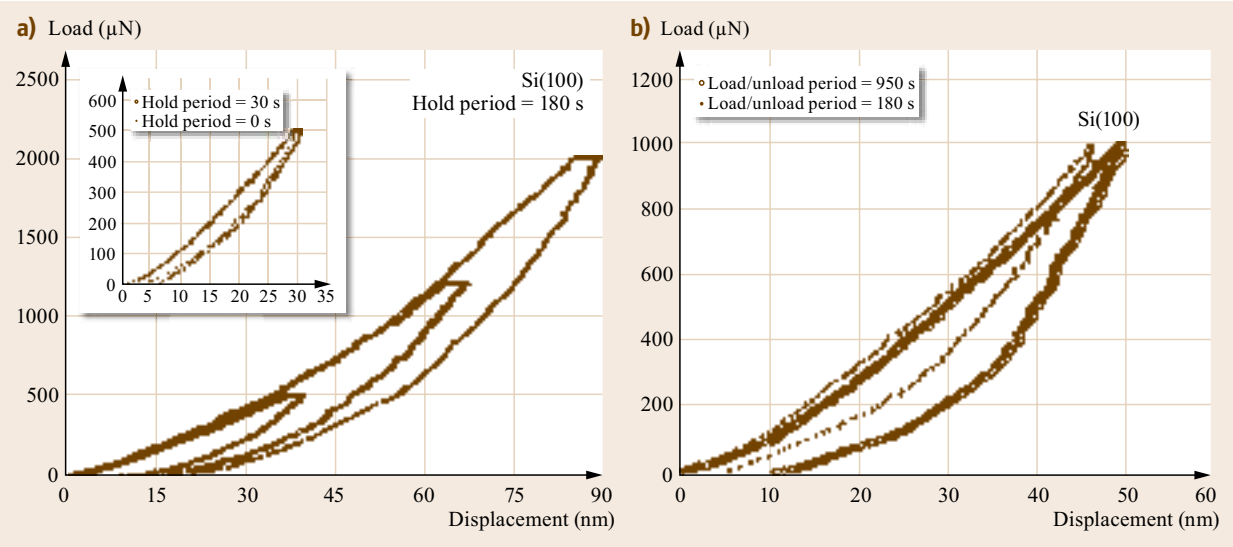

Fig. 27.60 **(a)** Creep behavior and **(b)** strain-rate sensitivity of Si(100) (after [27.60])

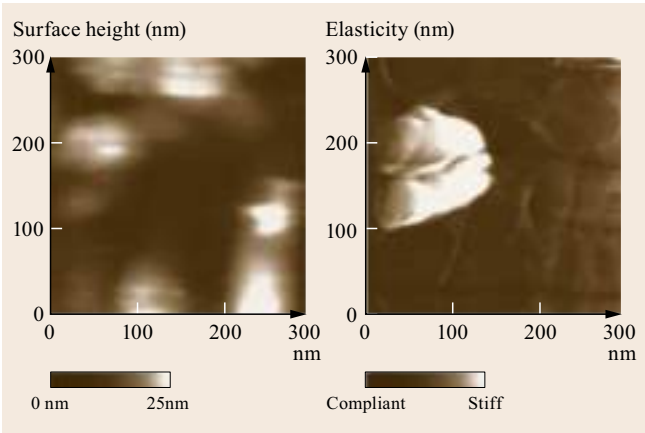

Fig. 27.61 Surface height and elasticity maps on a polymeric magnetic tape ($\sigma = 6.7$ nm and P–V $= 32$ nm; σ and P–V refer to standard deviation of surface heights and peak-to-valley distance, respectively). The gray scale on the elasticity map is arbitrary (after [27.66])

ramic particles in a polymeric matrix. Elasticity maps of a tape can be used to identify the relative distribution of the hard magnetic and nonmagnetic ceramic particles on the tape surface, which has an effect on friction and stiction at the head–tape interface [27.16]. Figure 27.61 shows the surface height and elasticity maps on a polymeric magnetic tape [27.66]. The elasticity image reveals sharp variations in the surface elasticity due to the composite nature of the film. As can be clearly seen, regions of high elasticity do not always correspond to high or low topography. On the basis of a Hertzian elastic-contact analysis, the static indentation depth of these samples during the force modulation scan is estimated to be about 1 nm. We conclude that the contrast seen is influenced most strongly by material properties in the top few nanometers, independent of the composite structure beneath the surface layer.

By using phase contrast microscopy, it is possible to obtain phase contrast maps or the contrast in viscoelastic properties of near surface regions with nanoscale lateral resolution. This technique has been successfully used for polymeric films and magnetic tapes which consist of ceramic particles in a polymeric matrix [27.69–72].

Figure 27.62 shows typical surface height, TR amplitude, and TR phase angle images for a MP tape using TR mode II, described earlier. The TR amplitude image provides contrast in lateral stiffness, and the TR phase angle image provides contrast in viscoelastic properties. In TR amplitude and phase angle images, the distribution of magnetic particles can be clearly seen and have better contrast than that in the TR surface height image. MP tape samples show a granular structure with elliptically shaped magnetic particle aggregates (50–100 nm in diameter). Studies by *Scott* and *Bhushan* [27.69], *Bhushan* and *Qi* [27.70], and *Kasai* et al. [27.71] have indicated that the phase shift can be related to the energy dissipation through the viscoelastic deformation process between the tip and the sample. Recent theoretical analysis has established a quantitative correlation between the lateral surface properties (stiffness and viscoelasticity) of materials and amplitude/phase angle shift in TR measurements [27.92]. The contrast in the TR amplitude and phase angle images is due to the in-plane (lateral) heterogeneity of the surface. The TR amplitude and phase angle images enable the lateral surface properties (lateral stiffness and viscoelasticity) of materials to be mapped.

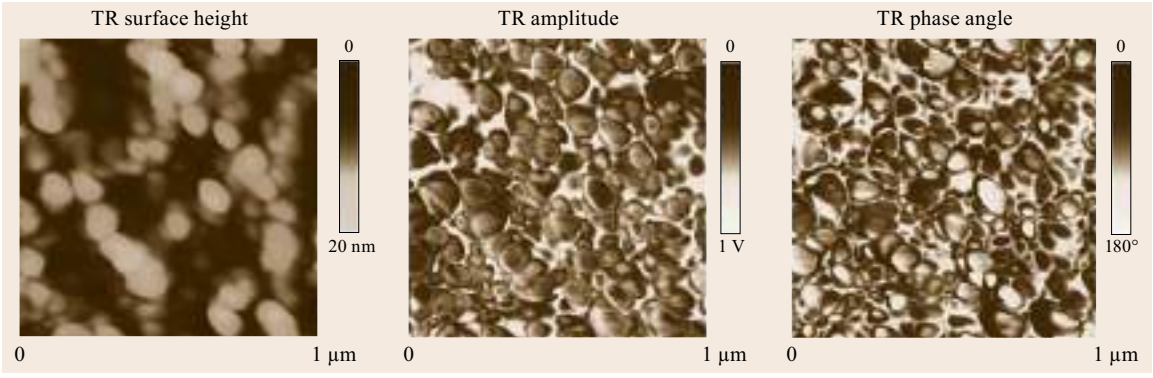

Fig. 27.62 Images of an MP tape obtained with TR mode II (constant deflection). TR mode II amplitude and phase angle images have the largest contrast among tapping, TR mode I, and TR mode II techniques (after [27.72])

27.5 Boundary Lubrication

27.5.1 Perfluoropolyether Lubricants

The classical approach to lubrication uses freely supported multimolecular layers of liquid lubricants [27.2, 9, 16, 149]. The liquid lubricants are sometimes chemically bonded to improve their wear resistance [27.2, 14, 16, 103, 104]. Partially chemically bonded, molecularly thick perfluoropolyether (PFPE) films are used for the lubrication of magnetic storage media because of their thermal stability and extremely low vapor pressure [27.16]. Chemically bonded lubricants are considered potential candidate lubricants for MEMS/NEMS. Molecularly thick PFPEs are well suited because of the following properties: low surface tension and a low contact angle which allows easy spreading on surfaces and provide hydrophobic properties; chemical and thermal stability which minimizes degradation under use; low vapor pressure which provides low out-gassing; high adhesion to substrate via organic functional bonds; and good lubricity which reduces contact surface wear.

For boundary lubrication studies, friction, adhesion, and durability experiments have been performed on virgin Si(100) surfaces and silicon surfaces lubricated with various PFPE lubricants [27.41–43, 47, 51, 53, 54]. More recently, there has been interest in selected ionic liquids for lubrication [27.150–152]. They possess efficient heat transfer properties. They are also electrically conducting, which is of interest in various MEMS/NEMS applications. Results of the following two PFPE lubricants will be presented here: Z-15 (with $-CF_3$ nonpolar end groups),

$$CF_3{-}O{-}(CF_2{-}CF_2{-}O)_m{-}(CF_2{-}O)_n{-}CF_3$$

($m/n \approx 2/3$) and Z-DOL (with $-OH$ polar end groups),

$$HO{-}CH_2{-}CF_2{-}O{-}(CF_2{-}CF_2{-}O)_m{-}(CF_2{-}O)_n{-}CF_2{-}CH_2{-}OH$$

($m/n \approx 2/3$). Z-DOL film was thermally bonded at 150 °C for 30 min, and the unbonded fraction was removed by a solvent (fully bonded) [27.16]. The thicknesses of Z-15 and Z-DOL films were 2.8 nm and 2.3 nm, respectively. The lubricant chain diameter of these molecules is about 0.6 nm, and molecularly thick films generally lie flat on surfaces with high coverage.

The adhesive forces of Si(100), Z-15, and Z-DOL (fully bonded) measured by a force calibration plot and a friction force versus normal load plot are summarized in Fig. 27.63 [27.47]. The data obtained by these two methods are in good agreement. Figure 27.63 shows that the presence of mobile Z-15 lubricant film increases the adhesive force as compared to that of Si(100) by meniscus formation. Whereas, the presence of the solid-like phase of the Z-DOL (fully bonded) film reduces the adhesive force as compared that of Si(100) because of the absence of mobile liquid. The schematic (bottom) in Fig. 27.63 shows the relative size and sources of the meniscus. It is well known that the native oxide layer (SiO_2) on top of the Si(100) wafer exhibits hydrophilic properties, and some water molecules can be adsorbed on this surface. The condensed water will form a meniscus as the tip approaches the sample surface. The larger adhesive force in Z-15 is not only caused by the Z-15 meniscus alone, the nonpolarized Z-15 liquid does not have good wettability and strong bonding with Si(100). Consequently, in the ambient environment, the condensed water molecules from the environment will permeate through the liquid Z-15 lubricant film and compete with the lubricant molecules present on the substrate. The interaction of the liquid lu-

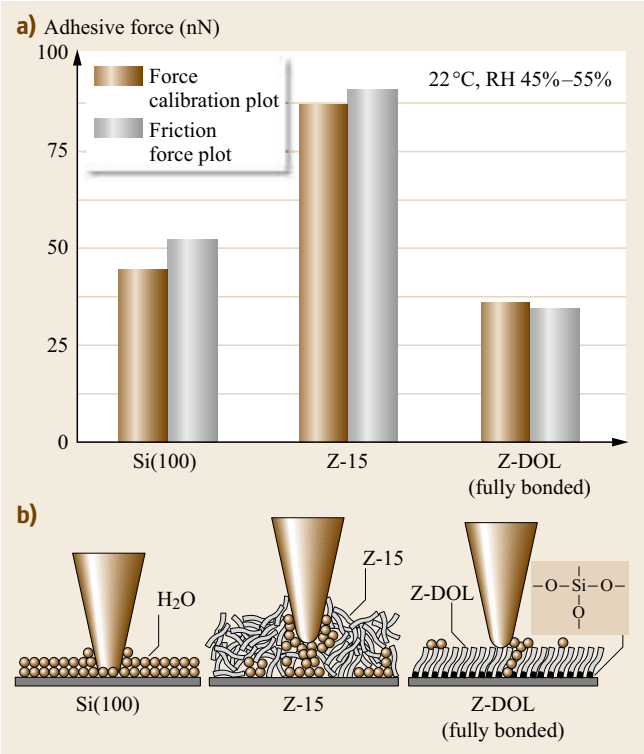

Fig. 27.63a,b Summary of the adhesive forces of Si(100) and Z-15 and Z-DOL (fully bonded) films measured by force calibration plots and friction force versus normal load plots in ambient air **(a)**. **(b)** Schematic showing the effect of the meniscus, formed between the AFM tip and the surface sample, on the adhesive and friction forces (after [27.47])

bricant with the substrate is weakened, and a boundary layer of the liquid lubricant forms puddles [27.42, 43]. This dewetting allows water molecules to be adsorbed on the Si(100) surface along with Z-15 molecules, and both of them can form a meniscus while the tip approaches the surface. Thus, the dewetting of the liquid Z-15 film results in a higher adhesive force and poorer lubrication performance. In addition, the Z-15 film is soft compared to the solid Si(100) surface, and penetration of the tip in the film occurs while pushing the tip down. This results in a large area of the tip being wetted by the liquid to form the meniscus at the tip–liquid (mixture of Z-15 and water) interface. It should also be noted that Z-15 has a higher viscosity compared to water, therefore the Z-15 film provides a higher resistance to motion and the coefficient of friction. In the case of the Z-DOL (fully bonded) film, both of the active groups of Z-DOL molecules are mostly bonded on the Si(100) substrate, thus the Z-DOL (fully bonded) film has low free surface energy and cannot be displaced readily by the water molecules or can readily adsorb the water molecules. Thus, the use of Z-DOL (fully bonded) can reduce the adhesive force.

To study the velocity effect on friction and adhesion, the variation of friction force, the adhesive force, and the coefficient of friction of Si(100), Z-15, and Z-DOL (fully bonded) as a function of velocity are summarized in Fig. 27.64 [27.47]. It indicates that for a silicon wafer, the friction force decreases logarithmically with increasing velocity. For Z-15, the friction force decreases with increasing velocity up to 10 μm/s, after which it remains almost constant. The velocity has a very small effect on the friction force of Z-DOL (fully bonded); it reduced slightly only at very high velocity. Figure 27.64 also indicates that the adhesive force of Si(100) is increased when the velocity is higher than 10 μm/s. The adhesive force of Z-15 is reduced dramatically with a velocity increase up to 20 μm/s, after which it is reduced slightly, and the adhesive force of Z-DOL (fully bonded) is also decreased at high velocity. In the testing range of velocity, only the coefficient of friction of Si(100) decreases with velocity, but the coefficients of friction of Z-15 and Z-DOL (fully bonded) almost remain constant. This implies that the friction mechanisms of Z-15 and Z-DOL (fully bonded) do not change with the variation of velocity.

The mechanisms of the effect of velocity on adhesion and friction are explained based on schematics shown in Fig. 27.65 (right) [27.47]. For Si(100), a tribochemical reaction plays a major role. Although, at high velocity, the meniscus is broken and does not have enough time to rebuild, the contact stresses and high velocity lead to tribochemical reactions of the Si(100) wafer (which has native oxide (SiO_2)) and Si_3N_4 tip with water molecules and they form $Si(OH)_4$. The $Si(OH)_4$ is removed and continuously replenished during sliding. The $Si(OH)_4$ layer between the tip and the Si(100) surface is known to be of low shear strength and causes a decrease in friction force and coefficient of friction [27.103, 104]. The chemical bonds of Si–

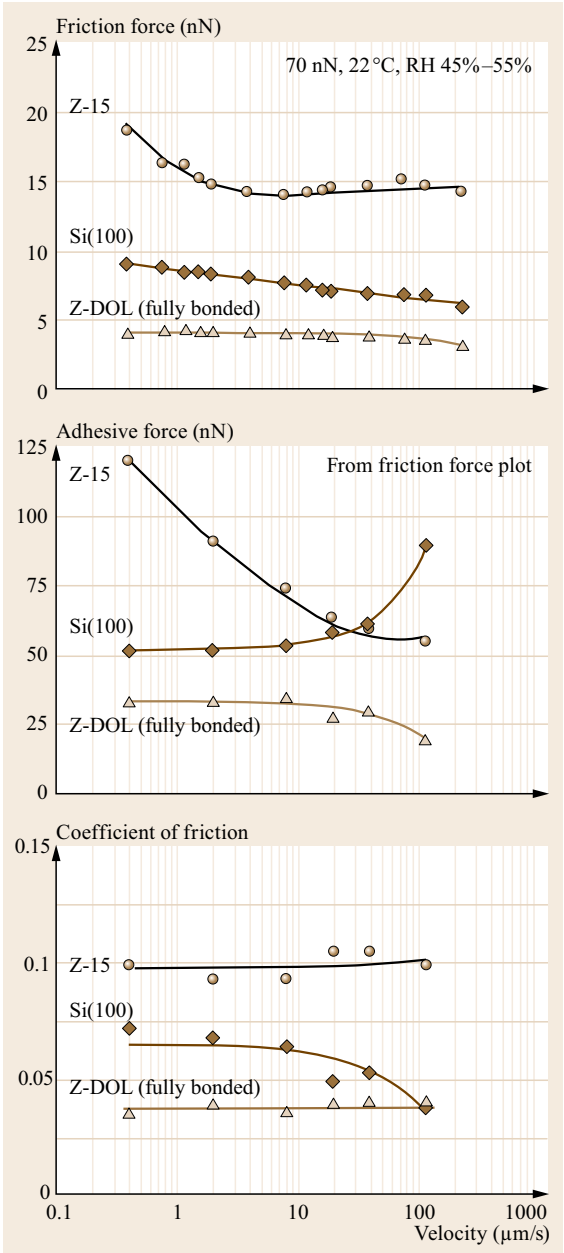

Fig. 27.64 The influence of velocity on the friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 and Z-DOL (fully bonded) films at 70 nN, in ambient air (after [27.47])

OH between the tip and Si(100) surface induce a large adhesive force. For the Z-15 film, at high velocity the meniscus formed by the condensed water and the Z-15 molecules is broken and does not have enough time to rebuild, therefore, the adhesive force and consequently friction force is reduced. The friction mechanisms for the Z-15 film still shear the same viscous liquid even at high velocity range, thus the coefficient of friction of the Z-15 film does not change with velocity. For the Z-DOL (fully bonded) film, the surface can adsorb a few water molecules in an ambient condition, and at high velocity these molecules are displaced, which is responsible for a slight decrease in friction force and adhesive force. *Koinkar* and *Bhushan* [27.42, 43] have suggested that in the case of samples with mobile films, such as condensed water and Z-15 films, alignment of the liquid molecules (shear thinning) is responsible for the drop in friction force with an increase in scanning velocity. This could be another reason for the decrease in friction force for the Si(100) and Z-15 films with velocity in this study.

To study the relative humidity effect on friction and adhesion, the variation of friction force, adhesive force, and the coefficient of friction of Si(100), Z-15, and Z-DOL (fully bonded) as a function of relative humidity are shown in Fig. 27.66 [27.47]. It shows that for Si(100) and Z-15 film, the friction force increases with a relative humidity increase up to 45%, and then it shows a slight decrease with a further increase in the relative humidity. Z-DOL (fully bonded) has a smaller friction force than Si(100) and Z-15 in the whole testing

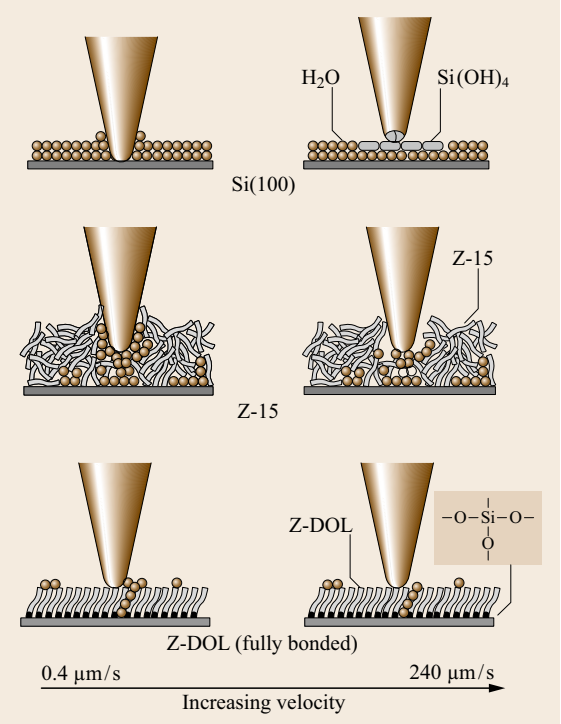

Fig. 27.65 The schematic shows the change of surface composition (by tribochemical reaction) and formation of a meniscus while increasing the velocity (after [27.47])

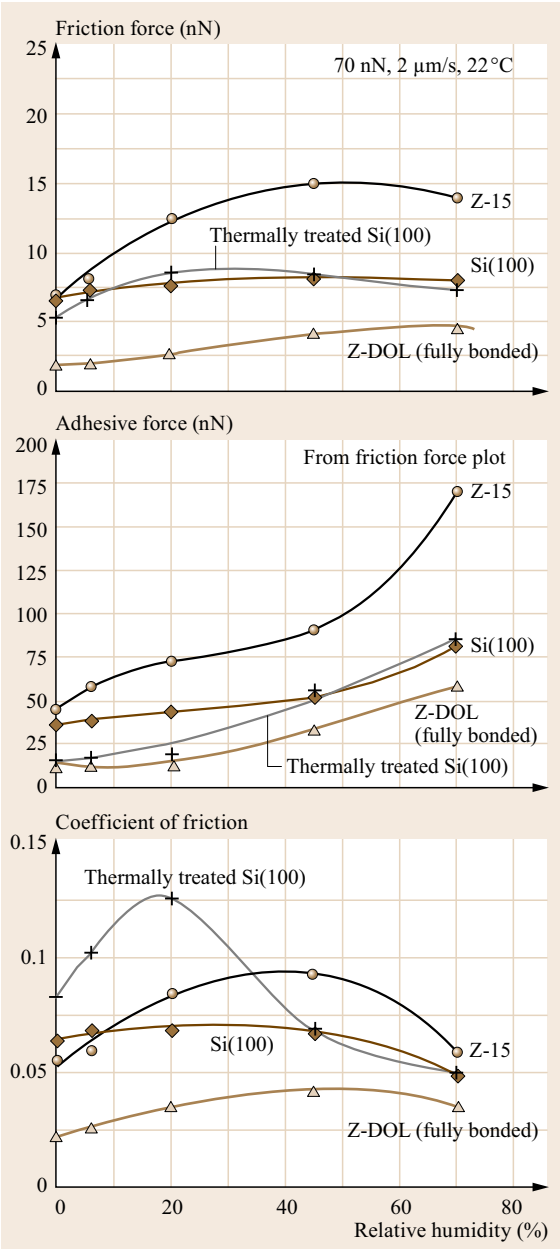

Fig. 27.66 The influence of relative humidity on the friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 and Z-DOL (fully bonded) films at 70 nN, 2 μm/s, and in 22 °C air (after [27.47])

range, and its friction force shows a relative apparent increase when the relative humidity is higher than 45%. For Si(100), Z-15, and Z-DOL (fully bonded), their adhesive forces increase with relative humidity, and their coefficients of friction increase with relative humidity up to 45%, after which they decrease with a further increase in relative humidity. It is also observed that the humidity effect on Si(100) really depends on the history of the Si(100) sample. As the surface of the Si(100) wafer readily adsorbs water in air, without any pretreatment the Si(100) used in our study almost reaches a saturated stage in terms of adsorbed water, and is responsible for less effect during increasing relative humidity. However, once the Si(100) wafer was thermally treated by baking at 150 °C for 1 h, a greater effect was observed.

The schematic (right) in Fig. 27.67 shows that because of its high free surface energy Si(100) can adsorb more water molecules during an increase in relative humidity [27.47]. As discussed earlier, for the Z-15 film in the humid environment, the condensed water from the humid environment competes with the lubricant film present on the sample surface, and the interaction of the liquid lubricant film with the silicon substrate is weakened and a boundary layer of the liquid lubricant forms puddles. This dewetting allows water molecules to be adsorbed on the Si(100) substrate mixed with Z-15 molecules [27.42, 43]. Obviously, more water molecules can be adsorbed on the

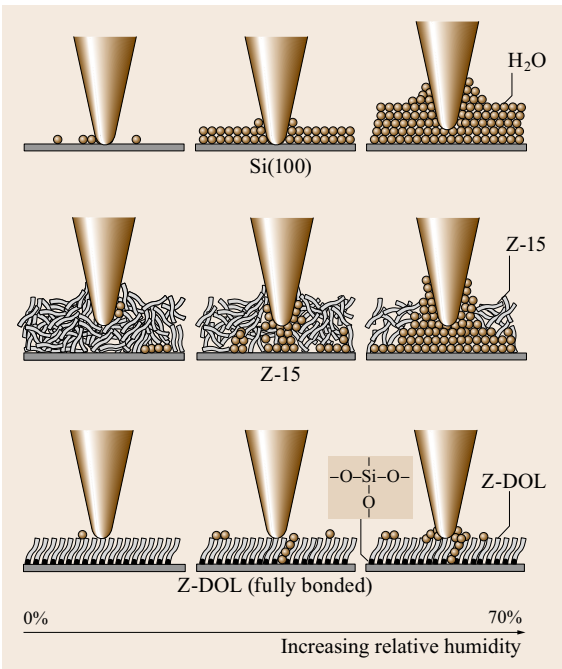

Fig. 27.67 Schematic shows the change of meniscus while increasing relative humidity. In this figure, the thermally treated Si(100) represents the Si(100) wafer that was baked at 150 °C for 1 h in an oven (in order to remove the adsorbed water) just before it was placed in the 0% RH chamber (after [27.47])

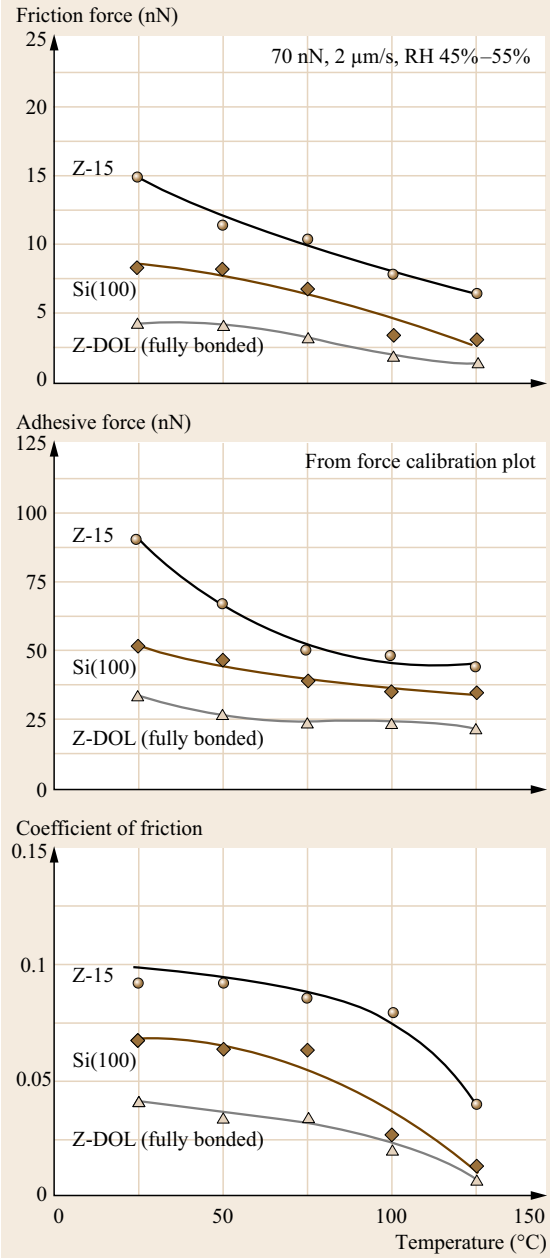

Fig. 27.68 The influence of temperature on the friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 and Z-DOL (fully bonded) films at 70 nN, 2 μm/s, and in RH 40–50% air (after [27.47])

Z-15 surface while increasing relative humidity. The more adsorbed water molecules in the case of Si(100), along with lubricant molecules in the Z-15 film case, form a bigger water meniscus which leads to an increase of friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 with humidity, but at a very high humidity of 70%, large quantities of adsorbed water can form a continuous water layer that separates the tip and sample surface and acts as a kind of lubricant, which causes a decrease in the friction force and the coefficient of friction. For the Z-DOL (fully bonded) film, because of their hydrophobic surface properties, water molecules can be adsorbed at humidity higher than 45%, and cause an increase in the adhesive force and friction force.

To study the temperature effect on friction and adhesion, the variation of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (fully bonded) as a function of temperature are summarized in Fig. 27.68 [27.47]. It shows that the increasing temperature causes a decrease of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (fully bonded). The schematic (right) in Fig. 27.69 indicates that at high temperature, desorption of water leads to a decrease of the friction force, the adhesive forces, and the coefficient of friction for all samples. For the Z-15 film, the reduction of viscosity at high temperature also has a contribution to the decrease of friction force and coefficient of friction. In the case of the Z-DOL (fully bonded) film, molecules can be more easily oriented at high temperature, which

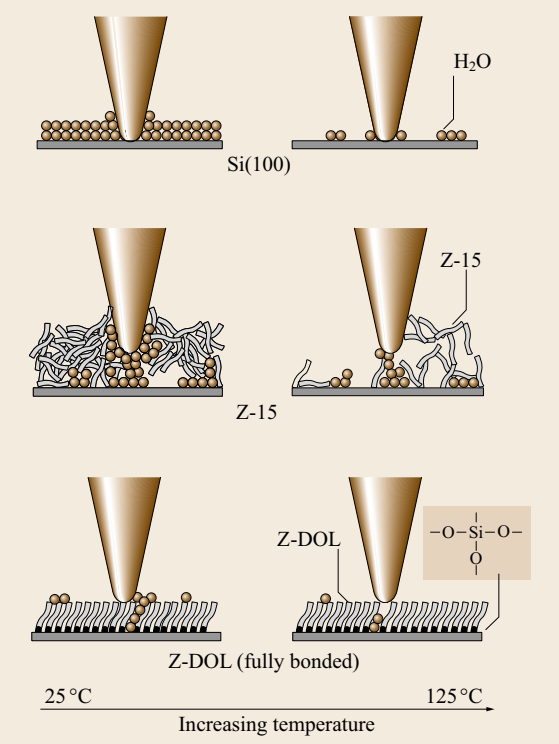

Fig. 27.69 The schematic shows that at high temperature, desorption of water decreases the adhesive forces. And the reduced viscosity of Z-15 leads to the decrease of coefficient of friction. High temperature facilitates orientation of molecules in the Z-DOL (fully bonded) film which results in a lower coefficient of friction (after [27.47])

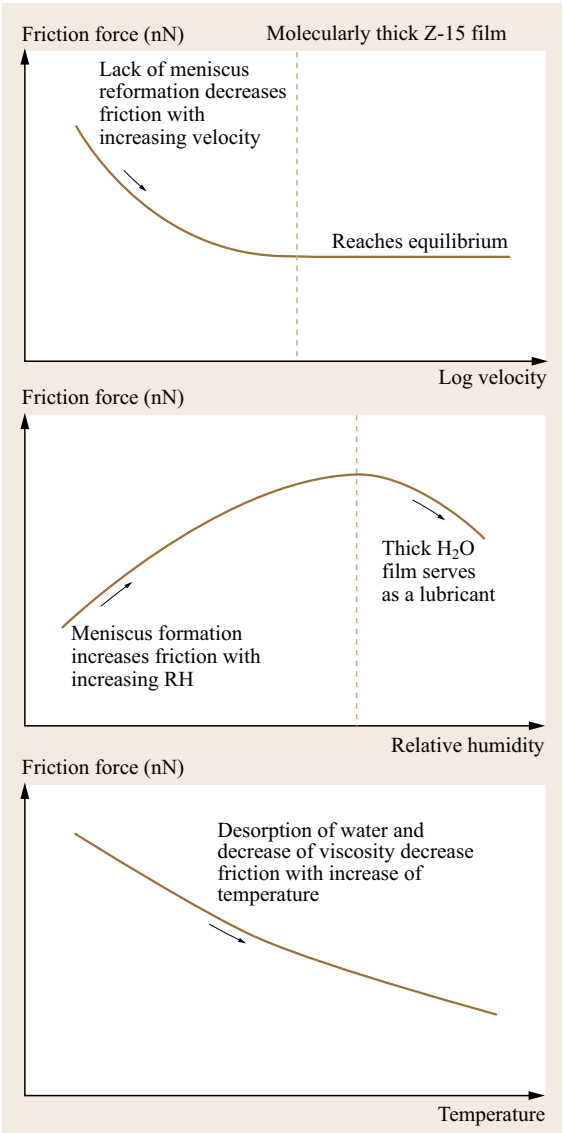

Fig. 27.70 Schematic shows the change of friction force of molecularly thick Z-15 films with log velocity, relative humidity, and temperature. The changing trends are also addressed in this figure (after [27.47])

may be partly responsible for the low friction force and coefficient of friction.

As a brief summary, the influence of velocity, relative humidity, and temperature on the friction force of a mobile Z-15 film is presented in Fig. 27.70 [27.47]. The changing trends are also addressed in this figure.

To study the durability of lubricant films at the nanoscale, the friction of Si(100), Z-15, and Z-DOL (fully bonded) as a function of the number of scanning cycles are shown in Fig. 27.71 [27.47]. As observed earlier, the friction force of Z-15 is higher than that of Si(100) with the lowest values for Z-DOL (fully bonded). During cycling, the friction force and the coefficient of friction of Si(100) show a slight decrease during the initial few cycles then remain constant. This is related to the removal of the native oxide. In the case of the Z-15 film, the friction force and coefficient of friction show an increase during the initial few cycles and then approach higher stable values. This is believed to be caused by the attachment of the Z-15 molecules to the tip. After several scans, the molecular interaction reaches equilibrium, and after that the friction force and coefficient of friction remain constant. In the case of the Z-DOL (fully bonded) film, the friction force and coefficient of friction start out low and remain low during the entire test for 100 cycles. This suggests that Z-DOL (fully bonded) molecules do not become attached or displaced as readily as Z-15.

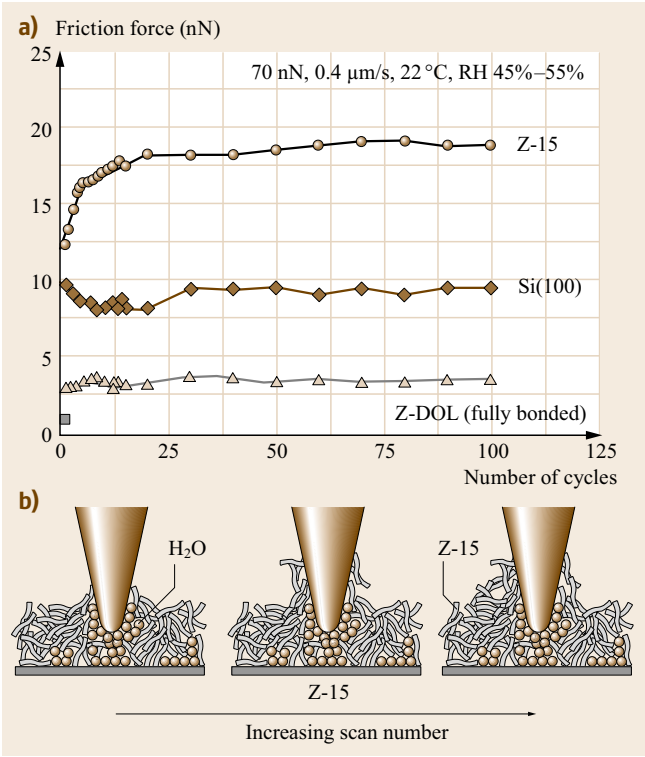

Fig. 27.71 **(a)** Friction force versus number of sliding cycles for Si(100) and Z-15 and Z-DOL (fully bonded) films at 70 nN, 0.8 μm/s, and in ambient air. **(b)** Schematic shows that some liquid Z-15 molecules can be attached to the tip. The molecular interaction between the molecules attached to the tip with the Z-15 molecules in the film results in an increase of friction force with multiscanning (after [27.47])

27.5.2 Self-Assembled Monolayers

For the lubrication of MEMS/NEMS, another effective approach involves the deposition of organized and dense molecular layers of long-chain molecules. Two common methods to produce monolayers and thin films are Langmuir–Blodgett (L–B) deposition and self-assembled monolayers (SAMs) by chemical grafting of molecules. LB films are physically bonded to the substrate by weak van der Waals attraction, while SAMs are chemically bonded via covalent bonds to the substrate. Because of the choice of chain length and terminal linking group that SAMs offer, they hold great promise for boundary lubrication of MEMS/NEMS. A number of studies have been conducted to study the tribological properties of various SAMs deposited on Si, Al, and Cu substrates [27.20, 39–41, 44–46, 48–50, 111, 153–159].

Bhushan and *Liu* [27.44] studied the effect of film compliance on adhesion and friction. They used hexadecane thiol (HDT), 1,1′-biphenyl-4-thiol (BPT), and crosslinked BPT (BPTC) solvent deposited on an Au(111) substrate (Fig. 27.72a). The average values and standard deviation of the adhesive force and coefficient of friction are presented in Fig. 27.72b. On the basis of this data, the adhesive force and coefficient of friction of SAMs are less than the corresponding substrates. Among various films, HDT exhibits the lowest values. Based on the stiffness measurements of various SAMs, HDT was most compliant, followed by BPT and BPTC. On the basis of friction and stiffness measurements, SAMs with high-compliance long carbon chains exhibit low friction; chain compliance is desirable for low friction. The friction mechanism of SAMs is explained by a so-called *molecular spring* model (Fig. 27.73). According to this model, the chemically adsorbed self-assembled molecules on a substrate are like assembled molecular springs anchored to the substrate. An asperity sliding on the surface of SAMs is like a tip sliding on the top of the *molecular springs or brush*. The molecular spring assembly has compliant features and can experience orientation and compression under load. The orientation of the molecular springs or brush under normal load reduces the shearing force at

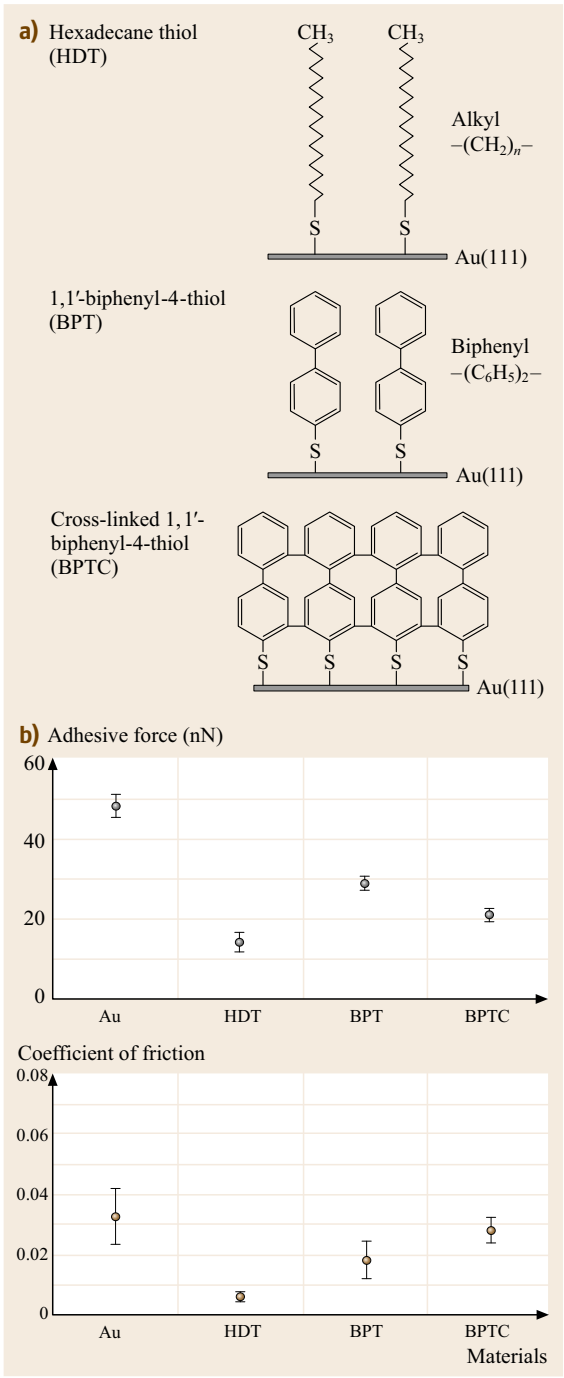

Fig. 27.72 **(a)** Schematics of structures of hexadecane thiol and biphenyl thiol SAMs on Au(111) substrates, and **(b)** adhesive force and coefficient of friction of Au(111) substrate and various SAMs (after [27.44]) ◄

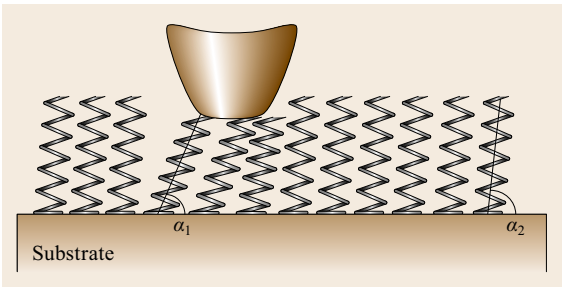

Fig. 27.73 Molecular spring model of SAMs. In this figure, $\alpha_1 < \alpha_2$, which is caused by further orientation under the normal load applied by an asperity tip (after [27.44])

the interface, which in turn reduces the friction force. The orientation is determined by the spring constant of a single molecule as well as by the interaction between the neighboring molecules, which can be reflected by the packing density or the packing energy. It should be noted that the orientation can lead to conformational defects along the molecular chains, which lead to energy dissipation.

An elegant way to demonstrate the influence of molecular stiffness on friction is to investigate SAMs with different structures on the same wafer. For this purpose, a micropatterned SAM was prepared. First, the biphenyldimethylchlorosilane (BDCS) was deposited on silicon by a typical self-assembly method [27.46]. Then the film was partially crosslinked using a mask technique with low-energy electron irradiation. Finally, the micropatterned BDCS films were realized, which had the as-deposited and crosslinked coating regions on the same wafer. The local stiffness properties of this micropatterned sample were investigated by the force-modulation AFM technique [27.66]. The variation in the deflection amplitude provides a measure of the relative local stiffness of the surface. Surface height, stiffness, and friction images of the micropatterned BDCS specimen were obtained and are presented in Fig. 27.74 [27.46]. The circular areas correspond to the as-deposited film, and the remaining area to the crosslinked film. Figure 27.74a indicates that crosslinking caused by the low-energy electron irradiation leads to about 0.5 nm decrease of the surface height of BDCS films. The corresponding stiffness images indicate that the crosslinked area has a higher stiffness than the as-deposited area. Figure 27.74b indicates that the as-deposited area (higher surface height area) has a lower friction force. Obviously, these data of the micropatterned sample prove that the local stiffness of SAMs has an influence on their friction performance. Higher stiffness leads to larger friction force. These results provide strong proof of the suggested molecular spring model.

The SAMs with high-compliance long carbon chains also exhibit the best wear resistance [27.44, 46].

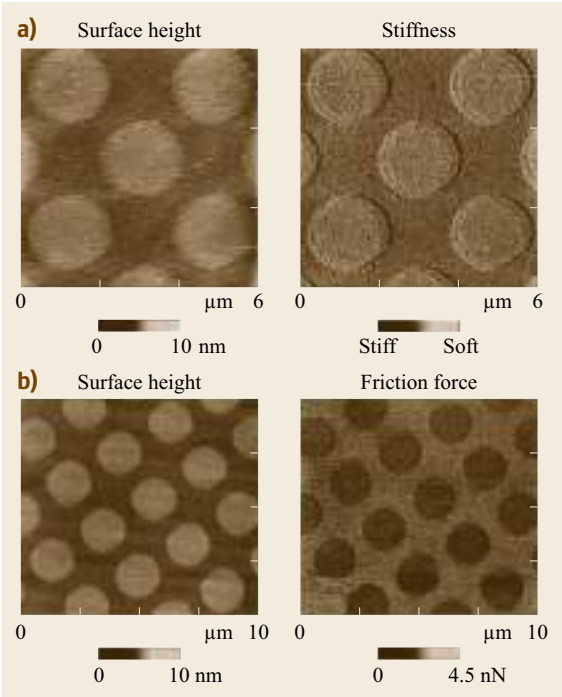

Fig. 27.74 **(a)** AFM gray-scale surface height and stiffness images, and **(b)** AFM gray-scale surface height and friction force images of micropatterned BDCS (after [27.46])

In wear experiments, the wear depth as a function of normal load curves shows a critical normal load, at which the film wears rapidly. A representative curve is shown in Fig. 27.75. Below the critical normal load, SAMs undergo orientation; at the critical load SAMs wear away from the substrate due to the relatively weak interface bond strengths, while above the critical normal load severe wear takes place on the substrate.

27.5.3 Liquid Film Thickness Measurements

Liquid film thickness mapping of ultrathin films (on the order of 2 nm) can be obtained using friction force microscopy [27.42] and adhesive force mapping [27.125]. Figure 27.76 shows the gray-scale plots of the surface topography and friction force obtained simultaneously for unbonded Demnum S-100-type PFPE lubricant film on silicon. Demnum-type PFPE lubricant (Demnum, Daikin, Japan) chains have $-CF_2-CH_2-OH$, a reactive end group on one end, whereas Z-DOL chains have the hydroxyl groups on both ends, as described earlier. The friction force plot shows well-distinguished low and high friction regions roughly corresponding to high and low regions in surface topography (thick and thin lubricant regions). A uniformly lubricated sample does not show such a variation in the friction.

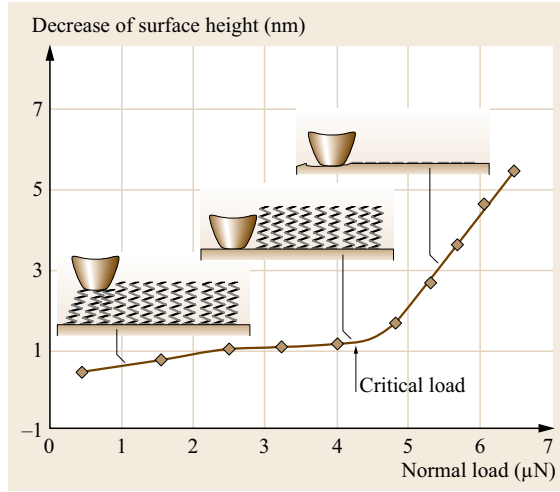

Fig. 27.75 Illustration of the wear mechanism of SAMs with increasing normal load (after [27.46])

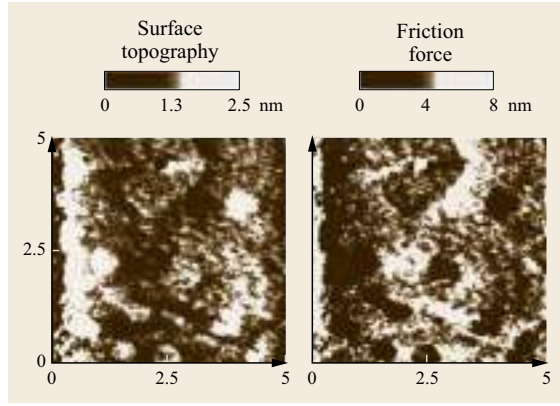

Fig. 27.76 Gray-scale plots of the surface topography and friction force obtained simultaneously for an unbonded Demnum-type perfluoropolyether lubricant film on silicon (after [27.42])

Friction force imaging can thus be used to measure the lubricant uniformity on the sample surface, which cannot be identified by surface topography alone. Figure 27.77 shows the gray-scale plots of the adhesive force distribution for silicon samples coated uniformly and nonuniformly with Z-DOL-type PFPE lubricant. It can be clearly seen that a region exists that has an adhesive force distinctly different from the other region for the nonuniformly coated sample. This implies that the liquid film thickness is nonuniform, giving rise to a difference in the meniscus forces.

Quantitative measurements of liquid film thickness of thin lubricant films (on the order of a few nm) with nanometer lateral resolution can be made with the AFM [27.2, 14, 72, 105]. The liquid film thickness is

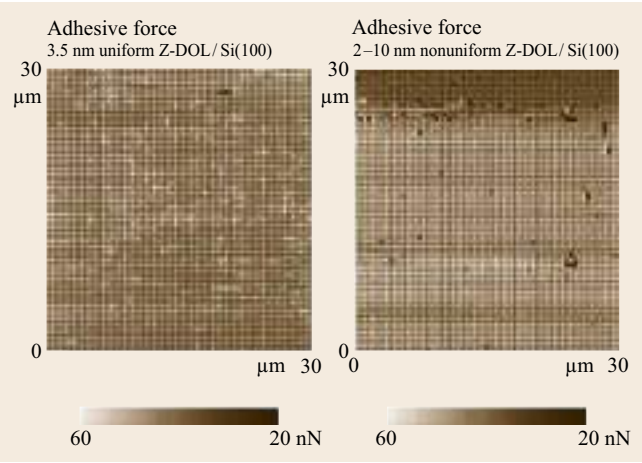

Fig. 27.77 Gray-scale plots of the adhesive force distribution of a uniformly coated, 3.5 nm thick unbonded Z-DOL film on silicon and 3–10 nm thick unbonded Z-DOL film on silicon that was deliberately coated nonuniformly by vibrating the sample during the coating process (after [27.125])

obtained by measuring the force on the tip as it approaches, contacts, and pushes through the liquid film and ultimately contacts the substrate. The distance between the sharp snap-in (owing to the formation of a liquid meniscus and van der Waals forces between the film and the tip) at the liquid surface and the hard repulsion at the substrate surface is a measure of the liquid film thickness. Figure 27.78 shows a plot of forces between the tip and both virgin hair and conditioner-treated hair. The hair sample was first brought into contact with the tip and then pulled away at a velocity of 400 nm/s. The zero tip–sample separation is defined to be the position where the force on the tip is zero, and the tip is not in contact with the sample. As the tip approaches the sample, a negative force exists which indicates an attractive force. The treated hair surface shows a much longer range of interaction with the tip compared to the very short range of interaction between virgin hair surfaces and the tip. Typically, the tip suddenly snaps into contact with the conditioner layer at a finite separation H (about 30 nm), which is proportional to conditioner thickness h. As the tip contacts the substrate, the tip travels with the sample. When the sample is withdrawn, the forces on the tip slowly decrease to zero once the meniscus of liquid is drawn out from the hair surface. It should be noted that the distance H between the sharp snap-in at the liquid surface and the hard wall contact with the substrate is not the real conditioner thickness h. Because of interaction of the liquid with the tip at some spacing distance, H tends to be thicker than the actual film thickness, but can still provide an estimate of the actual film thickness and upper limit of thickness.

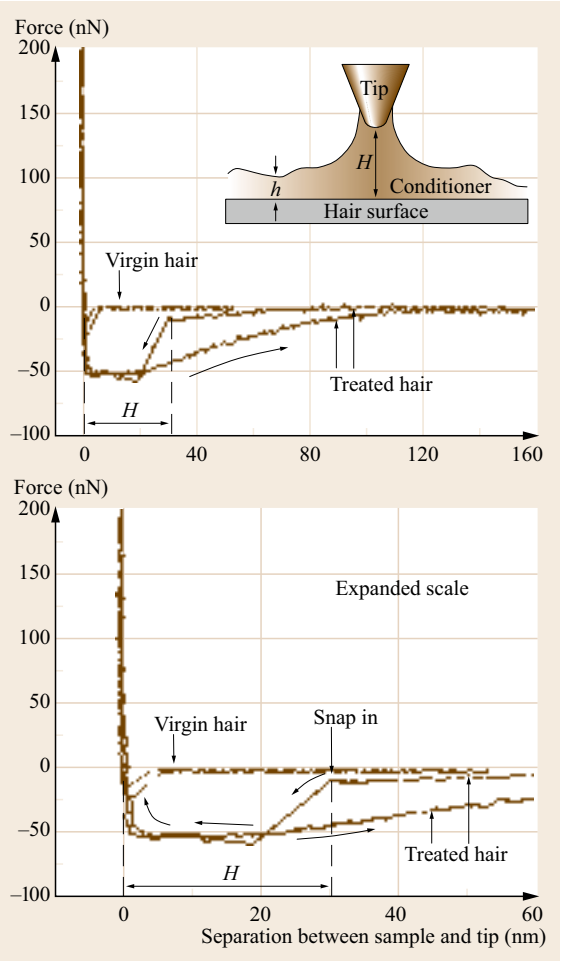

Fig. 27.78 Forces between tip and hair surface as a function of tip–sample separation for virgin hair and conditioner-treated hair. A schematic of measurement for localized conditioner thickness is shown in the *inset at the top*. The expanded scale view of force curve at small separation is shown *at the bottom* (after [27.72]) ◄

27.6 Conclusion

For most solid–solid interfaces of technological relevance, contact occurs at multiple asperities. A sharp AFM/FFM tip sliding on a surface simulates just one such contact. However, asperities come in all shapes and sizes. The effect of the radius of a single asperity (tip) on the friction/adhesion performance can be studied using tips of different radii. AFM/FFM are used to study various tribological phenomena including surface roughness, adhesion, friction, scratching, wear, indentation, detection of material transfer, and boundary lubrication. Measurement of the atomic-scale friction of a freshly cleaved, highly oriented, pyrolytic graphite exhibits the same periodicity as that of the corresponding topography. However, the peaks in friction and those in the corresponding topography are displaced relative to each other. Variations in atomic-scale friction and the observed displacement can be explained by the variation in interatomic forces in the normal and lateral directions. The relevant friction mechanism is atomic-scale stick-slip. Local variations in microscale friction occur and are found to correspond to the local slopes, suggesting that a ratchet mechanism and collision effects are responsible for this variation. Directionality in the friction is observed on both micro- and macroscales which results from the surface roughness and surface preparation. Anisotropy in surface roughness accentuates this effect. Friction contrast in conventional frictional measurements is based on interactions dependent upon interfacial material properties superimposed by roughness-induced lateral forces. To obtain roughness-independent friction, lateral or torsional modulation techniques can be used. These techniques also allow measurements over a small region. AFM/FFM experiments are generally conducted at relative velocities up to about 200 μm/s. High-velocity experiments can be performed by either mounting a sample on a shear wave transducer driven at very high frequencies or mounting a sample on a high-velocity piezo stage. By using these techniques, friction and wear experiments can be performed at a range of sliding velocities as well as normal loads, and the data have been used to develop nanoscale friction and wear maps. Relevant friction mechanisms are different for different ranges of sliding velocities and normal loads.

Adhesion and friction in a wet environment depend on the tip radius, surface roughness, and relative humidity. Superhydrophobic surfaces can be designed by roughness optimization.

Nanoscale friction is generally found to be smaller than microscale friction. There are several factors responsible for the differences including wear and contaminant particles, the transition from elasticity to plasticity, scale-dependent roughness and mechanical properties, and meniscus effects. Nanoscale friction values increase with an increase in the normal load above a certain critical load (pressure), approaching the macroscale friction. The critical contact pressure corresponds to the hardness of the softer of the two contacting materials.

The wear rate on the microscale for single-crystal silicon is negligible below 20 μN, and is much higher and remains approximately constant at higher loads. Elastic deformation at low loads is responsible for negligible wear. Most of the wear debris is loose. SEM and TEM studies of the wear region suggest that the material on the microscale is removed by plastic deformation with a small contribution from elastic fracture; this observation corroborates with the scratch data. Evolution of wear has also been studied using AFM. Wear is found to be initiated at nanoscratches. For a sliding interface requiring near-zero friction and wear, contact stresses should be below the hardness of the softer material to minimize plastic deformation and surfaces should be free of nanoscratches. Further, wear precursors can be detected at early stages of wear by using surface potential measurements. It is found that even in the case of zero wear (no measurable deformation of the surface using AFM), there can be a significant change in the surface potential inside the wear mark, which is useful for the study of wear precursors. Detection of material transfer on a nanoscale is possible with AFM.

In situ surface characterization of the local deformation of materials and thin coatings can be carried out using a tensile stage inside an AFM. An AFM can also be used for nanofabrication/nanomachining.

A modified AFM can be used to obtain load–displacement curves and for the measurement of nanoindentation hardness and Young's modulus of elasticity, with a depth of indentation as low as 1 nm. A continuous stiffness technique can be used to measure variations in mechanical properties of layered materials and nonhomogeneous composites. Mechanical properties are scale-dependent. For example, hardness of ceramics on nanoscales is found to be higher than that on the microscale. Ceramics exhibit significant plasticity and creep on a nanoscale. By using the force modulation technique, localized surface elasticity maps of composite materials with penetration depth as low as 1 nm can be obtained. By using phase contrast microscopy in tapping or torsional mode, it is possible to obtain phase contrast maps or the contrast in viscoelastic properties of near-surface regions. Scratching and indentation on the nanoscale are powerful ways to screen for adhesion and resistance to deformation of ultrathin films.

Boundary lubrication studies and measurement of lubricant-film thickness with a lateral resolution on the nanoscale can be conducted using AFM. Chemically bonded lubricant films and self-assembled monolayers are superior in friction and wear resistance. For chemically bonded lubricant films, the adsorption of water, formation of meniscus and its changes during sliding, and surface properties play an important role in regard to the adhesion, friction, and durability of these films. Sliding velocity, relative humidity, and temperature affect adhesion and friction. For SAMs, their friction mechanism is explained by a so-called *molecular spring* model. Films with high-compliance, long carbon chains exhibit low friction and wear. Also, perfluoroalkylsilane SAMs on Si appear to be more hydrophobic with lower adhesion than alkylsilane SAMs on Si.

Investigations of adhesion, friction, wear, scratching, and indentation on the nanoscale using an AFM can provide insight into the failure mechanisms of materials. Coefficients of friction, wear rates, and mechanical properties such as hardness have been found to be different on the nanoscale than on the macroscale; generally, the coefficients of friction and wear rates on micro- and nanoscales are smaller, whereas the hardness is greater. Therefore, nanotribological studies may help define the regimes for ultralow friction and near-zero wear. These studies also provide insight into the atomic origins of adhesion, friction, wear, and lubrication mechanisms.

28. Surface Forces and Nanorheology of Molecularly Thin Films

Dong Woog Lee, Marina Ruths, Jacob N. Israelachvili

In this chapter, we describe the static and dynamic normal forces that occur between surfaces in vacuum or liquid and the different modes of friction that can be observed between:

1. Bare surfaces in contact (dry or interfacial friction)
2. Surfaces separated by a thin liquid film (lubricated friction)
3. Surfaces coated with organic monolayers (boundary friction).

Experimental methods suitable for measuring normal surface forces, and adhesion and friction (lateral or shear) forces of different magnitude at the molecular level are described. We explain the molecular origin of van der Waals, electrostatic, solvation and polymer-mediated interactions, and basic models for the contact mechanics of adhesive and nonadhesive elastically deforming bodies. The effects of interaction forces, molecular shape, surface structure and roughness on adhesion and friction are discussed.

Simple models for the contributions of the adhesion force and external load to interfacial friction are illustrated with experimental data on both unlubricated and lubricated systems, as measured with the surface forces apparatus. We discuss rate-dependent adhesion (adhesion hysteresis) and how this is related to friction. Some examples of the transition from wearless friction to friction with wear are shown.

Lubrication in different lubricant thickness regimes is described together with explanations of nanorheological concepts. The occurrence of and transitions between smooth and stick–slip sliding in various types of dry (unlubricated and solid boundary lubricated) and liquid lubricated systems are discussed based on recent experimental results and models for stick–slip involving memory distance and dilatancy.

28.1 Types of Surface Forces

In this chapter, we discuss the most important types of surface forces and the relevant equations for the force and friction laws. Several different attractive and repulsive forces operate between surfaces and particles. Some forces occur in vacuum, for example attractive van der Waals and repulsive hard-core interactions. Other types of forces can arise only when the interacting surfaces are separated by another condensed phase, which is usually a liquid. The most common types of surface forces and their main characteristics are listed in Table 28.1.

In *vacuum*, the two main long-range interactions are the attractive van der Waals and electrostatic (Coulomb) forces. At smaller surface separations (corresponding to molecular contact at surface separations of $D \approx 0.2\,\text{nm}$), additional attractive interactions can be found such as covalent or metallic bonding forces. These attractive forces are stabilized by the hard-core repulsion. Together they determine the surface and interfacial energies of planar surfaces, as well as the strengths of materials and adhesive junctions. Adhesion forces are often strong enough to elastically or plastically deform bodies or particles when they come into contact.

In *vapors* (e.g., atmospheric air containing water and organic molecules), solid surfaces in, or close to, contact will generally have a surface layer of chemisorbed or physisorbed molecules, or a capillary condensed liquid bridge between them. A surface layer usually causes the adhesion to decrease, but in the case of capillary condensation, the additional Laplace pressure or attractive *capillary* force may make the adhesion between the surfaces stronger than in an inert gas or vacuum.

When totally immersed in a *liquid*, the force between particles or surfaces is completely modified from that in vacuum or air (vapor). The van der Waals attraction is generally reduced, but other forces can now arise that can qualitatively change both the range and even the sign of the interaction. The attractive force in such a system can be either stronger or weaker than in the absence of the intervening liquid. Depending on the different forces that may be operating simultaneously in solution, the overall force law is not generally monotonically attractive even at long range; it can be repulsive, or the force can change sign at some finite surface separation. In such cases, the potential-energy minimum, which determines the adhesion force or energy, does not occur at the true molecular contact between the surfaces, but at some small distance further out.

The forces between surfaces in a liquid medium can be particularly complex at *short range*, i. e., at surface separations below a few nanometers or 4–10 molecular diameters. This is partly because, with increasing confinement, a liquid ceases to behave as a structureless continuum with bulk properties; instead, the size and shape of its molecules begin to determine the overall interaction. In addition, the surfaces themselves can no longer be treated as inert and structureless walls (i. e., mathematically flat) and their physical and chemical properties at the atomic scale must now be taken into account. The force laws will then depend on whether the surfaces are amorphous or crystalline (and whether the lattices of crystalline surfaces are matched or not), rough or smooth, rigid or soft (fluid-like), and hydrophobic or hydrophilic.

It is also important to distinguish between *static* (i. e., equilibrium) interactions and *dynamic* (i. e., nonequilibrium) forces such as viscous and friction forces. For example, certain liquid films confined between two contacting surfaces may take a surprisingly long time to equilibrate, as may the surfaces themselves, so that the short-range and adhesion forces appear to be time dependent, resulting in aging effects.

Table 28.1 Types of surface forces in vacuum versus in liquid (colloidal forces). Note: (v) applies only to interactions in vacuum, (s) applies only to interactions in solution (or to surfaces separated by a liquid), and (v&s) applies to interactions occurring both in vacuum and in solution

Type of force	Subclasses or alternative names	Main characteristics
	Attractive forces	
van der Waals	Debye induced dipole force (v&s) London dispersion force (v&s) Casimir force (v&s)	Ubiquitous, occurs both in vacuum and in liquids
Electrostatic	Ionic bond (v) Coulombic force (v&s) Hydrogen bond (v) Charge-exchange interaction (v&s) Acid–base interaction (s) *Harpooning* interaction (v)	Strong, long-range, arises in polar solvents; requires surface charging or charge-separation mechanism
Ion correlation	van der Waals force of polarizable ions (s)	Requires mobile charges on surfaces in a polar solvent
Quantum mechanical	Covalent bond (v) Metallic bond (v) Exchange interaction (v)	Strong, short-range, responsible for contact binding of crystalline surfaces
Solvation	Oscillatory force (s) Depletion force (s)	Mainly entropic in origin, the oscillatory force alternates between attraction and repulsion
Hydrophobic	Attractive hydration force (s)	Strong, apparently long-range; origin not yet understood
Specific binding	*Lock-and-key* or complementary binding (v&s) Receptor–ligand interaction (s) Antibody–antigen interaction (s)	Subtle combination of different noncovalent forces giving rise to highly specific binding; main recognition mechanism of biological systems
	Repulsive forces	
van der Waals	van der Waals disjoining pressure (s)	Arises only between dissimilar bodies interacting in a medium
Electrostatic	Coulombic force (v&s)	Arises only for certain constrained surface charge distributions
Quantum mechanical	Hard-core or steric repulsion (v) Born repulsion (v)	Short-range, stabilizing attractive covalent and ionic binding forces, effectively determine molecular size and shape
Solvation	Oscillatory solvation force (s) Structural force (s) Hydration force (s)	Monotonically repulsive forces, believed to arise when solvent molecules bind strongly to surfaces
Entropic	Osmotic repulsion (s) Double-layer force (s) Thermal fluctuation force (s) Steric polymer repulsion (s) Undulation force (s) Protrusion force (s)	Due to confinement of molecular or ionic species; requires mechanism that keeps trapped species between the surfaces
	Dynamic interactions	
Nonequilibrium	Hydrodynamic forces (s) Viscous forces (s) Friction forces (v&s) Lubrication forces (s)	Energy-dissipating forces occurring during relative motion of surfaces or bodies

28.2 Methods Used to Study Surface Forces

28.2.1 Force Laws

The full force law $F(D)$ between two surfaces, i. e., the force F as a function of surface separation D, can be measured in a number of ways [28.1–3]. The simplest is to move the base of a spring by a known amount ΔD_0. Figure 28.1 illustrates this method when applied to the interaction of two magnets. However, the method is also applicable at the microscopic or molecular level, and it forms the basis of all direct force-measuring apparatuses such as the surface forces apparatus (SFA; [28.1, 4]). If there is a detectable force between the surfaces, this will cause the force-measuring spring to deflect by ΔD_s, while the surface separation changes by ΔD. These three displacements are related by

$$\Delta D_s = \Delta D_0 - \Delta D \,. \tag{28.1}$$

The difference in force, ΔF, between the initial and final separations is given by

$$\Delta F = k_s \Delta D_s \,, \tag{28.2}$$

where k_s is the spring constant. The equations above provide the basis for measurements of the force difference between any two surface separations. For example, if a force-measuring apparatus with a known k_s can measure D (and thus ΔD), ΔD_0, and ΔD_s, the force difference ΔF can be measured between a large initial or reference separation D, where the force is zero ($F = 0$), and another separation $D - \Delta D$. By working one's way in increasing increments of $\Delta D = \Delta D_0 - \Delta D_s$, the full force law $F(D)$ can be constructed over any desired distance regime.

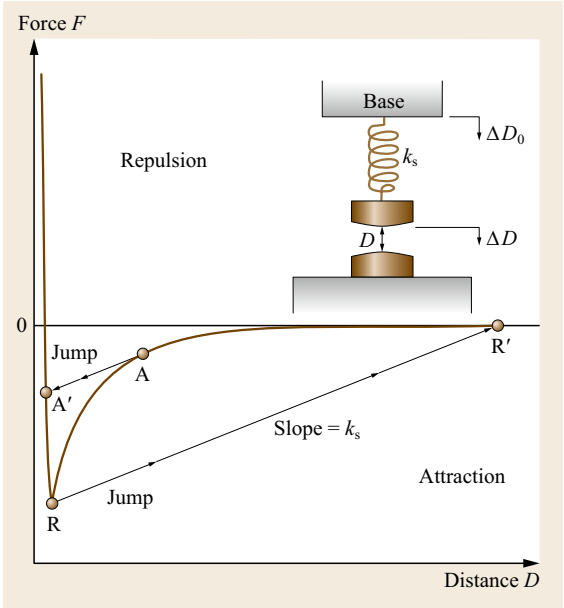
In order to measure an equilibrium force law, it is essential to establish that the two surfaces have stopped moving before the displacements are measured. When displacements are measured while two surfaces are still in relative motion, one also measures a viscous or frictional contribution to the total force. Such dynamic force measurements have enabled the viscosities of liquids near surfaces and in thin films to be accurately determined [28.6, 7]. In practice, it is difficult to measure the forces between two perfectly flat surfaces, because of the stringent requirement of perfect alignment for making reliable measurements at distances of a few tenths of a nanometer. It is far easier to measure the forces between curved surfaces, e.g., two spheres, a sphere and a flat surface, or two crossed cylinders. Furthermore, the force $F(D)$ measured between two curved surfaces can be directly related to the energy per unit area $E(D)$ between two flat surfaces at the same separation D by the so-called Derjaguin approximation [28.8]

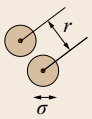
$$E(D) = \frac{F(D)}{2\pi R} \,, \tag{28.3}$$

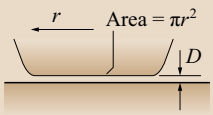
where R is the radius of the sphere (for a sphere and a flat surface) or the radii of the cylinders (for two crossed cylinders, Table 28.2).

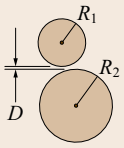
28.2.2 Adhesion Forces

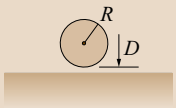
The most direct way to measure the adhesion of two solid surfaces (such as two spheres or a sphere on a flat surface) is to suspend one of them on a spring and measure the adhesion or pull-off force needed to separate

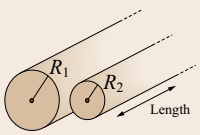


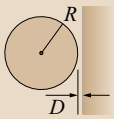












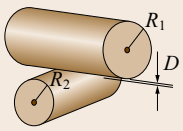


Fig. 28.1 Schematic attractive force law between two macroscopic objects such as two magnets, or between two microscopic objects such as the van der Waals force between a metal tip and a surface. On lowering the base supporting the spring, the latter will expand or contract such that, at any equilibrium separation D, the attractive force balances the elastic spring restoring force. If the gradient of the attractive force dF/dD exceeds the gradient of the spring's restoring force (defined by the spring constant k_s), the upper surface will jump from A into contact at A′ (A for advancing). On separating the surfaces by raising the base, the two surfaces will jump apart from R to R′ (R for receding). The distance R–R′ multiplied by k_s gives the adhesion force, i. e., the value of F at the point R (after [28.5] with permission)

Table 28.2 Van der Waals interaction energy and force between macroscopic bodies of different geometries

Geometry of bodies with surfaces D apart ($D \ll R$)			van der Waals interaction	
			Energy E	Force F
Two atoms or small molecules		$r \geq \sigma$	$\frac{-C_{vdW}}{r^6}$	$\frac{-6C_{vdW}}{r^7}$
Two flat surfaces (per unit area)		$r \gg D$	$\frac{-A_H}{12\pi D^2}$	$\frac{-A_H}{6\pi D^3}$
Two spheres or macromolecules of radii R_1 and R_2		$R_1, R_2 \gg D$	$\frac{-A_H}{6D}\left(\frac{R_1R_2}{R_1+R_2}\right)$	$\frac{-A_H}{6D^2}\left(\frac{R_1R_2}{R_1+R_2}\right)$
Sphere or macromolecule of radius R near a flat surface		$R \gg D$	$\frac{-A_H R}{6D}$	$\frac{-A_H R}{6D^2}$
Two parallel cylinders or rods of radii R_1 and R_2 (per unit length)		$R_1, R_2 \gg D$	$\frac{-A_H}{12\sqrt{2}D^{3/2}}\left(\frac{R_1R_2}{R_1+R_2}\right)^{1/2}$	$\frac{-A_H}{8\sqrt{2}D^{5/2}}\left(\frac{R_1R_2}{R_1+R_2}\right)^{1/2}$
Cylinder of radius R near a flat surface (per unit length)		$R \gg D$	$\frac{-A_H\sqrt{R}}{12\sqrt{2}D^{3/2}}$	$\frac{-A_H\sqrt{R}}{8\sqrt{2}D^{5/2}}$
Two cylinders or filaments of radii R_1 and R_2 crossed at 90°		$R_1, R_2 \gg D$	$\frac{-A_H\sqrt{R_1R_2}}{6D}$	$\frac{-A_H\sqrt{R_1R_2}}{6D^2}$

A negative force (A_H positive) implies attraction, a positive force means repulsion (A_H negative) (after [28.9], with permission)

the two bodies, using the deflection of the spring. If k_s is the stiffness of the force-measuring spring and ΔD is the distance the two surfaces jump apart when they separate, then the adhesion force F_{ad} is given by

$$F_{ad} = F_{max} = k_s \Delta D \,, \tag{28.4}$$

where we note that, in liquids, the maximum or minimum in the force may occur at some nonzero surface separation. From F_{ad} and a known surface geometry, and assuming that the surfaces were everywhere in molecular contact, one may also calculate the surface or interfacial energy γ. For an elastically deformable sphere of radius R on a flat surface, or for two crossed cylinders of radius R, we have [28.1, 10]

$$\gamma = \frac{F_{ad}}{3\pi R} \,, \tag{28.5}$$

while for two spheres of radii R_1 and R_2

$$\gamma = \frac{F_{ad}}{3\pi}\left(\frac{1}{R_1} + \frac{1}{R_2}\right), \tag{28.6}$$

where γ is in units of $\mathrm{J\,m^{-2}}$ (Sect. 28.5.2).

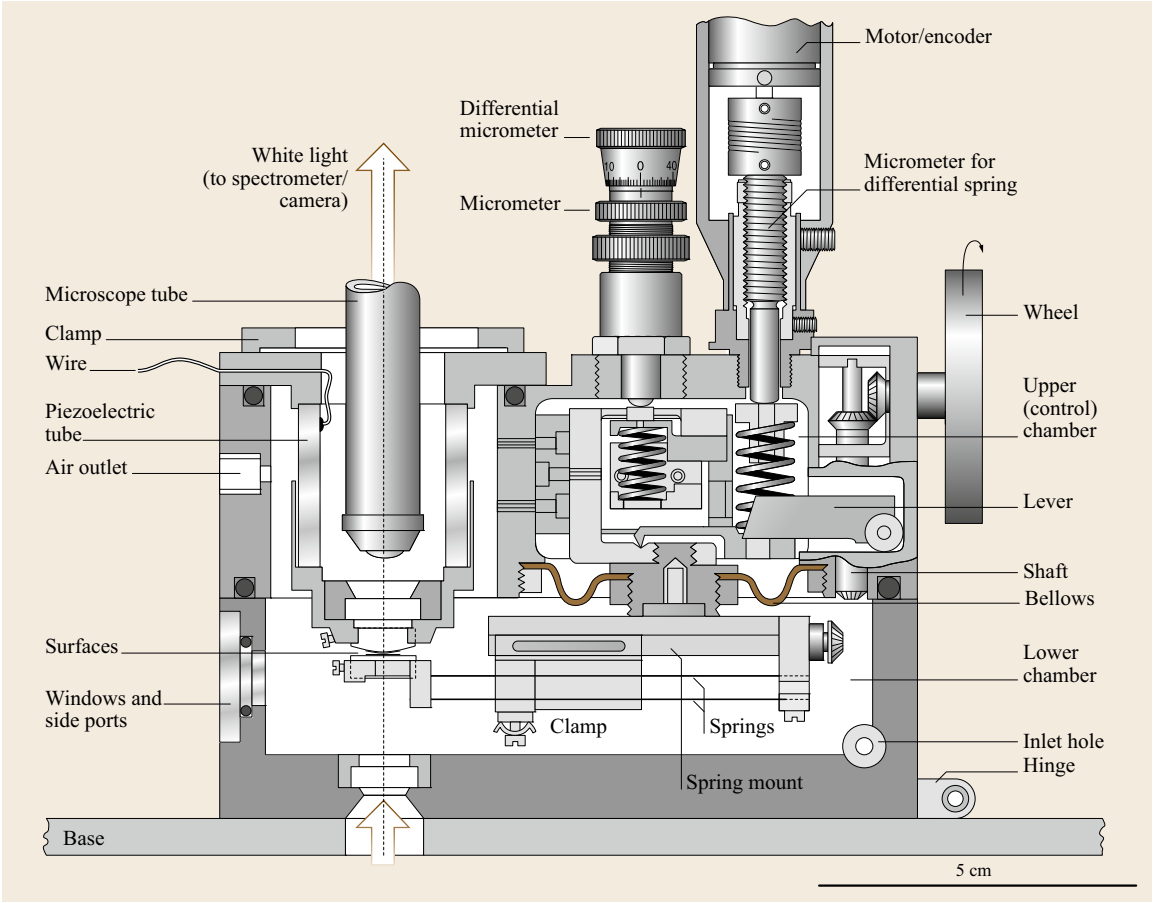

Fig. 28.2 An SFA where the intermolecular forces between two macroscopic, cylindrical surfaces of local radius R can be directly measured as a function of surface separation over a large distance regime from tenths of a nanometer to micrometers. Local or transient surface deformations can be detected optically. Various attachments for moving one surface laterally with respect to the other have been developed for friction measurements in different regimes of sliding velocity and sliding distance (after [28.11] with permission)

28.2.3 The SFA

The SFA (Fig. 28.2) is used for measurements of adhesion and force laws between two curved molecularly smooth surfaces immersed in liquids or controlled vapors [28.1, 4, 11]. In SFA experiments, ΔD_0 is changed by expanding or contracting a piezoelectric crystal by a known amount or by moving the base of the spring with sensitive motor-driven mechanical stages. The resulting change in surface separation ΔD is measured by multiple beam interferometry with an accuracy of ± 0.1 nm, and the spring deflection ΔD_s can then be obtained according to (28.1). From the shape of the interference fringes one also obtains the radius of the surfaces R and any surface deformation that arises during an interaction [28.12, 13]. The resolution in the lateral direction is about 1 μm. The surface separation can be independently controlled to within 0.1 nm, and the force sensitivity is about 10^{-10} N. For a typical surface radius of $R \approx 1$ cm, γ values can be measured to an accuracy of about 10^{-3} mJ m^{-2}.

Several different materials have been used to form the surfaces in the SFA, including mica [28.14, 15], silica [28.16], sapphire [28.17], and polymer sheets [28.18]. These materials can also be used as supporting substrates in experiments on the forces between adsorbed or chemically bound polymer layers [28.7, 19–22], surfactant and lipid monolayers and bilayers [28.9, 23–26], and metal and metal oxide layers [28.27–31]. The range of liquids and vapors that can be used is almost endless, and has thus far included aqueous solutions, organic liquids and solvents, polymer melts, various petroleum oils and lubricant liquids, dyes, and liquid crystals.

Friction attachments for the SFA [28.32–36] allow for the two surfaces to be sheared laterally past each other at varying sliding speeds or oscillating frequencies, while simultaneously measuring both the transverse (frictional or shear) force and the normal force (load) between them. The ranges of friction forces and sliding speeds that can be studied with such methods are currently 10^{-7}–10^{-1} N and 10^{-13}–10^{-2} m s^{-1} respectively [28.37]. The externally applied load L can be varied continuously, and both positive and negative loads can be applied. The distance between the surfaces D, their true molecular contact area, their elastic (or viscoelastic or elastohydrodynamic) deformation, and their lateral motion can all be monitored simultaneously by recording the moving interference fringe pattern. Equipment for dynamic measurements of normal forces has also been developed. Such measurements give information on the viscosity of the medium and the location of the shear or slip planes relative to the surfaces [28.6, 7].

28.3 Normal Forces Between Dry (Unlubricated) Surfaces

28.3.1 Van Der Waals Forces in Vacuum and Inert Vapors

Forces between macroscopic bodies (such as colloidal particles) across vacuum arise from interactions between the constituent atoms or molecules of each body across the gap separating them. These intermolecular interactions are electromagnetic forces between permanent or induced dipoles (van der Waals forces), and between ions (electrostatic forces). In certain systems, other types of interactions can also be observed between surfaces in vacuum, e.g., charge exchange interactions, sintering, and cold welding. In this section, we describe the van der Waals forces, which occur between all atoms and molecules and between all macroscopic bodies [28.1].

The interaction between two permanent dipoles with a fixed relative orientation can be attractive or repulsive. For the specific case of two freely rotating permanent dipoles in a liquid or vapor (orientational or Keesom interaction), and for a permanent dipole and an induced dipole in an atom or polar or nonpolar molecule (induction or Debye interaction), the interaction is on average always attractive. The third type of van der Waals interaction, the fluctuation or London dispersion interaction, arises from instantaneous polarization of one nonpolar or polar molecule due to fluctuations in the charge distribution of a neighboring nonpolar or polar molecule (Fig. 28.3). Correlation between these fluctuation-induced dipole moments gives an attraction that is present between any two molecules or surfaces across vacuum. At very small separations, the interaction will ultimately be repulsive as the electron clouds of atoms and molecules begin to overlap. The total interaction is thus a combination of a short-range repulsion and a relatively long-range attraction.

Except for in highly polar materials such as water, London dispersion interactions give the largest contribution (70%–100%) to the van der Waals attraction. The interaction energy of the van der Waals force between atoms or molecules depends on the separation r as

$$E(D) = -\frac{C_{\mathrm{vdW}}}{r^6}\,, \tag{28.7}$$

where the constant C_{vdW} depends on the dipole moments and polarizabilities of the molecules. At large separations (> 10 nm), the London interaction is weakened by a randomizing effect caused by the rapid fluctuations. That is, the induced temporary dipole moment of one molecule may have changed during the time needed for the transmission of the electromagnetic wave (photon) generated by its fluctuating charge density to another molecule and the return of the photon generated by the induced fluctuation in this second molecule. This phenomenon is called retardation and causes the interaction energy to decay as r^{-7} at large separations [28.38].

Dispersion interactions are to a first approximation additive, and their contribution to the interac-

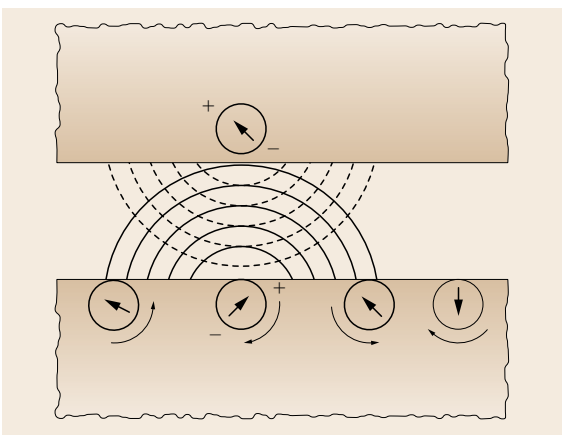

Fig. 28.3 Schematic representation of van der Waals interaction (dipole–induced dipole interaction)

tion energy between two macroscopic bodies (such as colloidal particles) across vacuum can be found by summing the pairwise interactions [28.39]. The interaction is generally described in terms of the Hamaker constant, A_H. Another approach is to treat the interacting bodies and an intervening medium as continuous phases and determine the strength of the interaction from bulk dielectric properties of the materials [28.40, 41]. Unlike the pairwise summation, this method takes into account the screening of the interactions between molecules inside the bodies by the molecules closer to the surfaces and the effects of the intervening medium. For the interaction between material 1 and material 3 across material 2, the nonretarded Hamaker constant given by the Lifshitz theory is approximately [28.1]

$$A_{H,123} = A_{H,\nu=0} + A_{H,\nu>0} \approx \frac{3}{4} k_B T \left(\frac{\varepsilon_1 - \varepsilon_2}{\varepsilon_1 + \varepsilon_2}\right)\left(\frac{\varepsilon_3 - \varepsilon_2}{\varepsilon_3 + \varepsilon_2}\right) + \frac{3h\nu_e}{8\sqrt{2}} \times \frac{\left(n_1^2 - n_2^2\right)\left(n_3^2 - n_2^2\right)}{\sqrt{\left(n_1^2 + n_2^2\right)}\sqrt{\left(n_3^2 + n_2^2\right)} \times \left(\sqrt{\left(n_1^2 + n_2^2\right)} + \sqrt{\left(n_3^2 + n_2^2\right)}\right)}, \quad (28.8)$$

where the first term ($\nu = 0$) represents the permanent dipole and dipole–induced dipole interactions and the second ($\nu > 0$) the London (dispersion) interaction. ε_i and n_i are the static dielectric constants and refractive indexes of the materials respectively. ν_e is the frequency of the lowest electron transition (around $3 \times 10^{15}\,s^{-1}$). Either one of the materials 1, 2, or 3 in (28.8) can be vacuum or air ($\varepsilon = n = 1$). A_H is typically 10^{-20}–10^{-19} J (the higher values are found for metals) for interactions between solids and liquids across vacuum or air.

The interaction energy between two macroscopic bodies is dependent on the geometry and is always attractive between two bodies of the same material (A_H positive, see (28.8)). The van der Waals interaction energy and force laws ($F = -dE(D)/dD$) for some common geometries are given in Table 28.2. Because of the retardation effect, the equations in Table 28.2 will lead to an overestimation of the dispersion force at large separations. It is, however, apparent that the interaction energy between macroscopic bodies decays more slowly with separation (i. e., has a longer range) than between two molecules. For inert nonpolar surfaces, e.g., consisting of hydrocarbons or van der Waals solids and liquids, the Lifshitz theory has been found to apply even at molecular contact, where it can be used to predict the surface energies (surface tensions) of such solids and liquids. For example, for hydrocarbon surfaces, $A_H = 5 \times 10^{-20}$ J. Inserting this value into the equation for two flat surfaces (Table 28.2) and using a cut-off distance of $D_0 \approx 0.165$ nm as an effective separation when the surfaces are in contact [28.1], we obtain for the surface energy γ (which is defined as half the interaction energy)

$$\gamma = \frac{E}{2} = \frac{A_H}{24\pi D_0^2} \approx 24\,\mathrm{mJ\,m^{-2}}, \quad (28.9)$$

a value that is typical for hydrocarbon solids and liquids [28.42]. If the adhesion force is measured between two crossed-cylindrical surfaces of $R = 1$ cm (a geometry equivalent to a sphere with $R = 1$ cm interacting with a flat surface, Table 28.2) using an SFA, we expect the adhesion force to be (Table 28.2) $F = A_H R/(6D_0^2) = 4\pi R\gamma \approx 3.0$ mN. Using a spring constant of $k_s = 100\,\mathrm{N\,m^{-1}}$, such an adhesive force will cause the two surfaces to jump apart by $\Delta D = F/k_s = 30\,\mu$m, which can be accurately measured. (For elastic bodies that deform in adhesive contact, R changes during the interaction and the measured adhesion force is 25% lower, see Sect. 28.5.2). Surface energies of solids can thus be directly measured with the SFA. The measured values are in good agreement with calculated values based on the known surface energies γ of the materials, and for nonpolar low-energy solids they are well accounted for by the Lifshitz theory [28.1].

28.4 Normal Forces Between Surfaces in Liquids

28.4.1 Van Der Waals Forces in Liquids

The dispersion interaction in a medium will be significantly lower than in vacuum, since the attractive interaction between two solute molecules in a medium (solvent) involves displacement and reorientation of the nearest-neighbor solvent molecules. Even though the surrounding medium may change the dipole moment and polarizability from that in vacuum, the interaction between two identical molecules remains attractive in a binary mixture. The extension of the interactions to the case of two macroscopic bodies is the same as described in Sect. 28.3.1. Typically, the Hamaker constants for interactions in a medium are an order of magnitude lower than in vacuum. Between macroscopic surfaces in liquids, van der Waals forces become im-

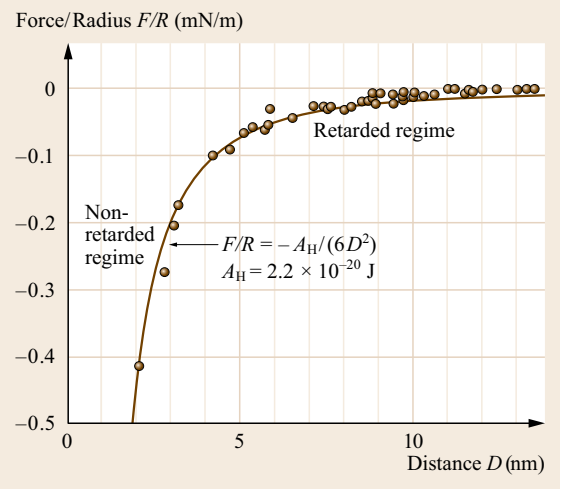

Fig. 28.4 Attractive van der Waals force F between two curved mica surfaces of radius $R \approx 1$ cm measured in water and various aqueous electrolyte solutions. The electrostatic interaction has been subtracted from the total measured force. The measured nonretarded Hamaker constant is $A_H = 2.2 \times 10^{-20}$ J. Retardation effects are apparent at distances larger than 5 nm, as expected theoretically (after [28.1], with permission from Elsevier Science)

portant at distances below 10−15 nm and may at these distances start to dominate interactions of different origin that have been observed at larger separations.

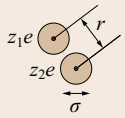
Figure 28.4 shows the measured van der Waals forces between two crossed-cylindrical mica surfaces in water and various salt solutions. Good agreement is obtained between experiment and theory. At larger surface separations, above about 5 nm, the measured forces fall off more rapidly than D^{-2}. This retardation effect (Sect. 28.3.1) is also predicted by the Lifshitz theory and is due to the time needed for propagation of the induced dipole moments over large distances.

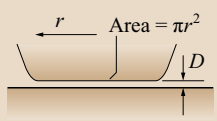
From Fig. 28.4 we may conclude that, at separations above about 2 nm, or 8 molecular diameters of water, the *continuum* Lifshitz theory is valid. This would mean that water films as thin as 2 nm may be expected to have bulk-like properties, at least as far as their interaction forces are concerned. Similar results have been obtained with other liquids, where in general continuum properties are manifested, both as regards to their interactions and other properties such as viscosity, at a film thickness larger than five or ten molecular diameters. In the absence of a solvent (in vacuum), the agreement of measured van der Waals forces with the continuum Lifshitz theory is generally good at all separations down to molecular contact ($D = D_0$).

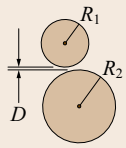
Van der Waals interactions in a system of three or more different materials (28.8) can be attractive or repulsive, depending on their dielectric properties. Numerous experimental studies show the attractive van der Waals forces in various systems [28.1], and repulsive van der Waals forces have also been measured directly [28.43]. A practical consequence of the repulsive interaction obtained across a medium with intermediate dielectric properties is that the van der Waals forces will give rise to preferential, nonspecific adsorption of molecules with an intermediate dielectric constant. It is possible to diminish the attractive interaction between dispersed colloidal particles by adsorption of a thin layer of material with dielectric properties close to those of the surrounding medium (matching of refractive index), or by adsorption of a polymer that gives a steric repulsive force that keeps the particles separated at a distance where the magnitude of the van der Waals attraction is negligible. Thermal motion will then keep the particles dispersed.

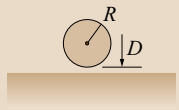
28.4.2 Electrostatic Forces

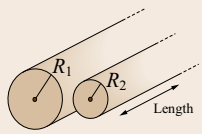
Most surfaces in contact with a highly polar liquid (such as water) acquire a surface charge, either by dissociation of ions from the surface into the solution or by preferential adsorption of certain ions from the solution. The surface charge is balanced by a layer of oppositely charged ions (counterions) in the solution at some small distance from the surface [28.1]. In dilute solution, this distance is the Debye length κ^{-1}, which is purely a property of the electrolyte solution. The Debye length falls with increasing ionic strength (i. e., with the molar concentration M_i and valency z_i) of the ions in solution

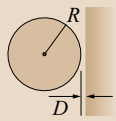


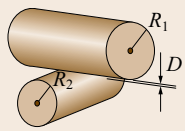












$$\kappa^{-1} = \left(\frac{\varepsilon \varepsilon_0 k_B T}{e^2 N_A \sum_i z_i^2 M_i} \right)^{1/2} , \qquad (28.10)$$

where e is the electronic charge. For example, for 1 : 1 electrolytes at 25 °C, $\kappa^{-1} = 0.304\,\text{nm}/\sqrt{M_{1:1}}$, where M_i is given in M (mol dm^{-3}). κ^{-1} is thus about 10 nm in a 1 mM NaCl solution and 0.3 nm in a 1 M solution. In totally pure water at pH 7, where $M_i = 10^{-7}$ M, κ^{-1} is 960 nm, or about 1 μm. The Debye length also relates the surface charge density σ of a surface to the electrostatic surface potential ψ_0 via the Grahame equation, which for 1 : 1 electrolytes can be expressed as

$$\sigma = \sqrt{8 \varepsilon \varepsilon_0 k_B T} \sinh \left(\frac{e \psi_0}{2 k_B T} \right) \sqrt{M_{1:1} N_A} . \qquad (28.11)$$

Since the Debye length is a measure of the thickness of the diffuse atmosphere of counterions near a charged surface, it also determines the range of the electrostatic double-layer interaction between two charged surfaces.

Table 28.3 Electrical double-layer interaction energy $E(D)$ and force ($F = -\mathrm{d}E/\mathrm{d}D$) between macroscopic bodies

Geometry of bodies with surfaces D apart ($D \ll R$)			Electric double-layer interaction	
			Energy E	Force F
Two ions or small molecules		$r \geq \sigma$	$\frac{\pm z_1 z_2 e^2}{4\pi\varepsilon\varepsilon_0 r} \frac{\mathrm{e}^{-\kappa(r-\sigma)}}{1+\kappa\sigma}$	$\frac{\pm z_1 z_2 e^2}{4\pi\varepsilon\varepsilon_0 r^2} \frac{(1+\kappa r)}{1+\kappa\sigma} \mathrm{e}^{-\kappa(r-\sigma)}$
Two flat surfaces (per unit area)		$r \gg D$	$\left(\frac{\kappa}{2\pi}\right) Z\mathrm{e}^{-\kappa D}$	$\left(\frac{\kappa^2}{2\pi}\right) Z\mathrm{e}^{-\kappa D}$
Two spheres or macromolecules of radii R_1 and R_2		$R_1, R_2 \gg D$	$\left(\frac{R_1 R_2}{R_1+R_2}\right) Z\mathrm{e}^{-\kappa D}$	$\kappa \left(\frac{R_1 R_2}{R_1+R_2}\right) Z\mathrm{e}^{-\kappa D}$
Sphere or macromolecule of radius R near a flat surface		$R \gg D$	$RZ\mathrm{e}^{-\kappa D}$	$\kappa RZ\mathrm{e}^{-\kappa D}$
Two parallel cylinders or rods of radii R_1 and R_2 (per unit length)		$R_1, R_2 \gg D$	$\frac{\kappa^{1/2}}{\sqrt{2\pi}} \left(\frac{R_1 R_2}{R_1+R_2}\right)^{1/2} Z\mathrm{e}^{-\kappa D}$	$\frac{\kappa^{3/2}}{\sqrt{2\pi}} \left(\frac{R_1 R_2}{R_1+R_2}\right)^{1/2} Z\mathrm{e}^{-\kappa D}$
Cylinder of radius R near a flat surface (per unit length)		$R \gg D$	$\kappa^{1/2} \sqrt{\frac{R}{2\pi}} Z\mathrm{e}^{-\kappa D}$	$\kappa^{3/2} \sqrt{\frac{R}{2\pi}} Z\mathrm{e}^{-\kappa D}$
Two cylinders or filaments of radii R_1 and R_2 crossed at 90°		$R_1, R_2 \gg D$	$\sqrt{R_1 R_2} Z\mathrm{e}^{-\kappa D}$	$\kappa \sqrt{R_1 R_2} Z\mathrm{e}^{-\kappa D}$

The interaction energy and force for bodies of different geometries is based on the Poisson–Boltzmann equation (a continuum, mean-field theory). Equation (28.14) gives the interaction constant Z (in terms of the surface potential ψ_0) for the interaction between similarly charged (ionized) surfaces in aqueous solutions of monovalent electrolyte. It can also be expressed in terms of the surface charge density σ by applying the Grahame equation (28.12) (after [28.9], with permission)

The electrostatic double-layer interaction is an entropic effect that arises upon decreasing the thickness of the liquid film containing the dissolved ions. Because of the attractive force between the dissolved ions and opposite charges on the surfaces, the ions stay between the surfaces, but an osmotic repulsion arises as their concentration increases. The long-range electrostatic interaction energy at large separations (weak overlap) between two similarly charged molecules or surfaces is typically repulsive and is roughly an exponentially decaying function of D

$$E(D) \approx +C_{\mathrm{ES}} \mathrm{e}^{-\kappa D} , \qquad (28.12)$$

where C_{ES} is a constant that depends on the geometry of the interacting surfaces, on their surface charge density, and on the solution conditions (Table 28.3). We see that the Debye length is the decay length of the interaction

energy between two surfaces (and of the mean potential away from one surface). C_{ES} can be determined by solving the so-called Poisson–Boltzmann equation or by using other theories [28.44, 45]. The equations in Table 28.3 are expressed in terms of a constant Z defined as

$$Z = 64\pi\varepsilon\varepsilon_0 \left(\frac{k_B T}{e}\right)^2 \tanh^2\left(\frac{ze\psi_0}{4k_B T}\right), \qquad (28.13)$$

which depends only on the properties of the surfaces.

The above approximate expressions are accurate only for surface separations larger than about one Debye length. At smaller separations one must use numerical solutions of the Poisson–Boltzmann equation to obtain the exact interaction potential, for which there are no simple expressions. In the limit of small D, it can be shown that the interaction energy depends on whether the surfaces remain at constant potential ψ_0 (as assumed in the above equations) or at constant charge σ (when the repulsion exceeds that predicted by the above equations), or somewhere between these limits. In the constant charge limit the total number of counterions in the compressed film does not change as D is decreased, whereas at constant potential the concentration of counterions is constant. The limiting pressure (or force per unit area) at constant charge is the osmotic pressure of the confined ions

$$F = k_B T \times \text{ion number density} = \frac{2\sigma k_B T}{zeD}, \text{ for } D \ll \kappa^{-1}. \qquad (28.14)$$

That is, as $D \to 0$ the double-layer pressure at constant surface charge becomes infinitely repulsive and independent of the salt concentration (at constant potential the force instead becomes a constant at small D). However, at small separations, the van der Waals attraction (which goes as D^{-2} between two spheres or as D^{-3} between two planar surfaces, see Table 28.2) wins out over the double-layer repulsion, unless some other short-range interaction becomes dominant (Sect. 28.4.4). This is the theoretical prediction that forms the basis of the so-called Derjaguin–Landau–Verwey–Overbeek (DLVO) theory [28.44, 46], illustrated in Fig. 28.5.

Because of the different distance dependences of the van der Waals and electrostatic interactions, the total force law, as described by the DLVO theory, can show several minima and maxima. Typically, the depth of the outer (secondary) minimum is a few $k_B T$, which is enough to cause reversible flocculation of particles from an aqueous dispersion. If the force barrier between the secondary and primary minimum is lowered, for example by increasing the electrolyte concentration, particles

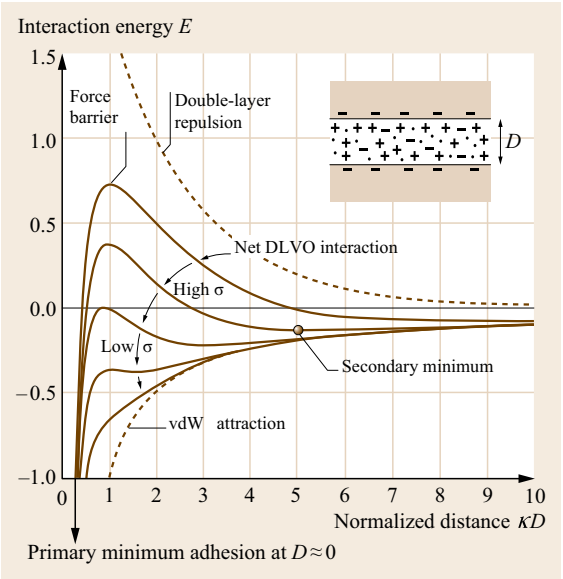


Fig. 28.5 Schematic plots of the DLVO interaction potential energy E between two flat, charged surfaces (or, according to the Derjaguin approximation, (28.3), the force F between two curved surfaces) as a function of the surface separation normalized by the Debye length κ^{-1}. The van der Waals attraction (inverse power-law dependence on D) together with the repulsive electrostatic double-layer force (roughly exponential) at different surface charge σ (or potential, see (28.11)) determine the net interaction potential in aqueous electrolyte solution (after [28.47] with permission)

can be irreversibly coagulated in the primary minimum. In practice, other forces (described in the following sections) often appear at very small separations, so that the full force law between two surfaces or colloidal particles in solution can be more complex than might be expected from the DLVO theory.

28.4.3 Solvation and Structural Forces

When a liquid is confined within a restricted space, for example a very thin film between two surfaces, it ceases to behave as a structureless continuum. At small surface separations (below about ten molecular diameters), the van der Waals force between two surfaces or even two solute molecules in a liquid (solvent) is no longer a smoothly varying attraction. Instead, there arises an additional solvation force that generally oscillates between attraction and repulsion with distance, with a periodicity equal to some mean dimension σ of the liquid molecules [28.51]. Figure 28.6a shows the force law between two smooth mica surfaces across the hydrocarbon liquid tetradecane, whose inert, chainlike

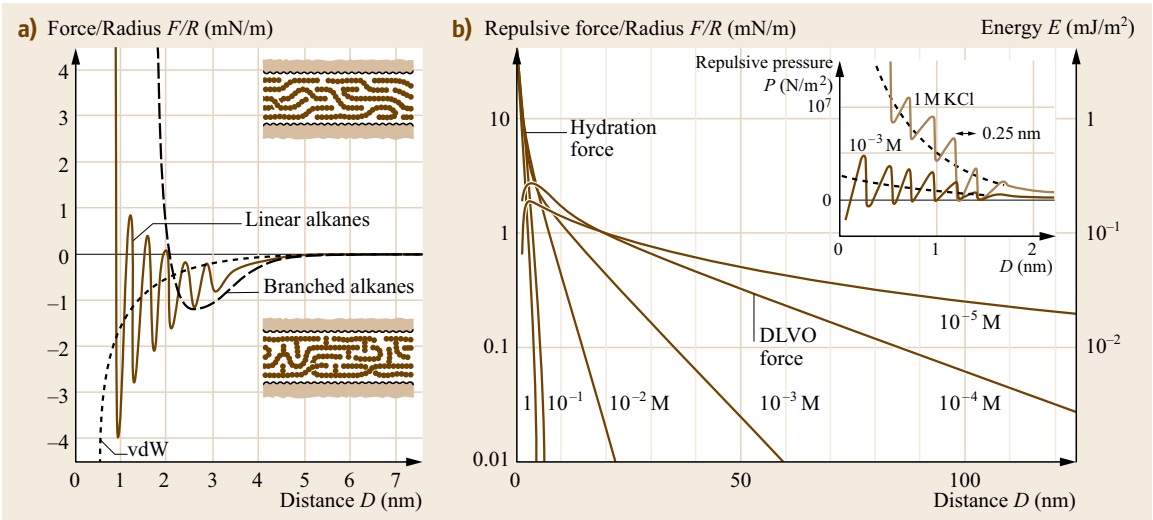

Fig. 28.6 **(a)** *Solid curve*: Forces measured between two mica surfaces across saturated linear chain alkanes such as *n*-tetradecane and *n*-hexadecane (after [28.48, 49]). The 0.4 nm periodicity of the oscillations indicates that the molecules are preferentially oriented parallel to the surfaces, as shown schematically in the *upper insert*. The theoretical continuum van der Waals attraction is shown as a *dotted curve*. *Dashed curve*: Smooth, nonoscillatory force law exhibited by irregularly shaped alkanes (such as 2-methyloctadecane) that cannot order into well-defined layers (*lower insert*) (after [28.48, 50]). Similar nonoscillatory forces are also observed between rough surfaces, even when these interact across a saturated linear chain liquid. This is because the irregularly shaped surfaces (rather than the liquid) now prevent the liquid molecules from ordering in the gap. **(b)** Forces measured between charged mica surfaces in KCl solutions of varying concentrations (after [28.14]). In dilute solutions (10^{-5} and 10^{-4} M), the measured forces are excellently described by the DLVO theory, based on exact solutions to the nonlinear Poisson–Boltzmann equation for the electrostatic forces and the Lifshitz theory for the van der Waals forces (using a Hamaker constant of $A_H = 2.2 \times 10^{-20}$ J). At higher concentrations, as more hydrated K^+ cations adsorb onto the negatively charged surfaces, an additional hydration force appears superimposed on the DLVO interaction at distances below 3–4 nm. This force has both an oscillatory and a monotonic component. *Insert*: Short-range hydration forces between mica surfaces shown as pressure versus distance. The *lower* and *upper curves* show surfaces 40% and 95% saturated with K^+ ions. At larger separations, the forces are in good agreement with the DLVO theory (after [28.1], with permission from Elsevier Science)

molecules have a width of $\sigma \approx 0.4$ nm. The short-range oscillatory force law is related to the density distribution function and potential of mean force characteristic of intermolecular interactions in liquids. These forces arise from the confining effects that the two surfaces have on liquid molecules, forcing them to order into quasidiscrete layers. Such layers are energetically or entropically favored and correspond to the minima in the free energy, whereas fractional layers are disfavored (energy maxima). This effect is quite general and arises in all simple liquids when they are confined between two smooth, rigid surfaces, both flat and curved.

Oscillatory forces are now well understood theoretically, at least for simple liquids, and a number of theoretical studies and computer simulations of various confined liquids (including water) that interact via some form of Lennard-Jones potential have invariably led to an oscillatory solvation force at surface separations below a few molecular diameters [28.52–55]. In a first approximation, the oscillatory force law may be described by an exponentially decaying cosine function of the form

$$E \approx E_0 \cos\left(\frac{2\pi D}{\sigma}\right) \mathrm{e}^{-D/\sigma} , \qquad (28.15)$$

where both theory and experiments show that the oscillatory period and the characteristic decay length of the envelope are close to σ.

Once the solvation zones of the two surfaces overlap, the mean liquid density in the gap is no longer the same as in the bulk liquid. Since the van der Waals interaction depends on the optical properties of the liquid, which in turn depend on the density, the van der Waals and the oscillatory solvation forces are not strictly additive. It is more correct to think of the solvation force as the van der Waals force at small separations with the molecular properties and density variations of the

medium taken into account. It is also important to appreciate that solvation forces do not arise simply because liquid molecules tend to structure into semi-ordered layers at surfaces. They arise because of the disruption or *change* of this ordering during the approach of a second surface. The two effects are related: the greater the tendency toward structuring at an isolated surface the greater the solvation force between two such surfaces; but there is a real distinction between the two phenomena that should be borne in mind.

Oscillatory forces lead to different adhesion values depending on the energy minimum from which two surfaces are being separated. For an interaction energy described by (28.15), quantized adhesion energies will be E_0 at $D = 0$ (primary minimum), E_0/e at $D = \sigma$, E_0/e^2 at $D = 2\sigma$, etc. E_0 can be thought of as a depletion force (Sect. 28.4.5) that is approximately given by the osmotic limit $E_0 \approx -k_B T/\sigma^2$, which can exceed the contribution to the adhesion energy in contact from the van der Waals forces (at $D_0 \approx 0.15{-}0.20\,\text{nm}$, as discussed in Sect. 28.3.1, keeping in mind that the Lifshitz theory fails to describe the force law at *intermediate distances*).

It is easy to understand how oscillatory forces arise between two flat, plane parallel surfaces. Between two curved surfaces, e.g., two spheres, one might imagine the molecular ordering and oscillatory forces to be smeared out in the same way that they are smeared out between two randomly rough surfaces (Sect. 28.5.3); however, this is not the case. Ordering can occur as long as the curvature or roughness is itself regular or uniform, i. e., not random. This is due to the Derjaguin approximation (28.3). If the energy between two flat surfaces is given by a decaying oscillatory function (for example, a cosine function as in (28.15)), then the force (and energy) between two curved surfaces will also be an oscillatory function of distance with some phase shift. Likewise, two surfaces with regularly curved regions will also retain their oscillatory force profile, albeit modified, as long as the corrugations are truly regular, i. e., periodic. On the other hand, surface roughness, even on the nanometer scale, can smear out oscillations if the roughness is random and the confined molecules are smaller than the size of the surface asperities [28.56, 57]. If an organic liquid contains small amounts of water, the expected oscillatory force can be replaced by a strongly attractive capillary force (Sect. 28.5.1).

28.4.4 Hydration and Hydrophobic Forces

There are many aqueous systems in which the DLVO theory fails and where there is an additional short-range force that is not oscillatory but monotonic. Between hydrophilic surfaces this force is exponentially repulsive and is commonly referred to as the hydration, or structural, force. The origin and nature of this force has long been controversial, especially in the colloidal and biological literature. Repulsive hydration forces are believed to arise from strongly hydrogen-bonding surface groups, such as hydrated ions or hydroxyl (−OH) groups, which modify the hydrogen-bonding network of liquid water adjacent to them. Because this network is quite extensive in range [28.58], the resulting interaction force is also of relatively long range.

Repulsive hydration forces were first extensively studied between clay surfaces [28.59]. More recently, they have been measured in detail between mica and silica surfaces [28.14–16], and even biological membranes [28.60, 61], where they have been found to decay exponentially with decay lengths of about 1 nm. Their effective range is 3−5 nm, which is about twice the range of the oscillatory solvation force in water. Empirically, the hydration repulsion between two hydrophilic surfaces appears to follow the simple equation

$$E = E_0 \mathrm{e}^{-D/\lambda_0}\,, \tag{28.16}$$

where $\lambda_0 \approx 0.6{-}1.1\,\text{nm}$ for 1 : 1 electrolytes and $E_0 = 3{-}30\,\text{mJ m}^{-2}$ depending on the hydration (hydrophilicity) of the surfaces, higher E_0 values generally being associated with lower λ_0 values.

The interactions between molecularly smooth mica surfaces in dilute electrolyte solutions obey the DLVO theory (Fig. 28.6b). However, at higher salt concentrations, specific to each electrolyte, hydrated cations bind to the negatively charged surfaces and give rise to a repulsive hydration force [28.14, 15]. This is believed to be due to the energy needed to dehydrate the bound cations, which presumably retain some of their water of hydration on binding. This conclusion was arrived at after noting that the strength and range of the hydration forces increase with the known hydration numbers of the electrolyte cations in the order: $Mg^{2+} > Ca^{2+} > Li^+ \approx Na^+ > K^+ > Cs^+$. Similar trends are observed with other negatively charged colloidal surfaces.

While the hydration force between two mica surfaces is overall repulsive below a distance of 4 nm, it is not always monotonic below about 1.5 nm but exhibits oscillations of mean periodicity of $0.25 \pm 0.03\,\text{nm}$, roughly equal to the diameter of the water molecule. This is shown in the insert in Fig. 28.6b, where we may note that the first three minima at $D = 0$, 0.28, and 0.56 nm occur at negative energies, a result that rationalizes observations on certain colloidal systems.

Surface force experiments have shown that hydration forces can be modified or *regulated* by exchanging ions of different hydration on surfaces, an effect that has

important practical applications in controlling the stability of colloidal dispersions. It has long been known that colloidal particles can be precipitated (coagulated or flocculated) by increasing the electrolyte concentration, an effect that was traditionally attributed to the reduced screening of the electrostatic double-layer repulsion between the particles due to the reduced Debye length. However, there are many examples where colloids are stabilized at high salt concentrations, not at low concentrations. This effect is now recognized as being due to the increased hydration repulsion experienced by certain surfaces when they bind highly hydrated ions at higher salt concentrations. Hydration regulation of adhesion and interparticle forces is an important practical method for controlling various processes such as clay swelling [28.62], ceramic processing and rheology [28.63], material fracture [28.63], and colloidal particle and bubble coalescence [28.64].

Water appears to be unique in having a solvation (hydration) force that exhibits both a monotonic and an oscillatory component. Between hydrophilic surfaces the monotonic component is repulsive (Fig. 28.6b), but between hydrophobic surfaces it is attractive and the final adhesion is much greater than expected from the Lifshitz theory.

A hydrophobic surface is one that is inert to water in the sense that it cannot bind to water molecules via ionic or hydrogen bonds. Hydrocarbons and fluorocarbons are hydrophobic, as is air, and the strongly attractive hydrophobic force has many important manifestations and consequences, such as the low solubility or miscibility of water and oil molecules, micellization, protein folding, strong adhesion and rapid coagulation of hydrophobic surfaces, nonwetting of water on hydrophobic surfaces, and hydrophobic particle attachment to rising air bubbles (the basic principle of froth flotation).

In recent years, there has been a steady accumulation of experimental data on the force laws between various hydrophobic surfaces in aqueous solution [28.65–76]. These studies have found that the force law between two macroscopic hydrophobic surfaces is of surprisingly long range, decaying exponentially with a characteristic decay length of 1–2 nm in the separation range of 0–10 nm, and then more gradually further out. The hydrophobic force can be far stronger than the van der Waals attraction, especially between hydrocarbon surfaces in water, for which the Hamaker constant is quite small.

For two surfaces in water the purely hydrophobic interaction energy (ignoring DLVO and oscillatory forces) in the range 0–10 nm is given by

$$E = -2\gamma e^{-D/\lambda_0} , \qquad (28.17)$$

where typically $\lambda_0 = 1–2$ nm, and $\gamma = 10–50\,\mathrm{mJ\,m^{-2}}$. The higher value corresponds to the interfacial energy of a pure hydrocarbon–water interface.

At a separation below 10 nm, the hydrophobic force appears to be insensitive or only weakly sensitive to changes in the type and concentration of electrolyte ions in the solution. The absence of a screening effect by ions attests to the nonelectrostatic origin of this interaction. In contrast, some experiments have shown that, at separations greater than 10 nm, the attraction does depend on the intervening electrolyte, and that in dilute solutions, or solutions containing divalent ions, it can continue to exceed the van der Waals attraction out to separations of 80 nm [28.68, 77]. Recent research suggests that the interactions at very long range might not represent a hydrophobic force since they are influenced by the presence of dissolved gas in the solution [28.73, 74], the stability of the hydrophobic surface [28.75], and on some types of surfaces, bridging submicroscopic bubbles [28.78, 79].

The long-range nature of the hydrophobic interaction has a number of important consequences. It accounts for the rapid coagulation of hydrophobic particles in water and may also account for the rapid folding of proteins. It also explains the ease with which water films rupture on hydrophobic surfaces. In this case, the van der Waals force across the water film is repulsive and therefore favors wetting, but this is more than offset by the attractive hydrophobic interaction acting between the two hydrophobic phases across water. Hydrophobic forces are increasingly being implicated in the adhesion and fusion of biological membranes and cells. It is known that both osmotic and electric-field stresses enhance membrane fusion, an effect that may be due to the concomitant increase in the hydrophobic area exposed between two adjacent surfaces [28.80].

From the previous discussion we can infer that even though highly related to each other [28.76], hydration and hydrophobic forces are not of a simple nature. These interactions are probably the most important, yet the least understood, of all the forces in aqueous solutions. The unusual properties of water and the nature of the surfaces (including their homogeneity and stability) appear to be equally important [28.80].

How do these exponentially decaying repulsive or attractive forces arise? Theoretical work and computer simulations [28.53, 54] suggest that the solvation forces in water should be purely oscillatory, whereas other theoretical studies [28.81–83] suggest a monotonically exponential repulsion or attraction, possibly superimposed on an oscillatory force. The latter is consistent with experimental findings, as shown in the *inset* in Fig. 28.6b, where it appears that the oscillatory force is simply additive with the monotonic hydration and

DLVO forces, suggesting that these arise from essentially different mechanisms.

Like the repulsive hydration force, the origin of the hydrophobic force is still unknown. A Monte Carlo simulation [28.83] of the interaction between two hydrophobic surfaces across water at separations below 1.5 nm showed a decaying oscillatory force superimposed on a monotonically attractive curve. In more recent computational and experimental work [28.84–86], it has been suggested that hydrophobic surfaces generate a depleted region of water around them, and that a long-range attractive force due to depletion arises between two such surfaces. Such a difference in density might also cause boundary slip of water at hydrophobic surfaces [28.87].

It is questionable whether the hydration or hydrophobic force should be viewed as an ordinary type of solvation or structural force that reflects the packing of water molecules. The energy (or entropy) associated with the hydrogen-bonding network, which extends over a much larger region of space than the molecular correlations, is probably at the root of the long-range interactions of water. The situation in water appears to be governed by much more than the molecular packing effects that dominate the interactions in simpler liquids.

28.4.5 Polymer-Mediated Forces

Polymers or macromolecules are chainlike molecules consisting of many identical segments (monomers or repeating units) held together by covalent bonds. The size of a polymer coil in solution or in the melt is determined by a balance between van der Waals attraction (and hydrogen bonding, if present) between polymer segments, and the entropy of mixing, which causes the polymer coil to expand. In polymer melts above the glass transition temperature, and at certain conditions in solution, the attraction between polymer segments is exactly balanced by the entropy effect. The polymer solution will then behave virtually ideally, and the density distribution of segments in the coil is Gaussian. This is called the theta (θ) condition, and it occurs at the theta or Flory temperature for a particular combination of polymer and solvent or solvent mixture. At lower temperatures (in a poor or bad solvent), the polymer-polymer interactions dominate over the entropic, and the coil will shrink or precipitate. At higher temperatures (good solvent conditions), the polymer coil will expand.

High-molecular-weight polymers form large coils, which significantly affect the properties of a solution even when the total mass of polymer is very low. The radius of the polymer coil is proportional to the segment length a and the number of segments n. At theta conditions, the hydrodynamic radius of the polymer coil (the root-mean-square separation of the ends of one polymer chain) is theoretically given by $R_h = an^{1/2}$, and the unperturbed radius of gyration (the average root-mean-square distance of a segment from the center of mass of the molecule) is $R_g = a(n/6)^{1/2}$. In a good solvent the perturbed size of the polymer coil, the Flory radius R_F, is proportional to $n^{3/5}$.

Polymers interact with surfaces mainly through van der Waals and electrostatic interactions. The physisorption of polymers containing only one type of segment is reversible and highly dynamic, but the rate of exchange of adsorbed chains with free chains in the solution is low, since the polymer remains bound to the surface as long as one segment along the chain is adsorbed. The adsorption energy per segment is on the order of k_BT. In a good solvent, the conformation of a polymer on a surface is very different from the coil conformation in bulk solution. Polymers adsorb in *trains*, separated by *loops* extending into the solution and dangling *tails* (the ends of the chain). Compared to adsorption at lower temperatures, good solvent conditions favor more of the polymer chain being in the solvent, where it can attain its optimum conformation. As a result, the extension of the polymer is longer, even though the total amount of adsorbed polymer is lower. In a good solvent, the polymer chains can also be effectively repelled from a surface, if the loss in conformational entropy close to the surface is not compensated for by a gain in enthalpy from adsorption of segments. In this case, there will be a layer of solution (thickness $\approx R_g$) close to the surfaces that is depleted of polymer.

The interaction forces between two surfaces across a polymer solution will depend on whether the polymer adsorbs onto the surfaces or is repelled from them, and also on whether the interaction occurs at *true* or *restricted* thermodynamic equilibrium. At true or full equilibrium, the polymer between the surfaces can equilibrate (exchange) with polymer in the bulk solution at all surface separations. Some theories [28.92, 93] predict that, at full equilibrium, the polymer chains would move from the confined gap into the bulk solution where they could attain entropically more favorable conformations, and that a monotonic attraction at all distances would result from bridging and depletion interactions (which will be discussed below). Other theories suggest that the interaction at small separations would be ultimately repulsive, since some polymer chains would remain in the gap due to their attractive interactions with many sites on the surface (enthalpic) – more sites would be available to the remaining polymer chains if some others desorbed and diffused out from the gap [28.94].

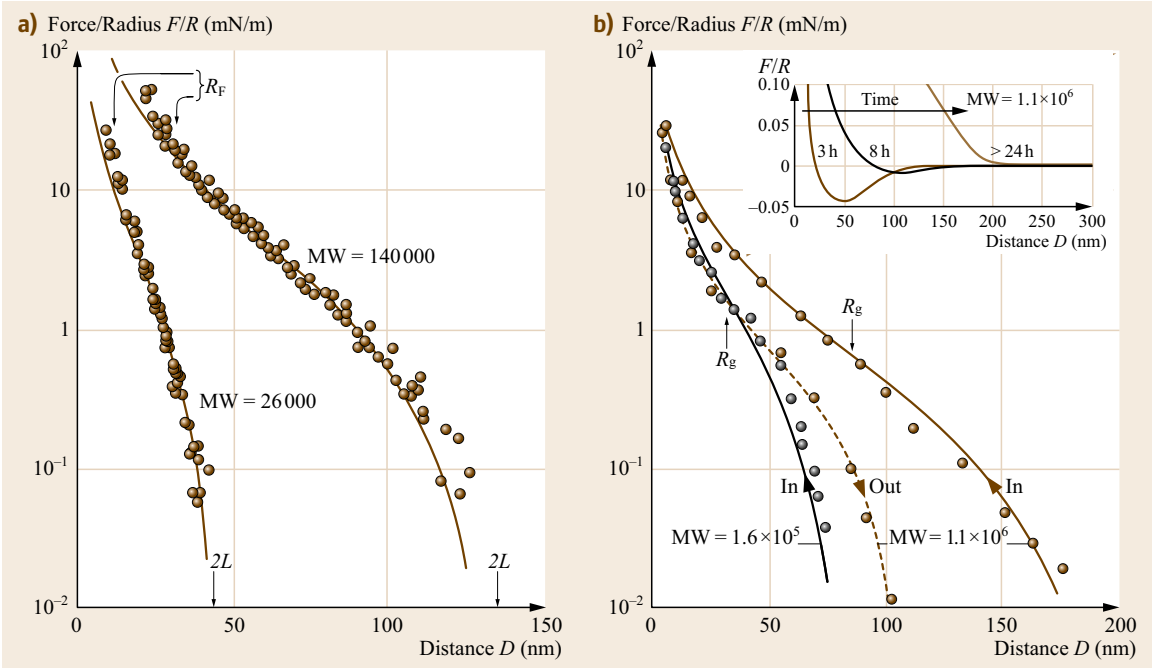

Fig. 28.7a,b Experimentally determined forces in systems of two interacting polymer layers: **(a)** Polystyrene brush layers grafted via an adsorbing chain-end group onto mica surfaces in toluene (a good solvent for polystyrene). *Left curve*: MW = 26 000 g/mol, R_F = 12 nm. *Right curve*: MW = 140 000 g/mol, R_F = 32 nm. Both force curves were reversible on approach and separation. The *solid curves* are theoretical fits using the Alexander–de Gennes theory with the following measured parameters: spacing between attachments sites s = 8.5 nm, brush thickness L = 22.5 and 65 nm (adapted from [28.88]). **(b)** Polyethylene oxide layers physisorbed onto mica from 150 µg/ml solution in aqueous 0.1 M KNO_3 (a good solvent for polyethylene oxide). *Main figure*: Equilibrium forces at full coverage after ≈ 16 h adsorption time. *Left curve*: MW = 160 000 g/mol, R_g = 32 nm. *Right curve*: MW = 1 100 000 g/mol, R_g = 86 nm. Note the hysteresis (irreversibility) on approach and separation for this physisorbed layer, in contrast to the absence of hysteresis with grafted chains in the case of **(a)**. The *solid curves* are based on a modified form of the Alexander–de Gennes theory. *Insert* in **(b)**: evolution of the forces with the time allowed for the higher MW polymer to adsorb from solution. Note the gradual reduction in the attractive bridging component (adapted from [28.89–91], after [28.1], with permission from Elsevier Science)

At restricted equilibrium, the polymer is kinetically trapped, and the adsorbed amount is thus constant as the surfaces are brought toward each other, but the chains can still rearrange on the surfaces and in the gap. Experimentally, the true equilibrium situation is very difficult to attain, and most experiments are done at restricted equilibrium conditions. Even the equilibration of conformations assumed in theoretical models for restricted equilibrium conditions can be so slow that this condition is difficult to reach experimentally.

In systems of adsorbing polymers, bridging of chains from one surface to the other can give rise to a long-range attraction, since the bridging chains would gain conformational entropy if the surfaces were closer together. In poor solvents, both bridging and intersegment interactions contribute to an attraction [28.20]. However, regardless of solvent and equilibrium conditions, a strong repulsion due to the osmotic interactions is seen at small surface separations in systems of adsorbing polymers at restricted equilibrium.

In systems containing high concentrations of nonadsorbing polymer, the difference in solute concentration in the bulk and between the surfaces at separations smaller than the approximate polymer coil diameter ($2R_g$, i. e., when the polymer has been squeezed out from the gap between the surfaces) may give rise to an attractive osmotic force (the depletion attraction) [28.95–98]. In addition, if the polymer coils become initially compressed as the surfaces approach each other, this can give rise to a repulsion (depletion stabilization) at large separations [28.97]. For a system of two cylindrical surfaces of radius R, the maximum depletion force F_{dep} is expected to occur when the surfaces are in contact and is given by multiplying the

depletion (osmotic) pressure, $P_{dep} = \rho k_B T$, by the contact area πr^2, where r is given by the chord theorem $r^2 = (2R - R_g)R_g \approx 2RR_g$ [28.1]

$$\frac{F_{dep}}{R} = -2\pi R_g \rho k_B T \,, \tag{28.18}$$

where ρ is the number density of the polymer in the bulk solution.

If a part of the polymer (typically an end group) is different from the rest of the chain, this part may preferentially adsorb to the surface. An end-adsorbed polymer is attached to the surface at only one point, and the extension of the chain is dependent on the grafting density, i. e., the average distance s between adsorbed end groups on the surface (Fig. 28.7). One distinguishes between different regions of increasing overlap of the chains (stretching) called pancake, mushroom, and brush regimes [28.99]. In the mushroom regime, where the coverage is sufficiently low so that there is no overlap between neighboring chains, the thickness of the adsorbed layer is proportional to $n^{1/2}$ (i. e., to R_g) at theta conditions and to $n^{3/5}$ in a good solvent.

Several models [28.99–103] have been developed for the extension and interactions between two brushes (strongly stretched grafted chains). They are based on a balance between osmotic pressure within the brush layers (uncompressed and compressed) and the elastic energy of the chains, and differ mainly in the assumptions of the segment density profile, which can be a step function or parabolic. At high coverage (in the brush regime), where the chains will avoid overlapping each other, the thickness of the layer is proportional to n.

Experimental work on both monodisperse [28.21, 104] and polydisperse [28.22] systems at different solvent conditions has confirmed the expected range and magnitude of the repulsive interactions resulting from compression of densely packed grafted layers.

28.5 Adhesion and Capillary Forces

28.5.1 Capillary Forces

When considering the adhesion of two solid surfaces or particles in air or in a liquid, it is easy to overlook or underestimate the important role of capillary forces, i. e., forces arising from the Laplace pressure of curved menisci formed by condensation of a liquid between and around two adhering surfaces (Fig. 28.8).

The adhesion force between a nondeformable spherical particle of radius R and a flat surface in an inert atmosphere (Fig. 28.8a) is

$$F_{ad} = 4\pi R \gamma_{SV} \,. \tag{28.19}$$

But in an atmosphere containing a condensible vapor, the expression above is replaced by

$$F_{ad} = 4\pi R(\gamma_{LV} \cos\theta + \gamma_{SL}) \,, \tag{28.20}$$

where the first term is due to the Laplace pressure of the meniscus and the second is due to the direct adhesion of the two contacting solids within the liquid. Note that the above equation does not contain the radius of curvature r of the liquid meniscus (Fig. 28.8b). This is because for smaller r the Laplace pressure γ_{LV}/r increases, but the area over which it acts decreases by the same amount, so the two effects cancel out. In experiments with inert liquids, such as hydrocarbons, condensing between two mica surfaces indicates that (28.20) is valid for values of r as small as 1–2 nm, corresponding to vapor pressures as low as 40% of saturation [28.105, 106]. Capillary condensation also occurs in binary liquid systems, e.g., when water dissolved in hydrocarbon liquids condenses around two contacting hydrophilic surfaces or when a vapor cavity forms in water around two hydrophobic surfaces. In the case of water condensing from vapor or from oil, it also appears that the bulk value of γ_{LV} is applicable for meniscus radii as small as 2 nm.

The capillary condensation of liquids, especially water, from vapor can have additional effects on the physical state of the contact zone. For example, if the surfaces contain ions, these will diffuse and build up within the liquid bridge, thereby changing the chemical composition of the contact zone, as well as influencing the adhesion. In the case of surfaces covered with surfactant or polymer molecules (amphiphilic surfaces), the molecules can turn over on exposure to humid air, so that the surface nonpolar groups become replaced by polar groups, which renders the surfaces hydrophilic. When two such surfaces come into contact, water will condense around the contact zone and the adhesion force will also be affected – generally increasing well above the value expected for inert hydrophobic surfaces. It is apparent that adhesion in vapor or a solvent is often largely determined by capillary forces arising from the condensation of liquid that may be present only in very small quantities, e.g., 10–20% of saturation in the vapor, or 20 ppm in the solvent.

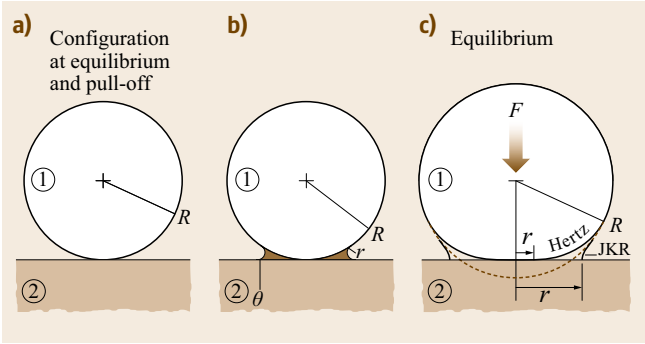

Fig. 28.8a–c Adhesion and capillary forces between materials 1 and 2 : **(a)** a nondeforming sphere on a rigid, flat surface in an inert atmosphere and **(b)** in a vapor that can capillary-condense around the contact zone. At equilibrium, the concave radius r of the liquid meniscus is given by the Kelvin equation. For a concave meniscus to form, the contact angle θ has to be less than 90°. In the case of hydrophobic surfaces surrounded by water, a vapor cavity can form between the surfaces. As long as the surfaces are perfectly smooth, the contribution of the meniscus to the adhesion force is independent of r (after [28.5] with permission). **(c)** Elastically deformable sphere on a rigid flat surface in the absence (Hertz) and presence (JKR) of adhesion (**(a,c)** after [28.1], with permission from Elsevier Science)

28.5.2 Adhesion Mechanics

Two bodies in contact deform as a result of surface forces and/or applied normal forces. For the simplest case of two interacting elastic spheres (a model that is easily extended to an elastic sphere interacting with an undeformable surface, or vice versa) and in the absence of attractive surface forces, the vertical central displacement (compression) was derived by *Hertz* [28.107] (Fig. 28.8c). In this model, the displacement and the contact area are equal to zero when no external force (load) is applied, i. e., at the points of contact and of separation. The contact area A increases with normal force or load as $L^{2/3}$.

In systems where attractive surface forces are present between the surfaces, the deformations are more complicated. Modern theories of the adhesion mechanics of two contacting solid surfaces are based on the Johnson–Kendall–Roberts (JKR) theory [28.10], or on the Derjaguin–Muller–Toporov (DMT) theory [28.108–110]. The JKR theory is applicable to easily deformable, large bodies with high surface energy, whereas the DMT theory better describes very small and hard bodies with low surface energy [28.111]. The intermediate regime has also been described [28.112].

In the JKR theory, two spheres of radii R_1 and R_2, bulk elastic modulus K, and surface energy γ will flatten due to attractive surface forces when in contact at no external load. The contact area will increase under an external load L or normal force F, such that at mechanical equilibrium the radius of the contact area r is given by

$$r^3 = \frac{R}{K}\left[F + 6\pi R\gamma + \sqrt{12\pi R\gamma F + (6\pi R\gamma)^2}\right], \tag{28.21}$$

where $R = R_1R_2/(R_1 + R_2)$. In the absence of surface energy γ, (28.21) is reduced to the expression for the radius of the contact area in the Hertz model. Another important result of the JKR theory gives the adhesion force or pull-off force

$$F_{\text{ad}} = -3\pi R\gamma_{\text{S}}\,, \tag{28.22}$$

where the surface energy γ_{S} is defined through $W = 2\gamma_{\text{S}}$, where W is the reversible work of adhesion. Note that, according to the JKR theory, a finite elastic modulus K, while having an effect on the load–area curve, has no effect on the adhesion force, an interesting and unexpected result that has nevertheless been verified experimentally [28.10, 113, 114]. Equations (28.21) and (28.22) provide the framework for analyzing results of adhesion measurements (Fig. 28.9) of contacting solids, known as contact mechanics, and for studying the effects of surface conditions and time on adhesion energy hysteresis (Sect. 28.5.4).

The JKR theory has been extended [28.115, 116] to consider rigid or elastic substrates separated by thin compliant layers of very different elastic moduli, a situation commonly encountered in SFA and atomic force microscopy (AFM) experiments. The deformation of the system is then strongly dependent on the ratio of r to the thickness of the confined layer. At small r (low L), the deformation occurs mostly in the thin confined layer, whereas at large r (large L), it occurs mainly in the substrates. Because of the changing distribution of traction across the contact, the adhesion force in a layered system is also modified from that of isotropic systems (28.22) so that it is no longer independent of the elastic moduli.

28.5.3 Effects of Surface Structure, Roughness, and Lattice Mismatch

In a contact between two rough surfaces, the real area of contact varies with the applied load in a different manner than between smooth surfaces [28.117, 118]. For nonadhering surfaces exhibiting an exponential distribution of *elastically* deforming asperities (spherical caps of equal radius), it has been shown that the contact area for rough surfaces increases approximately

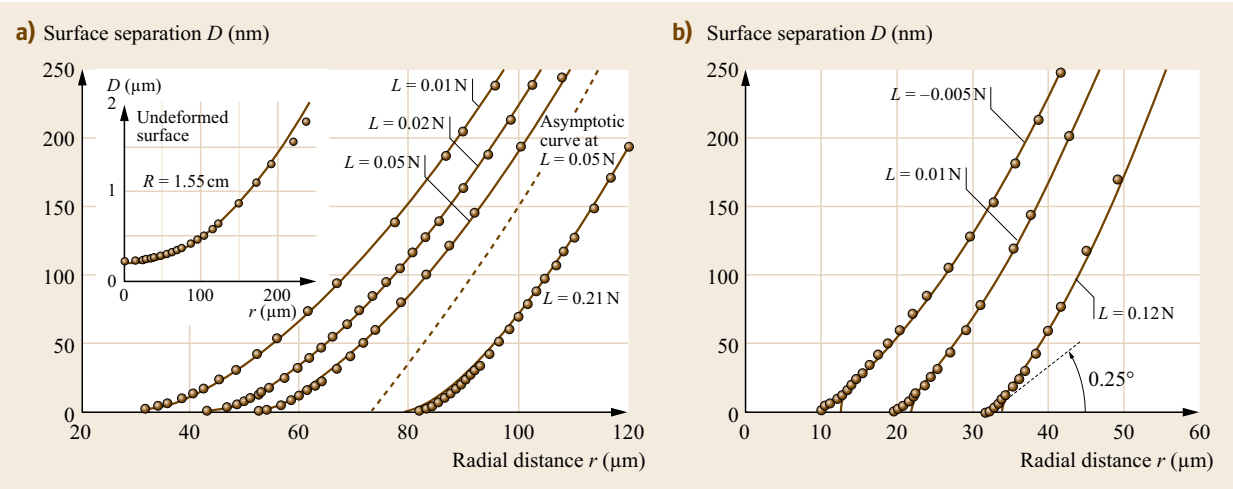

Fig. 28.9a,b Experimental data on contact mechanics for ideal Hertz and JKR contacts. **(a)** Measured profiles of surfaces in nonadhesive contact (*circles*) compared with Hertz profiles (*continuous curves*). The system was mica surfaces in a concentrated KCl solution in which the surfaces do not adhere. When not in contact, the surface shape is accurately described by a sphere of radius $R = 1.55\,\text{cm}$ (*insert*). The applied loads were 0.01, 0.02, 0.05, and 0.21 N. The last profile was measured in a different region of the surfaces where the local radius of curvature was 1.45 cm. The Hertz profiles correspond to central displacements of $\delta = 66.5, 124, 173,$ and 441 nm. The *dashed line* shows the shape of the undeformed sphere corresponding to the curve at a load of 0.05 N; it fits the experimental points at larger distances (not shown). **(b)** Surface profiles measured with adhesive contact (mica surfaces adhering in dry nitrogen gas) at applied loads of -0.005, 0.01, and 0.12 N. The *continuous lines* are JKR profiles obtained by adjusting the central displacement in each case to get the best fit to points at larger distances. The values are $\delta = -4.2, 75.6,$ and 256 nm. Note that the scales of this figure exaggerate the apparent angle at the junction of the surfaces. This angle, which is insensitive to load, is only about 0.25°. (after [28.113], with permission from Elsevier Science)

linearly with the applied normal force (load) L instead of as $L^{2/3}$ for smooth surfaces [28.117]. It has also been shown that for *plastically* deforming metal microcontacts the real contact area increases with load as $A \propto L$ [28.119, 120]. In systems with attractive surface forces, there is a competition between this attraction and repulsive forces arising from compression of high asperities. As a result, the adhesion in such systems can be very low, especially if the surfaces are not easily deformed [28.121, 122]. The opposite is possible for soft (viscoelastic) surfaces where the real (molecular) contact area might be larger than for two perfectly smooth surfaces [28.123]. The size of the real contact area at a given normal force is also an important issue in studies of nanoscale friction, both of single-asperity contacts (Sect. 28.7) and of contacts between rough surfaces (Sect. 28.9.2).

Adhesion forces may also vary depending on the commensurability of the crystallographic lattices of the interacting surfaces. The adhesion between two mica surfaces has been studied as a function of the orientation (twist angle) of their surface lattices [28.124]. The forces were measured in air, water, and an aqueous salt solution where oscillatory structural forces were present. In humid air, the adhesion was found to be relatively independent of the twist angle θ due to the adsorption of a 0.4 nm-thick amorphous layer of organics and water at the interface. In contrast, in water, sharp adhesion peaks (energy minima) occurred at $\theta = 0°$, $\pm 60°$, $\pm 120°$ and 180°, corresponding to the coincidence angles of the surface lattices (Fig. 28.10). As little as $\pm 1°$ away from these peaks, the energy decreased by 50%. In aqueous KCl solution, due to potassium ion adsorption, the water between the surfaces becomes ordered, resulting in an oscillatory force profile where the adhesive minima occur at discrete separations of about 0.25 nm, corresponding to integral numbers of water layers. The whole interaction potential was then found to depend on the orientation of the surface lattices, and the effect extended at least four molecular layers.

It has also been appreciated that the structure of the confining surfaces is just as important as the nature of the liquid for determining the solvation forces [28.56, 57, 126–128]. Between two surfaces that are completely flat but unstructured, the liquid molecules will order into layers, but there will be no lateral ordering within the layers. In other words, there will be positional ordering normal but not parallel to the surfaces. If the surfaces have a crystalline (periodic) lattice, this may

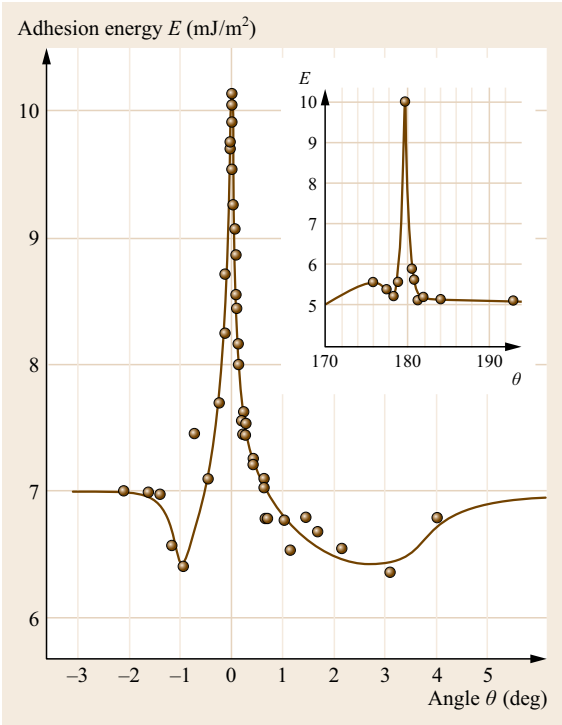

Fig. 28.10 Adhesion energy for two mica surfaces in contact in water (in the primary minimum of an oscillatory force curve) as a function of the mismatch angle θ about $\theta = 0°$ and 180° between the mica surface lattices (after [28.125] with permission)

induce ordering parallel to the surfaces as well, and the oscillatory force then also depends on the structure of the surface lattices. Further, if the two lattices have different dimensions (mismatched or incommensurate lattices), or if the lattices are similar but are not in register relative to each other, the oscillatory force law is further modified [28.124, 129] and the tribological properties of the film are also influenced, as discussed in Sect. 28.9 [28.129, 130].

As shown by the experiments, these effects can alter the magnitude of the adhesive minima found at a given separation within the last one or two nanometers of a thin film by a factor of two. The force barriers (maxima) may also depend on orientation. This could be even more important than the effects on the minima. A high barrier could prevent two surfaces from coming closer together into a much deeper adhesive well. Thus the maxima can effectively contribute to determining not only the final separation of two surfaces, but also their final adhesion. Such considerations should be particularly important for determining the thickness and strength of intergranular spaces in ceramics, the adhesion forces between colloidal particles in concentrated electrolyte solution, and the forces between two surfaces in a crack containing capillary-condensed water.

For surfaces that are randomly rough, oscillatory forces become smoothed out and disappear altogether, to be replaced by a purely monotonic solvation force [28.48, 56, 57]. This occurs even if the liquid molecules themselves are perfectly capable of ordering into layers. The situation of symmetric liquid molecules confined between rough surfaces is therefore not unlike that of asymmetric molecules between smooth surfaces (Sect. 28.4.3 and Fig. 28.6a). To summarize, for there to be an oscillatory solvation force, the liquid molecules must be able to be correlated over a reasonably long range. This requires that both the liquid molecules and the surfaces have a high degree of order or symmetry. If either is missing, so will the oscillations be. Depending on the size of the molecules to be confined, a roughness of only a few tenths of a nanometer is often sufficient to eliminate any oscillatory component of the force law [28.31, 56].

28.5.4 Nonequilibrium and Rate-Dependent Interactions: Adhesion Hysteresis

Under ideal conditions the adhesion energy is a well-defined thermodynamic quantity. It is normally denoted by E or W (the work of adhesion) or γ (the surface tension, where $W = 2\gamma$) and gives the reversible work done on bringing two surfaces together or the work needed to separate two surfaces from contact. Under ideal, equilibrium conditions these two quantities are the same, but under most realistic conditions they are not; the work needed to separate two surfaces is always greater than that originally gained by bringing them together. An understanding of the molecular mechanisms underlying this phenomenon is essential for understanding many adhesion phenomena, energy dissipation during loading-unloading cycles, contact angle hysteresis, and the molecular mechanisms associated with many frictional processes.

Adhesion hysteresis may be thought of as being due to mechanical effects such as instabilities, or chemical effects such as interdiffusion, interdigitation, molecular reorientations and exchange processes occurring at an interface after contact, as illustrated in Fig. 28.11. Such processes induce roughness and chemical heterogeneity even though initially (and after separation and reequilibration) both surfaces are perfectly smooth and chemically homogeneous. In general, if the energy change, or work done, on separating two surfaces from adhesive contact is not fully recoverable on bringing the two surfaces back into contact again, the adhesion hys-

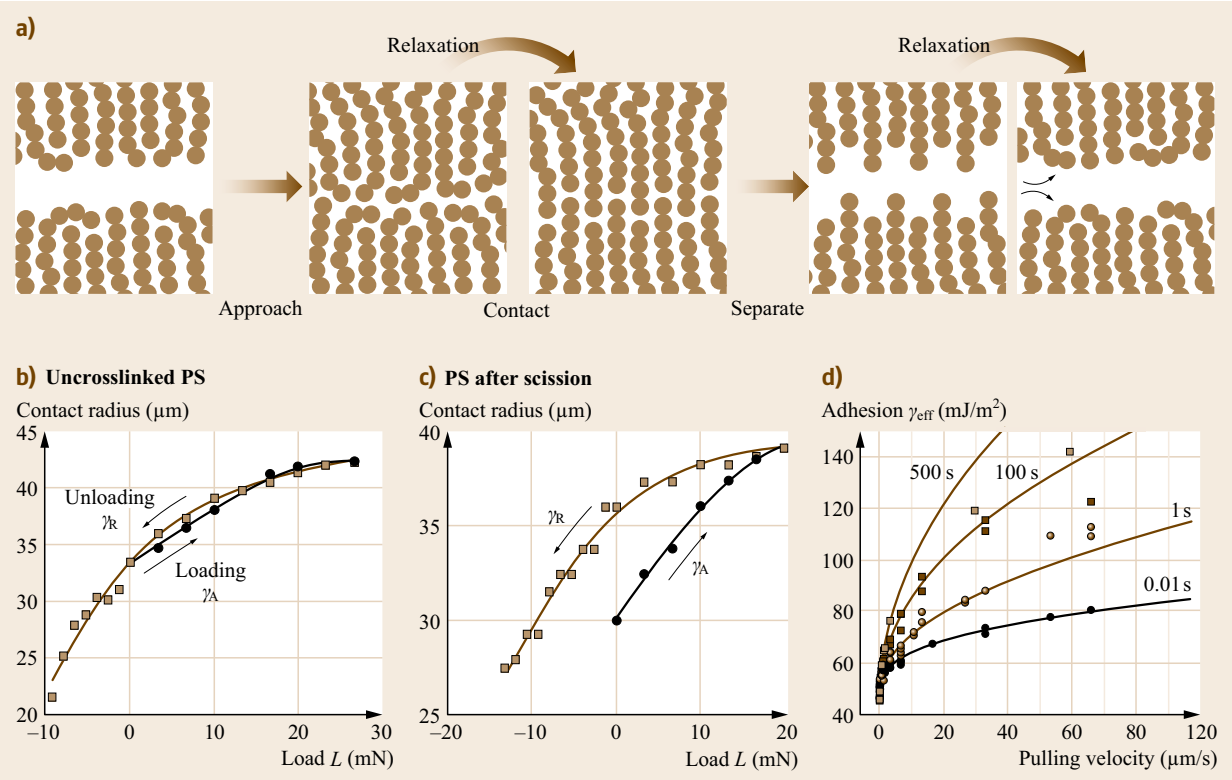

Fig. 28.11 **(a)** Schematic representation of interpenetrating chains. **(b,c)** JKR plots (contact radius r as a function of applied load L) showing small adhesion hysteresis for uncross-linked polystyrene and larger adhesion hysteresis after chain scission at the surfaces after 18 h irradiation with ultraviolet light in an oxygen atmosphere. The adhesion hysteresis continues to increase with the irradiation time. **(d)** Rate-dependent adhesion of hexadecyl trimethyl ammonium bromide (CTAB) surfactant monolayers. The *solid curves* (after [28.131]) are fits to experimental data on CTAB adhesion after different contact times (after [28.132]) using an approximate analytical solution for a JKR model, including crack tip dissipation. Due to the limited range of validity of the approximation, the fits rely on the part of the experimental data with low effective adhesion energy only. From the fits one can determine the thermodynamic adhesion energy, the characteristic dissipation velocity, and the intrinsic dissipation exponent of the model ((**a**) after [28.133], American Chemical Society), ((**b,c**) after [28.134], American Association for the Advancement of Science), ((**d**) after [28.131] American Chemical Society)

teresis may be expressed as

$$W_R > W_A \quad \text{or} \quad \Delta W = (W_R - W_A) > 0\,, \qquad (28.23)$$

where W_R and W_A are the adhesion or surface energies for receding (separating) and advancing (approaching) two solid surfaces respectively.

Hysteresis effects are also commonly observed in wetting/dewetting phenomena [28.135]. For example, when a liquid spreads and then retracts from a surface the advancing contact angle θ_A is generally larger than the receding angle θ_R. Since the contact angle θ is related to the liquid–vapor surface tension γ_L and the solid–liquid adhesion energy W by the Dupré equation

$$(1 + \cos\theta)\gamma_L = W\,, \qquad (28.24)$$

we see that wetting hysteresis or contact angle hysteresis ($\theta_A > \theta_R$) actually implies adhesion hysteresis, $W_R > W_A$, as given by (28.23).

Energy-dissipating processes such as adhesion and contact angle hysteresis arise because of practical constraints of the *finite time* of measurements and the *finite elasticity* of materials. This prevents many loading-unloading or approach-separation cycles from being thermodynamically reversible, even though they would be if carried out infinitely slowly. By thermodynamically irreversible one simply means that one cannot go through the approach-separation cycle via a continuous series of equilibrium states, because some of these are connected via spontaneous – and therefore thermodynamically irreversible – instabilities or transitions where energy is liberated and therefore *lost*

via heat or phonon release [28.136]. This is an area of much current interest and activity, especially regarding the fundamental molecular origins of adhesion and friction in polymer and surfactant systems, and the relationships between them [28.131, 132, 134, 137].

28.6 Introduction: Different Modes of Friction

Most frictional processes occur with the sliding surfaces becoming damaged in one form or another [28.138]. This may be referred to as normal friction. In the case of brittle materials, the damaged surfaces slide past each other while separated by relatively large, micrometer-sized wear particles. With more ductile surfaces, the damage remains localized to nanometer-sized, plastically deformed asperities. Some features of the friction between damaged surfaces will be described in Sect. 28.7.4.

There are also situations in which sliding can occur between two perfectly smooth, undamaged surfaces. This may be referred to as interfacial sliding or boundary friction and is the focus of the following sections. The term boundary lubrication is more commonly used to denote the friction of surfaces that contain a thin protective lubricating layer such as a surfactant monolayer, but here we shall use the term more broadly to include any molecularly thin solid, liquid, surfactant, or polymer film.

Experiments have shown that as a liquid film becomes progressively thinner its physical properties change, at first quantitatively and then qualitatively [28.33, 35, 139, 140]. The quantitative changes are manifested by an increased viscosity, non-Newtonian flow behavior, and the replacement of normal melting by a glass transition, but the film remains recognizable as a liquid (Fig. 28.12). In tribology, this regime is commonly known as the mixed lubrication regime, where the rheological properties of a film are intermediate between the bulk and boundary properties. One may also refer to it as the intermediate regime (Table 28.4).

For even thinner films, the changes in behavior are more dramatic, resulting in a qualitative change in properties. Thus first-order phase transitions can now occur to solid or liquid-crystalline phases [28.34, 128, 133, 141–145], whose properties can no longer be characterized even qualitatively in terms of bulk or continuum liquid properties such as viscosity. These films now exhibit yield points (characteristic of fracture in solids) and their molecular diffusion and relaxation times can be ten orders of magnitude longer than in the bulk liquid or even in films that are just slightly thicker. The three friction regimes are summarized in Table 28.4.

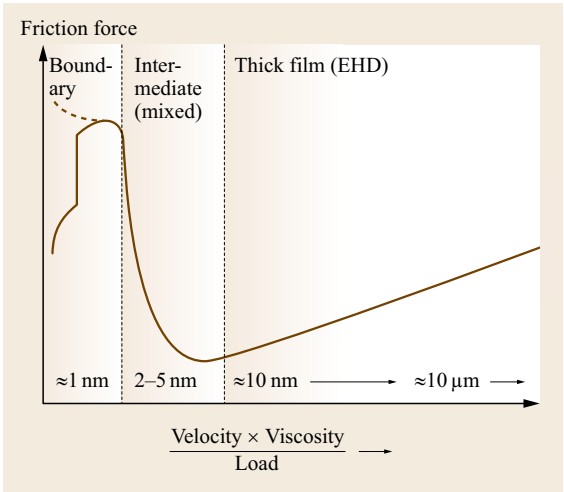

Fig. 28.12 Stribeck curve: an empirical curve giving the trend generally observed in the friction forces or friction coefficients as a function of sliding velocity, the bulk viscosity of the lubricating fluid, and the applied load (normal force). The three friction/lubrication regimes are known as the boundary lubrication regime (Sect. 28.7), the intermediate or mixed lubrication regime (Sect. 28.8.2), and the thick film or elastohydrodynamic (EHD) lubrication regime (Sect. 28.8.1). The film thicknesses believed to correspond to each of these regimes are also shown. For thick films, the friction force is purely viscous, e.g., Couette flow at low shear rates, but may become complicated at higher shear rates where EHD deformations of surfaces can occur during sliding (after [28.5], with permission)

Table 28.4 The three main tribological regimes characterizing the changing properties of liquids subjected to increasing confinement between two solid surfaces[a]. Based on work by *Granick* et al. [28.139], and others [28.28, 133, 141], on the dynamic properties of short-chain molecules such as alkanes and polymer melts confined between surfaces

Regime	Conditions for getting into this regime	Static/equilibrium properties[b]	Dynamic properties[c]
Bulk		Bulk (continuum) properties:	Bulk (continuum) properties:
	• Thick films (> 10 molecular diameters, $\gg R_g$ for polymers) • Low or zero loads • High shear rates	• Bulk liquid density • No long-range order	• Newtonian viscosity • Fast relaxation times • No glass temperature • No yield point • Elastohydrodynamic lubrication
Intermediate mixed		Modified fluid properties include:	Modified rheological properties include:
	• Intermediately thick films (4−10 molecular diameters, $\approx R_g$ for polymers) • Low loads or pressure	• Modified positional and orientational order[a] • Medium- to long-range molecular correlations • Highly entangled states	• Non-Newtonian flow • Glassy states • Long relaxation times • Mixed lubrication
Boundary		Onset of nonfluid-like properties:	Onset of tribological properties:
	• Molecularly thin films (< 4 molecular diameters) • High loads or pressure • Low shear rates • Smooth surfaces or asperities	• Liquid-like to solid-like phase transitions • Appearance of new liquid-crystalline states • Epitaxially induced long-range ordering	• No flow until yield point or critical shear stress reached • Solid-like film behavior characterized by defect diffusion, dislocation motion, shear melting • Boundary lubrication

[a] Confinement can lead to an increased or decreased order in a film, depending both on the surface lattice structure and the geometry of the confining cavity
[b] In each regime both the static and dynamic properties change. The static properties include the film density, the density distribution function, the potential of mean force, and various positional and orientational order parameters
[c] Dynamic properties include viscosity, viscoelastic constants, and tribological yield points such as the friction coefficient and critical shear stress

28.7 Relationship Between Adhesion and Friction

28.7.1 Amontons' Law

Early theories and mechanisms for the dependence of friction on the applied normal force or load L were developed by da Vinci, Amontons, Coulomb and Euler [28.146]. For the macroscopic objects investigated, the friction was found to be directly proportional to the load, with no dependence on the contact area. This is described by the so-called Amontons' law

$$F = \mu L\,, \tag{28.25}$$

where F is the shear or friction force and μ is a constant defined as the coefficient of friction. This friction law is still the principal means of quantitatively describing the friction between surfaces. However, particularly in the case of adhering surfaces, Amontons' law does not adequately describe the friction behavior with load, because of the finite friction force measured at zero and even negative applied loads.

When a lateral force, or shear stress, is applied to two surfaces in adhesive contact, the surfaces initially remain *pinned* to each other until some critical shear force is reached. At this point, the surfaces begin to slide past each other either smoothly or in jerks. The frictional force needed to initiate sliding from rest is known as the static friction force, denoted by F_s, while the force needed to maintain smooth sliding is referred to as the kinetic or dynamic friction force, denoted by F_k. In general, $F_s > F_k$. Two sliding surfaces may

also move in regular jerks, known as stick–slip sliding, which is discussed in more detail in Sect. 28.8.3. Such friction forces cannot be described by models used for thick films that are viscous (Sect. 28.8.1) and, therefore, shear as soon as the smallest shear force is applied.

28.7.2 Adhesion Force and Load Contribution to Interfacial Friction

In an adhesive contact, the contact area as a function of load is thus generally well described by the JKR (28.21). The friction force between two molecularly smooth surfaces sliding in adhesive contact is not simply proportional to the applied load L as might be expected from Amontons' law. There is an additional adhesion contribution that is proportional to the area of contact, A. Thus, in general, the interfacial friction force of dry, unlubricated surfaces sliding smoothly past each other in adhesive contact is given by

$$F = F_{\mathrm{k}} = S_{\mathrm{c}}A + \mu L\,, \tag{28.26}$$

where S_{c} is the critical shear stress (assumed to be constant), $A = \pi r^2$ is the contact area of radius r given by (28.21), and μ is the coefficient of friction. For low loads we have

$$F = S_{\mathrm{c}}A = S_{\mathrm{c}}\pi r^2 = S_{\mathrm{c}}\pi\left[\frac{R}{K}\left(L + 6\pi R\gamma + \sqrt{12\pi R\gamma L + (6\pi R\gamma)^2}\right)\right]^{2/3}, \tag{28.27}$$

whereas for high loads (or high μ), or when γ is very low [28.147–151], (28.26) reduces to Amontons' law: $F = \mu L$. Depending on whether the friction force in (28.26) is dominated by the first or second term, one may refer to the friction as adhesion-controlled or load-controlled respectively.

The following friction model (Fig. 28.13a), first proposed by *Tabor* [28.152] and developed further by others [28.32, 153, 154], has been quite successful at explaining the interfacial and boundary friction of two solid crystalline surfaces sliding past each other in the absence of wear. The surfaces may be unlubricated, or they may be separated by a monolayer or more of some boundary lubricant or liquid molecules. In this model, the values of the critical shear stress S_{c}, and the coefficient of friction μ, in (28.26) are calculated in terms of the energy needed to overcome the attractive intermolecular forces and compressive externally applied load as one surface is raised and then slid across the molecular-sized asperities of the other.

This model is similar to pushing a cart over a road of cobblestones where the cartwheels (which represent the molecules of the upper surface or film) must be made to roll over the cobblestones (representing the molecules of the lower surface) before the cart can move. When at rest, the cartwheels find grooves between the cobblestones where they sit in potential-energy minima, and so the cart is at some stable mechanical equilibrium. A certain lateral force (the push) is required to raise the cartwheels against the force of gravity in order to initiate motion. Motion will continue as long as the cart is pushed, and rapidly stops once it is no longer pushed. Energy is dissipated by the liberation of heat every time a wheel hits the next cobblestone. The cobblestone model is not unlike the Coulomb and interlocking asperity models of friction [28.146] except that it is being applied at the molecular level and for a situation where the external load is augmented by attractive intermolecular forces.

There are thus two contributions to the force pulling two surfaces together: the externally applied load or pressure, and the (internal) attractive intermolecular forces that determine the adhesion between the two surfaces. Each of these contributions affects the friction force in a different way, which we will discuss in more detail below.

Adhesion Force Contribution

When the two surfaces are initially in adhesive contact, the surface molecules will adjust themselves to fit snugly together [28.156], in an analogous manner to the self-positioning of the cartwheels on the cobblestone road. A small tangential force applied to one surface will therefore not result in the sliding of that surface relative to the other. The attractive van der Waals forces between the surfaces must first be overcome by having the surfaces separate by a small amount. To initiate motion, let the separation between the two surfaces increase by a small amount ΔD, while the lateral distance moved is $\Delta\sigma$. The energy put into the system by the force F acting over a lateral distance $\Delta\sigma$ is

$$\text{Input energy: } F \times \Delta\sigma\,. \tag{28.28}$$

This energy may be equated with the change in interfacial or surface energy associated with separating the surfaces by ΔD, i. e., from the equilibrium separation $D = D_0$ to $D = (D_0 + \Delta D)$. Since $\gamma \propto D^{-2}$ for two flat surfaces (Sect. 28.3.1, Table 28.2), the energy cost may be approximated by

$$\text{Surface energy change} \times \text{area:}\quad 2\gamma A\left[1 - \frac{D_0^2}{(D_0 + \Delta D)^2}\right] \approx 4\gamma A\left(\frac{\Delta D}{D_0}\right), \tag{28.29}$$
