Fig. 28.13 **(a)** Schematic illustration of how one molecularly smooth surface moves over another when a lateral force F is applied (the *cobblestone model*). As the upper surface moves laterally by some fraction of the lattice dimension $\Delta\sigma$, it must also move up by some fraction of an atomic or molecular dimension ΔD before it can slide across the lower surface. On impact, some fraction ε of the kinetic energy is *transmitted* to the lower surface, the rest being *reflected* back to the colliding molecule (upper surface) (after [28.155], with permission). **(b)** Difference in the local distribution of the total applied external load or normal adhesive force between load-controlled nonadhering surfaces and adhesion-controlled surfaces. In the former case, the total friction force F is given either by $F = \mu L$ for one contact point (*left side*) or by $F = 1/3\mu L + 1/3\mu L + 1/3\mu L = \mu L$ for three contact points (*right side*). Thus the load-controlled friction is always proportional to the applied load, independently of the number of contacts and of their geometry. In the case of adhering surfaces, the effective *internal* load is given by kA, where A is the real local contact area, which is proportional to the number of intermolecular bonds being made and broken across each single contact point. The total friction force is now given by $F = \mu kA$ for one contact point (*left side*), and $F = \mu(kA_1 + kA_2 + kA_3) = \mu kA_{\text{tot}}$ for three contact points (*right side*). Thus, for adhesion-controlled friction, the friction is proportional to the real contact area, at least when no additional external load is applied to the system (after [28.151], with permission, American Chemical Society). **(c,d)** Friction force between benzyltrichlorosilane monolayers chemically bound to glass or Si, measured in ethanol ($\gamma < 1\,\text{mJ/m}^2$). **(c)** SFA measurements where both glass surfaces were covered with a monolayer. *Circles* and *squares* show two different experiments: one with $R = 2.6\,\text{cm}$, $v = 0.15\,\mu\text{m/s}$, giving $\mu = 0.33 \pm 0.01$; the other with $R = 1.6\,\text{cm}$, $v = 0.5\,\mu\text{m/s}$, giving $\mu = 0.30 \pm 0.01$. **(d)** Friction force microscopy (FFM) measurements of a monolayer-functionalized Si tip ($R = 11\,\text{nm}$) sliding on a monolayer-covered glass surface at $v = 0.15\,\mu\text{m/s}$, giving $\mu = 0.30 \pm 0.01$. Note the different scales in **(c,d)** (after [28.150], with permission, American Chemical Society)

where γ is the surface energy, A the contact area, and D_0 the surface separation at equilibrium. During steady-state sliding (kinetic friction), not all of this energy will be lost or absorbed by the lattice every time the surface molecules move by one lattice spacing: some fraction will be reflected during each impact of the cartwheel molecules [28.155]. Assuming that a fraction ε of the above surface energy is lost every time the surfaces move across the characteristic length $\Delta\sigma$ (Fig. 28.13a), we obtain after equating (28.28)

and (28.29)

$$S_c = \frac{F}{A} = \frac{4\gamma\varepsilon\Delta D}{D_0\Delta\sigma} \,. \tag{28.30}$$

The above model suggests that all interfaces, whether dry or lubricated, dilate just before they shear or slip. This dilation, which provides the crucial extra space for the molecules to slide across each other, is known to occur in macroscopic systems [28.157] and for nanoscopic systems it has been computed [28.128] and also measured experimentally [28.158].

This model may be extended to lubricated sliding, where a thin liquid film is present between the surfaces. With an increase in the number of liquid layers between the surfaces, D_0 increases while ΔD decreases, hence the friction force decreases. This is precisely what is observed, but with more than one liquid layer between two surfaces the situation becomes too complex to study analytically. Furthermore, even in systems as simple as linear alkanes, interdigitation and interdiffusion have been found to contribute strongly to the properties of the system [28.159]. Sophisticated modeling based on computer simulations is now required, as discussed in the following section.

Relation Between Boundary Friction and Adhesion Energy Hysteresis

While the above equations suggest that there is a direct correlation between friction and adhesion, this is not the case. The correlation is really between friction and adhesion hysteresis, described in Sect. 28.5.4. In the case of friction, this subtle point is hidden in the factor ε, which is a measure of the amount of energy absorbed (dissipated, transferred, or lost) by the lower surface when it is impacted by a molecule from the upper surface. If $\varepsilon = 0$, all the energy is reflected, and there will be no kinetic friction force or any adhesion hysteresis, but the absolute magnitude of the adhesion force or energy will remain finite and unchanged. This is illustrated in Fig. 28.17.

The following simple model shows how adhesion hysteresis and friction may be quantitatively related. Let $\Delta\gamma = \gamma_R - \gamma_A$ be the adhesion energy hysteresis per unit area, as measured during a typical loading-unloading cycle. Now consider the same two surfaces sliding past each other and assume that frictional energy dissipation occurs through the same mechanism as adhesion energy dissipation, and that both occur over the same characteristic molecular length scale σ. Thus, when the two surfaces (of contact area $A = \pi r^2$) move a distance σ, equating the frictional energy $(F \times \sigma)$ to the dissipated adhesion energy $(A \times \Delta\gamma)$, we obtain

$$\text{Friction force: } F = \frac{A\,\Delta\gamma}{\sigma} = \frac{\pi r^2}{\sigma}(\gamma_R - \gamma_A) \,, \tag{28.31}$$

$$\text{or critical shear stress: } S_c = \frac{F}{A} = \frac{\Delta\gamma}{\sigma} \,, \tag{28.32}$$

which is the desired expression and has been found to give order-of-magnitude agreement between measured friction forces and adhesion energy hysteresis [28.133]. If we equate (28.32) with (28.30), since $4\Delta D/(D_0\Delta\sigma) \approx 1/\sigma$, we obtain the intuitive relation

$$\varepsilon = \frac{\Delta\gamma}{\gamma} \,. \tag{28.33}$$

External Load Contribution to Interfacial Friction

When there is no interfacial adhesion, S_c is zero. Thus, the only attractive force that needs to be overcome for sliding to occur is the externally applied load or pressure, as shown in Fig. 28.13b.

For a general semiquantitative analysis, again consider the cobblestone model used to derive (28.30), but now include an additional contribution to the surface-energy change of (28.29) due to the work done against the external load or pressure, $L\Delta D = P_{ext}A\Delta D$ (this is equivalent to the work done against gravity in the case of a cart being pushed over cobblestones). Thus

$$S_c = \frac{F}{A} = \frac{4\gamma\varepsilon\Delta D}{D_0\Delta\sigma} + \frac{P_{ext}\varepsilon\Delta D}{\Delta\sigma} \,, \tag{28.34}$$

which gives the more general relation

$$S_c = \frac{F}{A} = C_1 + C_2 + P_{ext} \,, \tag{28.35}$$

where $P_{ext} = L/A$ and C_1 and C_2 are characteristics of the surfaces and sliding conditions. The constant $C_1 = 4\gamma\varepsilon\Delta D/(D_0\Delta\sigma)$ depends on the mutual adhesion of the two surfaces, while both C_1 and $C_2 = \varepsilon\Delta D/\Delta\sigma$ depend on the topography or atomic bumpiness of the surface groups (Fig. 28.13a). The smoother the surface groups the smaller the ratio $\Delta D/\Delta\sigma$ and hence the lower the value of C_2. In addition, both C_1 and C_2 depend on ε (the fraction of energy dissipated per collision), which depends on the relative masses of the shearing molecules, the sliding velocity, the temperature, and the characteristic molecular relaxation processes of the surfaces. This is by far the most difficult parameter to compute, and yet it is the most important since it represents the energy-transfer mechanism in any friction process, and since ε can vary

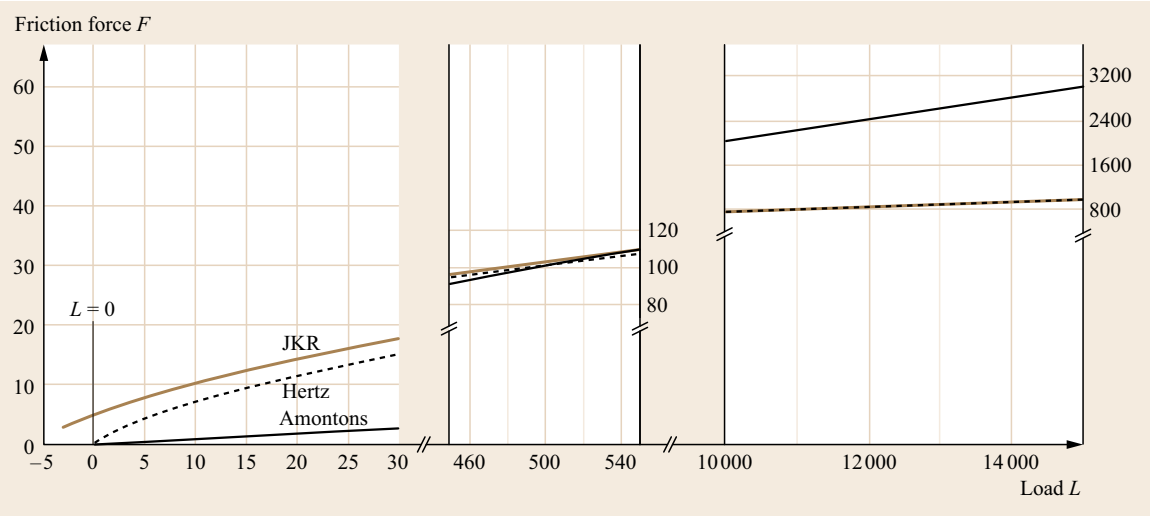

Fig. 28.14 Friction as a function of load for smooth surfaces. At low loads, the friction is dominated by the C_1A term of (28.36). The adhesion contribution (JKR curve) is most prominent near zero load where the Hertzian and Amontons' contributions to the friction are minimal. As the load increases, the adhesion contribution becomes smaller as the JKR and Hertz curves converge. In this range of loads, the linear C_2L contribution surpasses the area contribution to the friction. At much higher loads the explicit load dependence of the friction dominates the interactions, and the observed behavior approaches Amontons' law. It is interesting to note that for smooth surfaces the pressure over the contact area does not increase as rapidly as the load. This is because as the load is increased, the surfaces deform to increase the surface area and thus moderate the contact pressure (after [28.160])

between 1 and 0, it determines whether a particular friction force will be large or close to zero.

Finally, the above equation may also be expressed in terms of the friction force F

$$F = S_c A = C_1 A + C_2 L\,. \tag{28.36}$$

Equations similar to (28.35) and (28.36) were previously derived by *Derjaguin* [28.161, 162] and by *Briscoe* and *Evans* [28.163], where the constants C_1 and C_2 were interpreted somewhat differently than in this model. In the absence of any attractive interfacial force, we have $C_1 \approx 0$, and the second term in (28.35) and (28.36) should dominate (Fig. 28.14). Such situations typically arise when surfaces repel each other across the lubricating liquid film. In such cases, the total frictional force should be low and should increase linearly with the external load according to

$$F = C_2 L\,. \tag{28.37}$$

An example of such lubricated sliding occurs when two mica surfaces slide in water or in salt solution (Fig. 28.18a) where the short-range hydration forces between the surfaces are repulsive. Thus, for sliding in 0.5 M KCl it was found that $C_2 = 0.015$ [28.147]. Another case where repulsive surfaces eliminate the adhesive contribution to friction is for polymer chains attached to surfaces at one end and swollen by a good solvent [28.104]. For this class of systems, $C_2 < 0.001$ for a finite range of polymer layer compressions (normal loads L). The low friction between the surfaces in this regime is attributed to the entropic repulsion between the opposing brush layers with a minimum of entanglement between the two layers. However, with higher normal loads, the brush layers become compressed and begin to entangle, which results in higher friction [28.164]. It is important to note that (28.37) has exactly the same form as Amontons' law (28.25).

Figure 28.13c,d shows the kinetic friction force measured with both SFA and FFM (friction force microscopy, using AFM) on a system where both surfaces were covered with a chemically bound benzyltrichlorosilane monolayer [28.150]. When immersed in ethanol, the adhesion in this system is low, and very different contact areas and loads give a linear dependence of F on L with the same friction coefficients, and $F \to 0$ as $L \to 0$. In the FFM measurements (Fig. 28.13d), the plateau in the data at higher loads suggests a transition in the monolayers, similar to previous observations on other monolayer systems. The pressure in the contact region in the SFA is much lower than in the FFM, and no transitions in the friction forces or in the thickness of the confined monolayers were observed in the SFA experiments (and no damage to the monolayers or the

underlying substrates was observed during the experiments, indicating that the friction was wearless).

A thermodynamic analog of the Coulomb or cobblestone models (Sect. 28.7.2) based on the contact value theorem [28.1, 147, 160] can explain why $F \propto L$ also holds at the microscopic or molecular level. In this analysis we consider the surface molecular groups as being momentarily compressed and decompressed as the surfaces move along. Under irreversible conditions, which always occur when a cycle is completed in a finite amount of time, the energy lost in the compression-decompression cycle is dissipated as heat. For two nonadhering surfaces, the stabilizing pressure P_i acting locally between any two elemental contact points i of the surfaces may be expressed by the contact value theorem [28.1]

$$P_i = \rho_i k_B T = \frac{k_B T}{V_i} , \tag{28.38}$$

where $\rho_i = V_i^{-1}$ is the local number density (per unit volume) or activity of the interacting entities, be they molecules, atoms, ions or the electron clouds of atoms. This equation is essentially the osmotic or entropic pressure of a gas of confined molecules. As one surface moves across the other, local regions become compressed and decompressed by a volume ΔV_i. The work done per cycle can be written as $\varepsilon P_i \Delta V_i$, where ε ($\varepsilon \leq 1$) is the fraction of energy per cycle lost as heat, as defined earlier. The energy balance shows that, for each compression-decompression cycle, the dissipated energy is related to the friction force by

$$F_i x_i = \varepsilon P_i \Delta V_i , \tag{28.39}$$

where x_i is the lateral distance moved per cycle, which can be the distance between asperities or the distance between surface lattice sites. The pressure at each contact junction can be expressed in terms of the local normal load L_i and local area of contact A_i as $P_i = L_i/A_i$. The volume change over a cycle can thus be expressed as $\Delta V_i = A_i z_i$, where z_i is the vertical distance of confinement. Inserting these into (28.39), we get

$$F_i = \varepsilon L_i \left(\frac{z_i}{x_i}\right) , \tag{28.40}$$

which is independent of the local contact area A_i. The total friction force is thus

$$F = \sum F_i = \sum \varepsilon L_i \left(\frac{z_i}{x_i}\right) = \varepsilon \left\langle \frac{z_i}{x_i} \right\rangle \sum L_i = \mu L , \tag{28.41}$$

where it is assumed that on average the local values of L_i and P_i are independent of the local slope z_i/x_i. Therefore, the friction coefficient μ is a function only of the average surface topography and the sliding velocity, but is independent of the local (real) or macroscopic (apparent) contact areas. While this analysis explains nonadhering surfaces, there is still an additional explicit contact area contribution for the case of adhering surfaces, as in (28.36). The distinction between the two cases arises because the initial assumption of the contact value theorem (28.38) is incomplete for adhering systems.

Molecular-scale roughness, real contact areas, and changes therein are difficult to quantify in nanoscale friction experiments, which involve deformable substrates in continuous motion under considerable pressure. In contrast, the nominal contact area can be either directly measured (e.g., in the SFA) or estimated from contact mechanics models, although concerns have been raised about the applicability of such models on the nanometer and subnanometer scale [28.165] where atomic-level roughness causes local changes in the pressure. Recent computer simulations [28.166–168] have suggested that within the nominal contact area, the size of the real, molecular contact area and its increase with increasing load are adhesion dependent, but in a different manner than that observed for nominal or macroscopic contacts.

28.7.3 Examples of Experimentally Observed Friction of Dry Surfaces

Numerous model systems, including a variety of both unlubricated and solid- and liquid-lubricated surfaces, have been studied with a surface forces apparatus (SFA) modified for friction experiments (Sect. 28.2.3). The apparatus allows for control of load (normal force) and sliding speed, and simultaneous measurement of surface separation, surface shape, true (molecular) area of contact between smooth surfaces, and friction forces.

Figure 28.15 shows the contact area A and friction force F, both plotted against the applied load L in an experiment in which two molecularly smooth surfaces of mica in adhesive contact were slid past each other in an atmosphere of dry nitrogen gas. This is an example of the low-load adhesion-controlled limit, which is excellently described by (28.27). In a number of different experiments, S_c was measured to be $2.5 \times 10^7\,\mathrm{N\,m^{-2}}$ and to be independent of the sliding velocity [28.32, 169]. Note that there is a friction force even at negative loads, where the surfaces are still sliding in adhesive contact.

The high friction force of unlubricated sliding can often be reduced by treating the solid surface with a boundary layer of some other solid material that exhibits lower friction, such as a surfactant monolayer,

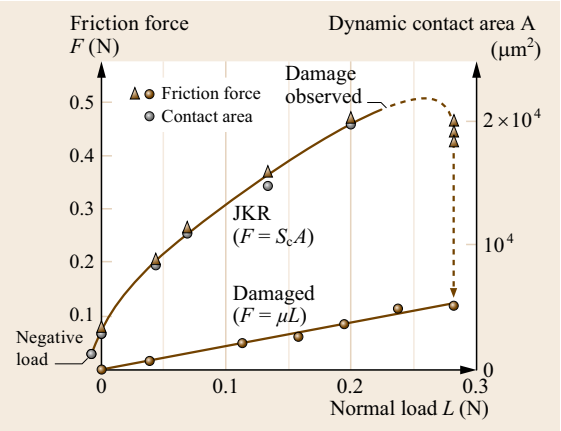

Fig. 28.15 Friction force F and contact area A versus load L for two mica surfaces sliding in adhesive contact in dry air. The contact area is well described by the JKR theory, (28.21), even during sliding, and the friction force is found to be directly proportional to this area, (28.27). The *vertical dashed line* and *arrow* show the transition from interfacial to normal friction with the onset of wear (*lower curve*). The sliding velocity is $0.2\,\mu m\,s^{-1}$ (after [28.32], with permission, American Society of Mechanical Engineers)

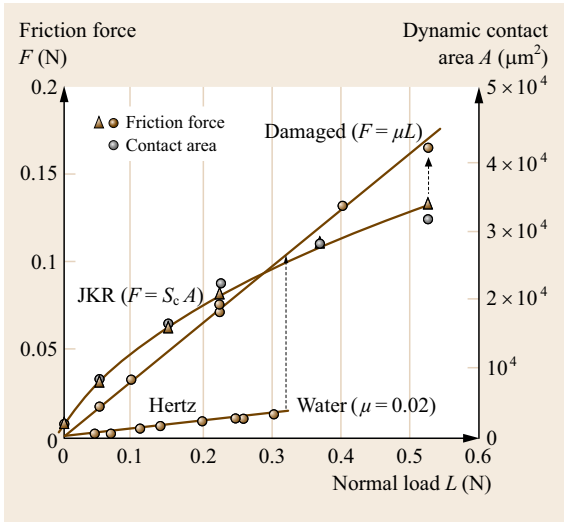

Fig. 28.16 Sliding of mica surfaces, each coated with a 2.5 nm-thick monolayer of calcium stearate surfactant, in the absence of damage (obeying JKR-type boundary friction) and in the presence of damage (obeying Amontons-type normal friction). Note that both for this system and for the bare mica in Figs. 28.15 and 28.18a, the friction force obeys Amontons' law with a friction coefficient of $\mu \approx 0.3$ after damage occurs. At much higher applied loads, the undamaged surfaces also follow Amontons-type sliding, but for a different reason: the dependence on adhesion becomes smaller. *Lower line*: interfacial sliding with a monolayer of water between the mica surfaces (load-controlled friction, Fig. 28.18a), shown for comparison (after [28.169], with permission from Elsevier Science)

or by ensuring that during sliding a thin liquid film remains between the surfaces (as will be discussed in Sect. 28.8). The effectiveness of a solid boundary lubricant layer on reducing the forces of friction is illustrated in Fig. 28.16. Comparing this with the friction of the unlubricated/untreated surfaces (Fig. 28.15) shows that the critical shear stress has been reduced by a factor of about ten: from 2.5×10^7 to $3.5\times10^6\,N\,m^{-2}$. At much higher applied loads or pressures, the friction force is proportional to the load, rather than the area of contact [28.170], as expected from (28.26).

The adhesion and friction of fluorocarbon surfaces (surfactant-coated boundary lubricant layers) have been compared to those of hydrocarbon surfaces [28.171]. It was concluded that well-ordered fluorocarbon surfaces have high friction, in spite of their lower adhesion energy. The low friction coefficient of Teflon (polytetrafluoroethylene, PTFE) must, therefore, be due to some effect other than low adhesion. On a related issue, it has been found that C_{60} surfaces also exhibit low adhesion but high friction [28.172]. In both cases the high friction appears to arise from the bulky surface groups – fluorocarbon compared to hydrocarbon groups in the former, large fullerene spheres in the latter. Apparently, the fact that C_{60} molecules rotate *in their lattice* does not make them a good lubricant: the molecules of the opposing surface must still climb over them in order to slide, and this requires energy that is independent of whether the surface molecules are fixed or freely rotating.

Figure 28.17 illustrates the relationship between adhesion hysteresis and friction for surfactant-coated surfaces under different conditions. This effect, however, is much more general and has been shown to hold for other surfaces as well [28.30, 134, 155, 173].

Direct comparisons between absolute adhesion energies and friction forces show little correlation. In some cases, higher adhesion energies for the same system under different conditions correspond to lower friction forces. For example, for hydrophilic silica surfaces it was found that with increasing relative humidity the adhesion energy increases, but the adhesion energy hysteresis measured in a loading–unloading cycle decreases, as does the friction force [28.30].

A liquid lubricant film (Sect. 28.8.3) is usually much more effective at lowering the friction of two surfaces than a solid boundary lubricant layer. However, to use a liquid lubricant successfully, it must *wet* the surfaces, that is, it should have a high affinity for the

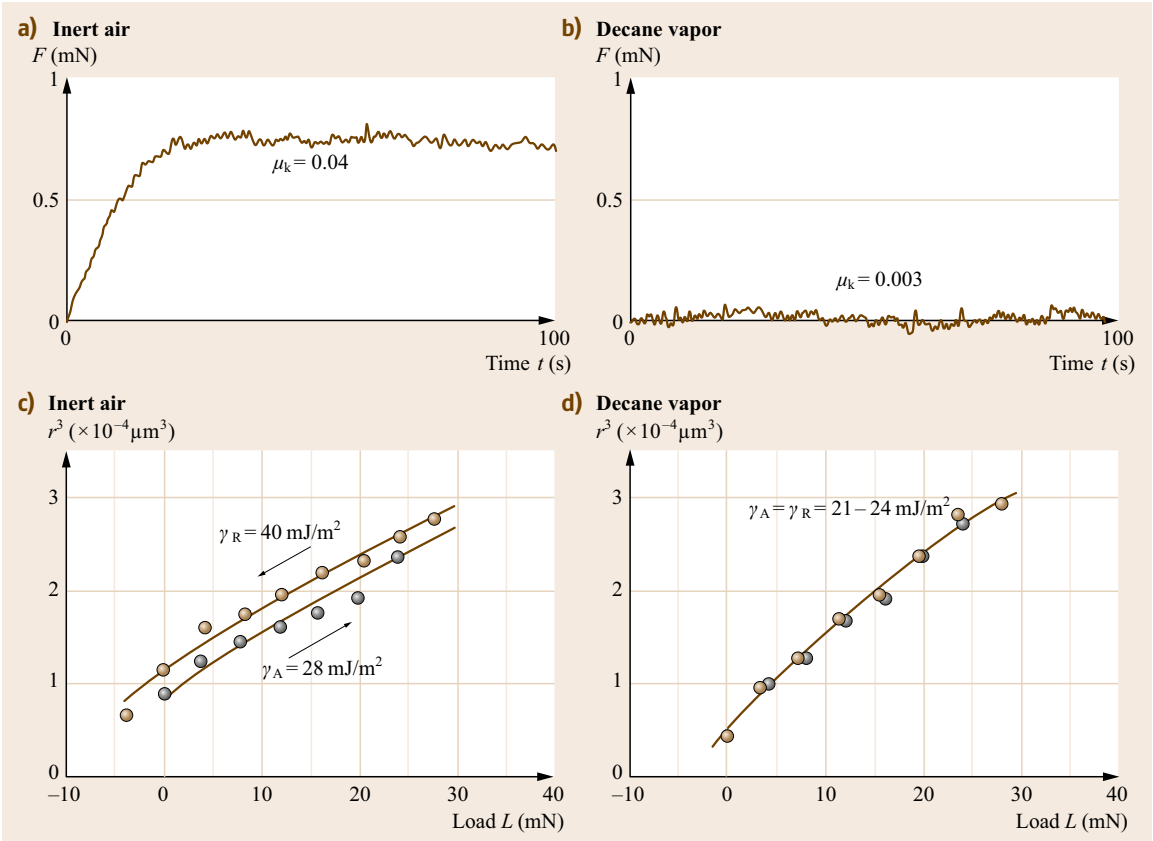

Fig. 28.17a–d *Top*: friction traces for two fluid-like calcium alkylbenzene sulfonate monolayer-coated surfaces at 25 °C showing that the friction force is much higher between dry monolayers **(a)** than between monolayers whose fluidity has been enhanced by hydrocarbon penetration from vapor **(b)**. *Bottom*: Contact radius versus load (r^3 versus L) data measured for the same two surfaces as above and fitted to the JKR equation (28.21), shown by the *solid curves*. For dry monolayers **(c)** the adhesion energy on unloading ($\gamma_R = 40\,\mathrm{mJ\,m^{-2}}$) is greater than that on loading ($\gamma_A = 28\,\mathrm{mJ\,m^{-2}}$), which is indicative of an adhesion energy hysteresis of $\Delta\gamma = \gamma_R - \gamma_A = 12\,\mathrm{mJ\,m^{-2}}$. For monolayers exposed to saturated decane vapor **(d)** their adhesion hysteresis is zero ($\gamma_A = \gamma_R$), and both the loading and unloading data are well fitted by the thermodynamic value of the surface energy of fluid hydrocarbon chains, $\gamma = 24\,\mathrm{mJ\,m^{-2}}$ (after [28.133], with permission, American Chemical Society)

surfaces, so that not all the liquid molecules become squeezed out when the surfaces come close together, even under a large compressive load. Another important requirement is that the liquid film remains a liquid under tribological conditions, i. e., that it does not epitaxially solidify between the surfaces.

Effective lubrication usually requires that the lubricant be injected between the surfaces, but in some cases the liquid can be made to condense from the vapor. This is illustrated in Fig. 28.18a for two untreated mica surfaces sliding with a thin layer of water between them. A monomolecular film of water (of thickness 0.25 nm per surface) has reduced S_c from its value for dry surfaces (Fig. 28.15) by a factor of more than 30, which may be compared with the factor of ten attained with the boundary lubricant layer (of thickness 2.5 nm per surface) in Fig. 28.16. Water appears to have unusual lubricating properties and usually gives wearless friction with no stick–slip [28.174].

The effectiveness of a water film only 0.25 nm thick to lower the friction force by more than an order of magnitude is attributed to the hydrophilicity of the mica surface (mica is wetted by water) and to the existence of a strongly repulsive short-range hydration force between such surfaces in aqueous solutions, which effectively removes the adhesion-controlled contribution to the friction force [28.148]. It is also interesting that a 0.25 nm-thick water film between two mica surfaces is sufficient to bring the coefficient of friction down to 0.01–0.02, a value that corresponds to the unusually

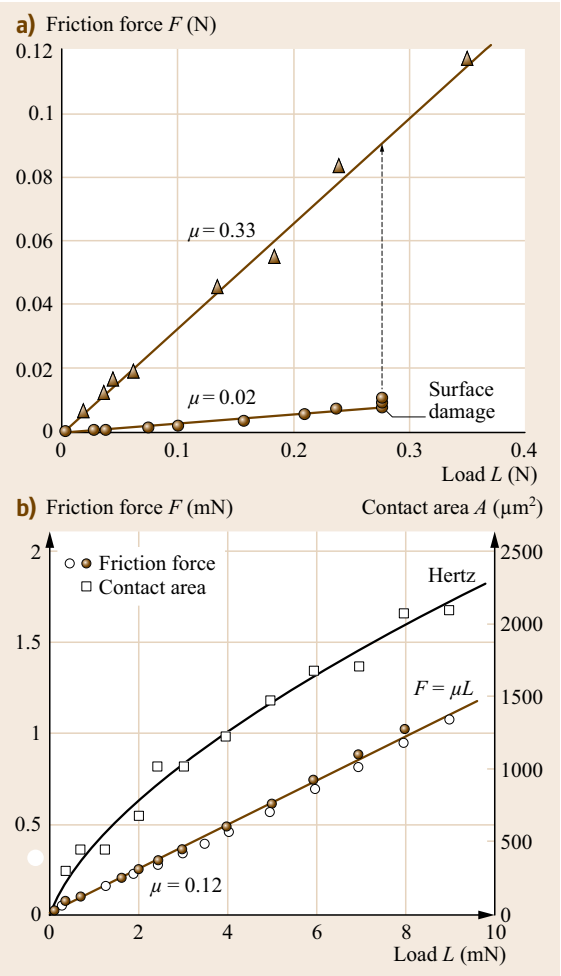

Fig. 28.18a,b Load-controlled friction. **(a)** Two mica surfaces sliding past each other while immersed in a 0.01 M KCl salt solution (nonadhesive conditions). The water film is molecularly thin, 0.25–0.5 nm thick, and the interfacial friction force is very low: $S_c \approx 5\times10^5\,\mathrm{N\,m^{-2}}$, $\mu \approx 0.02$ (before damage occurs). After the surfaces have become damaged, the friction coefficient is about 0.3 (after [28.169], with permission from Elsevier Science). **(b)** Steady-state friction force and contact area measured on a confined squalane film between two undamaged mica surfaces at $v = 0.6\,\mu\mathrm{m/s}$ in the smooth sliding regime (no stick–slip). *Open circles* show F obtained on loading (increasing L); *solid circles* show unloading. Both datasets are *straight lines* passing through the origin, as shown by the *brown line* ($\mu = 0.12$). The *black curve* is a fit of the Hertz equation (Sect. 28.5.2 and [28.1]) to the A versus L data (*open squares*) using $K = 10^{10}\,\mathrm{N/m^2}$, $R = 2\,\mathrm{cm}$. The thickness D varies monotonically from $D = 2.5$ to 1.7 nm as the load increases from $L = 0$ to 10 mN (adapted from [28.149], American Physical Society)

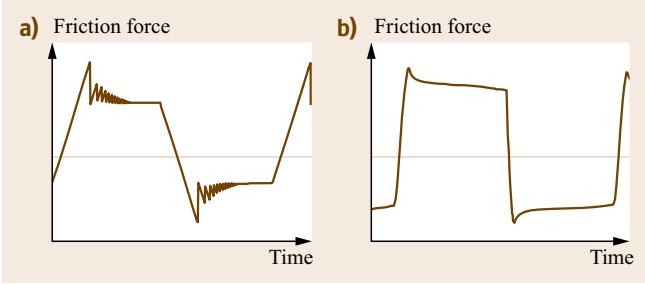

Fig. 28.19a,b Typical friction traces showing how the friction force varies with the sliding time for two symmetric, glassy polymer films under dry conditions. Qualitative features that are common to both polystyrene and polyvinyl benzyl chloride: **(a)** Decaying stick–slip motion is observed until smooth sliding is attained if the motion continues for a sufficiently long distance. **(b)** Smooth sliding observed at sufficiently high speeds. Similar observations have been made (after [28.175]) in measurements on polymethyl methacrylate (after [28.134], with permission, American Association for the Advancement of Science)

low friction of ice. Clearly, a single monolayer of water can be a very good lubricant – much better than most other monomolecular liquid films – for reasons that will be discussed in Sect. 28.9. A linear dependence of F on L has also been observed for mica surfaces separated by certain hydrocarbon liquids [28.141, 149]. Figure 28.18b shows the kinetic friction forces measured at a high velocity across thin films of squalane, a branched hydrocarbon liquid ($C_{30}H_{62}$), which is a model for lubricating oils. Very low adhesive forces are measured between mica surfaces across this liquid [28.149] and the film thickness decreases monotonically with load. The friction force at a given load was found to be velocity dependent, whereas the contact area was not [28.149].

Dry polymer layers (Fig. 28.19) typically show a high initial static friction (stiction) as sliding commences from rest in adhesive contact. The development of the friction force after a change in sliding direction, a gradual transition from stick–slip to smooth sliding, is shown in Fig. 28.19. As shown in Fig. 28.11b,c, the adhesion hysteresis for polystyrene surfaces can be increased by irradiation to induce scission of chains, and it has been found that the steady-state friction force (kinetic friction) shows a similar increase with irradiation time [28.134].

28.7.4 Transition from Interfacial to Normal Friction with Wear

Frictional damage can have many causes, such as adhesive tearing at high loads or overheating at high sliding speeds. Once damage occurs, there is a transition

from interfacial to normal or load-controlled friction as the surfaces become forced apart by the torn-out asperities (wear particles). For low loads, the friction changes from obeying $F = S_c A$ to obeying Amontons' law, $F = \mu L$, as shown in Figs. 28.15 and 28.16, and sliding now proceeds smoothly with the surfaces separated by a 10–100 nm forest of wear debris (in this case, mica flakes). The wear particles keep the surfaces apart over an area that is much greater than their size, so that even one submicroscopic particle or asperity can cause a significant reduction in the area of contact and, therefore, in the friction [28.169]. For this type of frictional sliding, one can no longer talk of the molecular contact area of the two surfaces, although the macroscopic or apparent area is still a useful parameter.

One remarkable feature of the transition from interfacial to normal friction of brittle surfaces is that, while the strength of interfacial friction, as reflected in the values of S_c, is very dependent on the type of surface and on the liquid film between the surfaces, this is not the case once the transition to normal friction has occurred. At the onset of damage, the material properties of the underlying substrates control the friction. In Figs. 28.15, 28.16, and 28.18a the friction for the damaged surfaces is that of any damaged mica-mica system, $\mu \approx 0.3$, *independent of the initial surface coatings or liquid films between the surfaces*. A similar friction coefficient was found for damaged silica surfaces [28.30].

Clearly, the mechanism and factors that determine normal friction are quite different from those that govern interfacial friction (Sects. 28.7.1 and 28.7.2). This effect is not general and may only apply to brittle materials. For example, the friction of ductile surfaces is totally different and involves the continuous plastic deformation of contacting surface asperities during sliding, rather than the rolling of two surfaces on hard wear particles [28.138]. Furthermore, in the case of ductile surfaces, water and other surface-active components do have an effect on the friction coefficients under normal sliding conditions.

28.8 Liquid Lubricated Surfaces

28.8.1 Viscous Forces and Friction of Thick Films: Continuum Regime

Experimentally, it is usually difficult to unambiguously establish which type of sliding mode is occurring, but an empirical criterion, based on the Stribeck curve (Fig. 28.12), is often used as an indicator. This curve shows how the friction force or the coefficient of friction is expected to vary with sliding speed, depending on which type of friction regime is operating. For thick liquid lubricant films whose behavior can be described by bulk (continuum) properties, the friction forces are essentially the hydrodynamic or viscous drag forces. For example, for two plane parallel surfaces of area A separated by a distance D and moving laterally relative to each other with velocity v, if the intervening liquid is Newtonian, i. e., if its viscosity η is independent of the shear rate, the frictional force experienced by the surfaces is given by

$$F = \frac{\eta A v}{D} , \tag{28.42}$$

where the shear rate $\dot{\gamma}$ is defined by

$$\dot{\gamma} = \frac{v}{D} . \tag{28.43}$$

At higher shear rates, two additional effects often come into play. First, certain properties of liquids may change at high $\dot{\gamma}$ values. In particular, the effective viscosity may become non-Newtonian, one form given by

$$\eta \propto \dot{\gamma}^n , \tag{28.44}$$

where $n = 0$ (i. e., $\eta_{\text{eff}} =$ constant) for Newtonian fluids, $n > 0$ for shear-thickening (dilatant) fluids, and $n < 0$ for shear-thinning (pseudoplastic) fluids (the latter become less viscous, i. e., flows more easily, with increasing shear rate). An additional effect on η can arise from the higher local stresses (pressures) experienced by the liquid film as $\dot{\gamma}$ increases. Since the viscosity is generally also sensitive to the pressure (usually increasing with P), this effect also acts to increase η_{eff} and thus the friction force.

A second effect that occurs at high shear rates is surface deformation, arising from the large hydrodynamic forces acting on the sliding surfaces. For example, Fig. 28.20 shows how two surfaces deform elastically when the sliding speed increases to a high value. These deformations alter the hydrodynamic friction forces, and this type of friction is often referred to as elastohydrodynamic lubrication (EHD) or (EHL), as mentioned in Table 28.4.

How thin can a liquid film be before its dynamic, e.g., viscous flow, behavior ceases to be described by bulk properties and continuum models? Concerning the static properties, we have already seen in Sect. 28.4.3

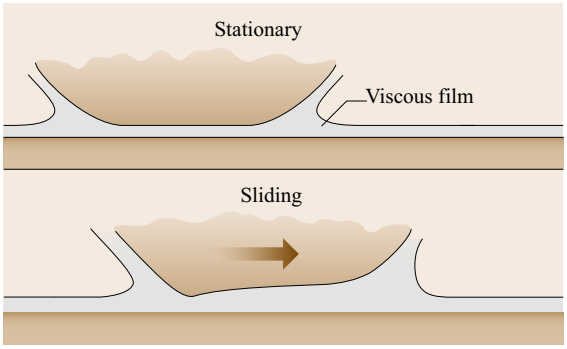

Fig. 28.20 *Top*: Stationary surfaces (one more deformable and one rigid) separated by a thick liquid film. *Bottom*: Elastohydrodynamic deformation of the upper surface during sliding (after [28.5], with permission)

that films composed of simple liquids display continuum behavior down to thicknesses of 4–10 molecular diameters. Similar effects have been found to apply to the dynamic properties, such as the viscosity, of simple liquids in thin films. Previous studies [28.6, 7, 176, 177] show that, for simple liquids including linear chain molecules such as alkanes, the viscosity in thin films is the same, within 10%, as the bulk even for films as thin as 10 molecular diameters (or segment widths). This implies that the shear plane is effectively located within one molecular diameter of the solid–liquid interface, and these conclusions were found to remain valid even at the highest shear rates studied (of $\approx 2\times10^5\,\mathrm{s}^{-1}$). These results appear to be independent of the existence of electrostatic double-layer or hydration forces. For the case of the simple liquid toluene confined between surfaces with adsorbed layers of C_{60} molecules, this type of viscosity measurement has shown that the traditional no-slip assumption for flow at a solid interface does not always hold [28.178]. The C_{60} layer at the mica–toluene interface results in a full-slip boundary, which dramatically lowers the viscous drag or effective viscosity for regular Couette or Poiseuille flow.

With polymeric liquids (polymer melts) such as polydimethylsiloxanes (PDMS) and polybutadienes (PBD), or with polystyrene (PS) adsorbed onto surfaces from solution, the far-field viscosity is again equal to the bulk value, but with the nonslip plane (hydrodynamic layer thickness) being located at $D = 1–2R_g$ away from each surface [28.6, 35], or at $D = L$ or less for polymer brush layers of thickness L per surface [28.7, 179]. In contrast, the same technique was used to show that, for nonadsorbing polymers in solution, there is actually a depletion layer of nearly pure solvent that exists at the surfaces that affects the confined solution flow properties [28.180]. These effects are observed from near contact to surface separations in excess of 200 nm.

Further experiments with surfaces closer than a few molecular diameters ($D < 2–4$ nm for simple liquids, or $D < 2–4R_g$ for polymer fluids) indicate that large deviations occur for thinner films, described below. One important conclusion from these studies is, therefore, that the dynamic properties of simple liquids, including water, near an isolated surface are similar to those of the bulk *liquid already within the first layer of molecules adjacent to the surface*, only changes when another surface approaches the first due to the constraining effects on the liquid molecules.

28.8.2 Friction of Intermediate Thickness Films

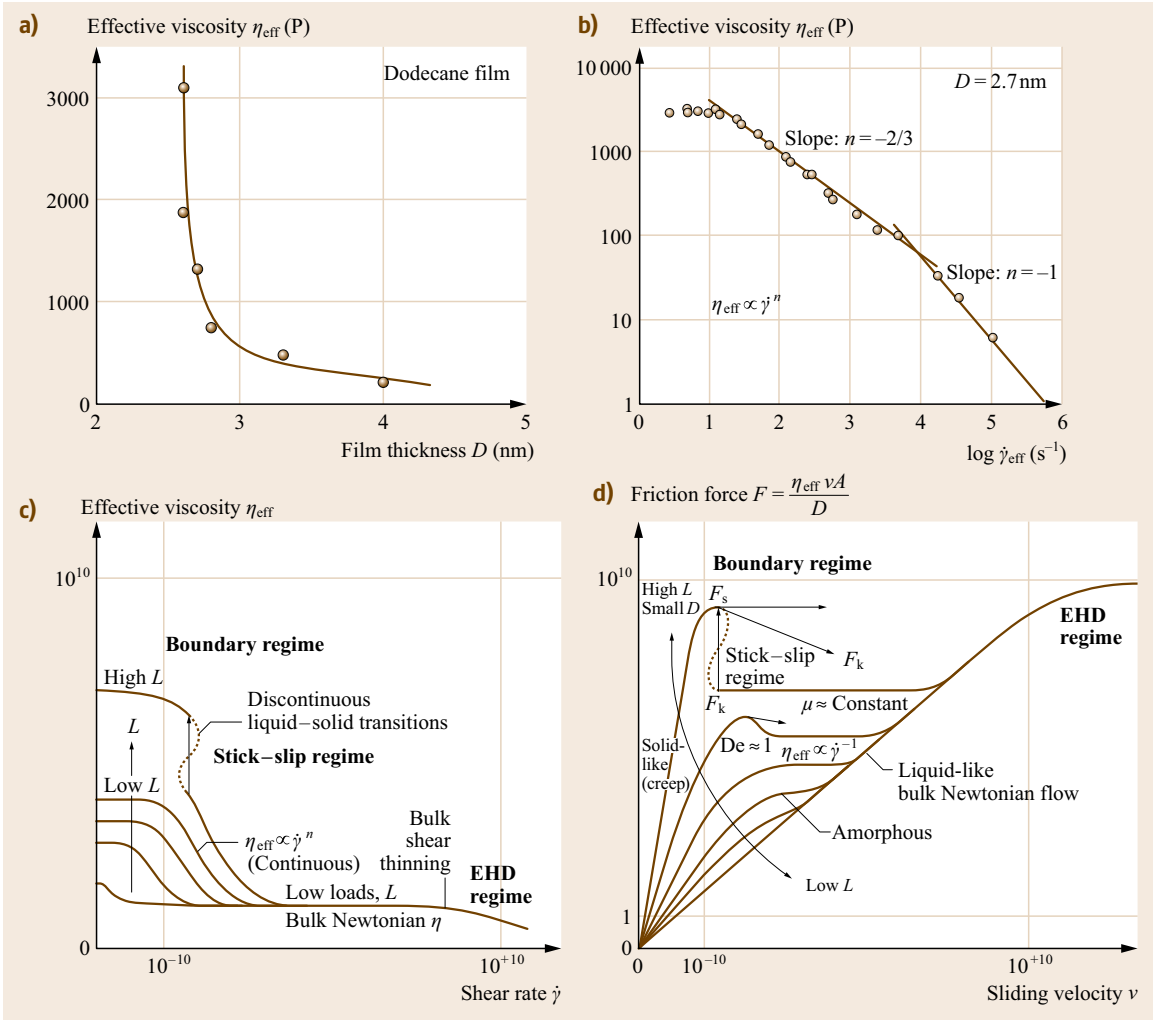
For liquid films in the thickness range between 4 and 10 molecular diameters, the properties can be significantly different from those of bulk films. Still, the fluids do not undergo a phase transition into a solid or liquid-crystalline phase. Films of simple liquids have been found to become non-Newtonian in the 2.5–5 nm regime (about 10 molecular diameters, Fig. 28.21) [28.139] while polymer melts are known to become non-Newtonian at much larger film thicknesses, depending on their molecular weight [28.35].

Based on studies of interaction forces and friction of small quasispherical liquid molecules such as cyclohexane between molecularly smooth mica surfaces [28.34, 144], it has been concluded that surface epitaxial effects can cause the liquid film to solidify already at six molecular diameters, resulting in a sudden (discontinuous) jump to high friction at low shear rates. Such dynamic first-order transitions, however, may depend on the shear rate.

A generalized friction map (Fig. 28.21c,d) has been proposed [28.181, 182] that illustrates the changes in η_{eff} from bulk Newtonian behavior ($n = 0$, $\eta_{\mathrm{eff}} = \eta_{\mathrm{bulk}}$) through the transition regime where n reaches a minimum of -1 with decreasing shear rate to the solid-like creep regime at very low $\dot{\gamma}$ where n returns to 0. A number of results from experimental, theoretical, and computer simulation work have shown values of n from $-1/2$ to -1 for this transition regime for a variety of systems and assumptions [28.139, 140, 183–185].

The intermediate regime appears to extend over a narrow range of film thickness, from about 4–10 molecular diameters or polymer radii of gyration. Thinner films begin to adopt boundary or interfacial friction properties (described below, see also Table 28.5). Note that the intermediate regime is actually a very narrow one when defined in terms of film thickness, for ex-

Fig. 28.21a–d Typical rheological behavior of liquid films in the mixed lubrication regime. **(a)** Increase in effective viscosity of dodecane film between two mica surfaces with decreasing film thickness. At distances larger than 4–5 nm, the effective viscosity η_{eff} approaches the bulk value η_{bulk} and does not depend on the shear rate $\dot{\gamma}$ (after [28.139], American Association for the Advancement of Science). **(b)** Non-Newtonian variation of η_{eff} with shear rate of a 2.7 nm-thick dodecane film at a net normal pressure of 0.12 MPa and at 28 °C. The effective viscosity decays as a power law, as in (28.44). In this example, $n = 0$ at the lowest $\dot{\gamma}$ and changes to $n = -2/3$ and -1 at higher $\dot{\gamma}$. For films of bulk thickness, dodecane is a low-viscosity Newtonian fluid ($n = 0$). **(c)** Proposed general friction map of effective viscosity η_{eff} (arbitrary units) as a function of effective shear rate $\dot{\gamma}$ (arbitrary units) on logarithmic scales. Three main classes of behavior emerge: (i) Thick films: EHD sliding. At $L = 0$, approximating bulk conditions, η_{eff} is independent of shear rate except when shear thinning might occur at sufficiently large $\dot{\gamma}$. (ii) Boundary layer films, intermediate regime. A Newtonian regime is again observed ($\eta_{\text{eff}} =$ constant, $n = 0$ in (28.44)) at low loads and low shear rates, but η_{eff} is much higher than the bulk value. As the shear rate $\dot{\gamma}$ increases beyond $\dot{\gamma}_{\text{min}}$, the effective viscosity starts to drop with a power-law dependence on the shear rate **(b)** with n in the range $-1/2$ to -1 most commonly observed. As the shear rate $\dot{\gamma}$ increases still more, beyond $\dot{\gamma}_{\text{max}}$, a second Newtonian plateau is encountered. (iii) Boundary layer films, high load. The η_{eff} continues to grow with load and to be Newtonian provided that the shear rate is sufficiently low. Transition to sliding at high velocity is discontinuous ($n < -1$) and usually of the stick–slip variety. **(d)** Proposed friction map of friction force as a function of sliding velocity in various tribological regimes. With increasing load, Newtonian flow in the EHD regimes crosses into the boundary regime of lubrication. Note that even EHD lubrication changes, at the highest velocities, to limiting shear stress response. At the highest loads (L) and smallest film thickness (D), the friction force goes through a maximum (the static friction F_s) followed by a regime where the friction coefficient (μ) is roughly constant with increasing velocity (meaning that the kinetic friction, F_k, is roughly constant). Non-Newtonian shear thinning is observed at somewhat smaller load and larger film thickness; the friction force passes through a maximum at the point where De = 1. De – the Deborah number – is the point at which the applied shear rate exceeds the natural relaxation time of the boundary layer film. The velocity axis from 10^{-10} to 10^{10} (arbitrary units) indicates a large span. (Panels **(b–d)** after [28.181, 182], with permission from Elsevier Science) ►



ample varying from about $D = 2$–4 nm for hexadecane films [28.139].

A fluid's effective viscosity η_{eff} in the intermediate regime is usually higher than in the bulk, but η_{eff} usually decreases with increasing sliding velocity, v (known as shear thinning). When two surfaces slide in the intermediate regime, the motion tends to thicken the film (dilatancy). This sends the system into the bulk EHD regime where, as indicated by (28.42), the friction force now increases with velocity. This initial decrease, followed by an increase, in the frictional forces of many lubricant systems is the basis for the empirical Stribeck

Table 28.5 Effect of molecular shape and short-range forces on tribological properties for molecularly thin liquid films between two shearing mica surfaces at 20 °C

Liquid	Short-range force	Type of friction	Friction coefficient	Bulk liquid viscosity (cP)
Organic (water-free) Cyclohexane	Oscillatory	Quantized stick–slip	$\gg 1$	0.6
OMCTS[a]	Oscillatory	Quantized stick–slip	$\gg 1$	2.3
Octane	Oscillatory	Quantized stick–slip	1.5	0.5
Tetradecane	Oscillatory ↔ smooth	stick–slip ↔ smooth	1.0	2.3
Octadecane (branched)	Oscillatory ↔ smooth	stick–slip ↔ smooth	0.3	5.5
PDMS[a] ($M = 3700\,\text{g mol}^{-1}$, melt)	Oscillatory ↔ smooth	Smooth	0.4	50
PBD[a] ($M = 3500\,\text{g mol}^{-1}$, branched)	Smooth	Smooth	0.03	800
Water				
Water (KCl solution)	Smooth	Smooth	0.01–0.03	1.0

curve of Fig. 28.12. In the transition from bulk to boundary behavior there is first a quantitative change in the material properties (viscosity and elasticity), which can be continuous, to discontinuous qualitative changes that result in yield stresses and nonliquid-like behavior.

28.8.3 Boundary Lubrication of Molecularly Thin Films: Nanorheology

When a liquid is confined between two surfaces or within any narrow space whose dimensions are less than 4–10 molecular diameters, both the static (equilibrium) and dynamic properties of the liquid, such as its compressibility and viscosity, can no longer be described even qualitatively in terms of the bulk properties. The molecules confined within such molecularly thin films become ordered into layers (out-of-plane ordering), and within each layer they can also have lateral order (in-plane ordering). Such films may be thought of as behaving more like a liquid crystal or a solid than a liquid, and the structuring of molecules in thin films and the oscillatory forces it gives rise to (Sect. 28.4.3) are now reasonably well understood, both experimentally and theoretically, at least for simple liquids.

Work has also recently been done on the dynamic, e.g., viscous or shear, forces associated with molecularly thin films. Both experiments [28.28, 34, 129, 141, 144, 145, 187] and theory [28.127, 128, 183, 188] indicate that, even when two surfaces are in steady-state sliding, they still prefer to remain in one of their stable potential-energy minima, i. e., a sheared film of liquid can retain its basic layered structure. Thus even during motion the film does not become totally liquid-like. Indeed, if there is some in-plane ordering within a film, it will exhibit a yield point before it begins to flow. Such films can therefore sustain a finite shear stress,

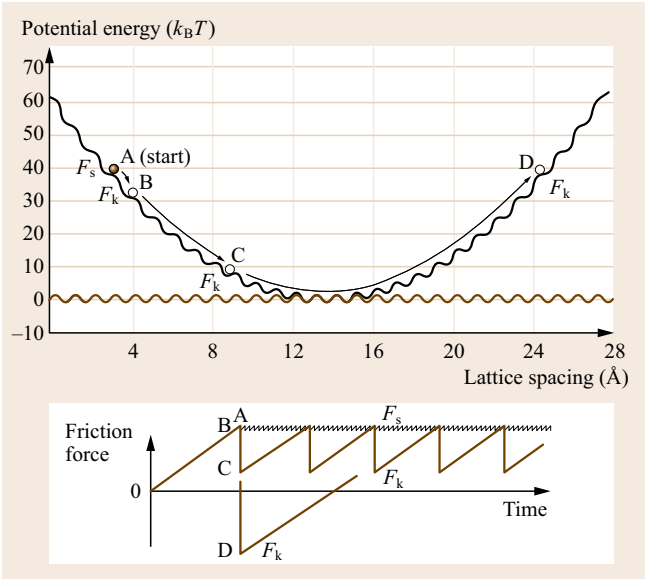

Fig. 28.22 Simple schematic illustration of the most common molecular mechanism leading from smooth to stick–slip sliding in terms of the efficiency of the energy transfer from mechanical to kinetic to phonons. The potential energy of the corrugated surface lattice is shown by the *horizontal sine wave*. Let the depth of each minimum be ε, which is typically $> k_BT$. At equilibrium, a molecule will *sit* at one of these minima. When the molecule is connected to a horizontal spring, a smooth parabolic curve must be added to the horizontal curve. If this spring is now pushed or pulled laterally at a constant velocity v, the sine curve will move like a wave along the parabola carrying the molecule up with it (towards point A). When the point of inflection at A is reached the molecule will drop and acquire a kinetic energy greater than ε even before it reaches the next lattice site. This energy can be *released* at the next lattice site (i. e., on the first collision), in which case the processes will now be repeated – each time the molecule reaches point A it will fall to point B. This type of motion will give rise to periodic changes in temperature at the interface, as predicted by computer simulations (after [28.186]). The stick–slip here will have a magnitude of the lattice dimension and the measured macro- and microscopic friction forces will be smooth and independent of v. If the energy dissipation (or *transfer*) mechanism is less than 100% efficient on each collision, the molecule will move further before it stops. In this case the stick–slip amplitude can be large (point C), and the kinetic friction F_k can even be negative in the case of an overshoot (point D) (after [28.151], with permission, American Chemical Society)

in addition to a finite normal stress. The value of the yield stress depends on the number of layers comprising the film and represents another quantized property of molecularly thin films [28.127].

The dynamic properties of a liquid film undergoing shear are very complex. Depending on whether the film is more liquid-like or solid-like, the motion will be smooth or of the stick–slip type illustrated schematically in Fig. 28.22. During sliding, transitions can occur between n layers and $(n-1)$ or $(n+1)$ layers. The details of the motion depend critically on the externally applied load, the temperature, the sliding velocity, the twist angle between the two surface lattices, and the sliding direction relative to the lattices.

Smooth and Stick–Slip Sliding

Recent advances in friction-measuring techniques have enabled the interfacial friction of molecularly thin films to be measured with great accuracy. Some of these advances have involved the surface forces apparatus technique [28.28, 32–35, 140, 141, 144, 145, 149, 150, 158, 159, 169, 174, 187, 189]. In addition, computer simulations [28.57, 127, 128, 151, 188, 190] have become sufficiently sophisticated to enable fairly complex tribological systems to be studied. All these advances are necessary if one is to probe such subtle effects as smooth or stick–slip friction, transient and memory effects, and ultralow friction mechanisms at the molecular level.

stick–slip occurs between a static state with high friction and a low-friction kinetic state, and a transition from this sliding regime to smooth sliding can be induced by an increase in velocity. Experimental data on various systems showing this behavior are shown below. Recent studies on adhesive systems have revealed the possibility of other dynamic responses such as inverted stick–slip between two kinetic states of higher and lower friction and with a transition from smooth sliding to stick–slip with increasing velocity [28.191]. Similar friction responses have also been seen in computer simulations [28.192].

With the added insights provided by computer simulations, a number of distinct molecular processes have been identified during smooth and stick–slip sliding in model systems for the more familiar static-to-kinetic stick–slip and transition from stick–slip to smooth sliding. These are shown schematically in Fig. 28.23 for the case of spherical liquid molecules between two solid crystalline surfaces. The following regimes may be identified:

- *Surfaces at rest* (Fig. 28.23a): Even with no externally applied load, solvent–surface epitaxial interactions can cause the liquid molecules in the film to attain a solid-like state. Thus at rest the surfaces are stuck to each other through the film.
- *Sticking regime (frozen, solid-like film)* (Fig. 28.23b): A progressively increasing lateral shear stress is applied. The solid-like film responds elastically with a small lateral displace-

ment and a small increase or dilatancy in film thickness (of less than a lattice spacing or molecular dimension σ). In this regime the film retains its frozen, solid-like state: all the strains are elastic and reversible, and the surfaces remain effectively stuck to each other. However, slow creep may occur over long time periods.

- *Slipping and sliding regimes (molten, liquid-like film)* (Fig. 28.23c–c″): When the applied shear stress or force has reached a certain critical value, the static friction force F_s, the film suddenly melts (known as shear melting) or rearranges to allow for wall slip or slip within the film to occur at which point the two surfaces begin to slip rapidly past each other. If the applied stress is kept at a high value, the upper surface will continue to slide indefinitely.
- *Refreezing regime (resolidification of film)* (Fig. 28.23d): In many practical cases, the rapid slip of the upper surface relieves some of the applied force, which eventually falls below another critical value, the kinetic friction force F_k, at which point the film resolidifies and the whole stick–slip cycle is repeated. On the other hand, if the slip rate is smaller than the rate at which the external stress is applied, the surfaces will continue to slide smoothly in the kinetic state and there will be no more stick–slip.

Experiments on the friction of two molecularly smooth mica surfaces separated by three molecular layers of the liquid octamethylcyclotetrasiloxane (OMCTS, Fig. 28.24) show how the friction increases to higher values in a quantized way when the number of layers falls from $n = 3$ to $n = 2$ and then to $n = 1$. Computer simulations for simple spherical molecules [28.128] further indicate that during slip the film thickness is roughly 15% higher than at rest (i. e., the film density falls), and that the order parameter within the film drops from 0.85 to about 0.25. Such dilatancy has been investigated both experimentally [28.158] and in further computer simulations [28.190]. The changes in thickness and in the order parameter are consistent with a disorganized state for the whole film during the slip [28.188], as illustrated schematically in Fig. 28.23c. At this stage, we can only speculate on other possible configurations of molecules in the slipping and sliding regimes. This probably depends on the shapes of the molecules (e.g., whether they are spherical or linear or branched), on the atomic structure of the surfaces, on the sliding velocity, etc. [28.193]. Figure 28.23c–c″ shows three possible sliding modes wherein the shearing film either totally melts, or where the molecules retain their layered structure and where slip occurs between two or more layers.

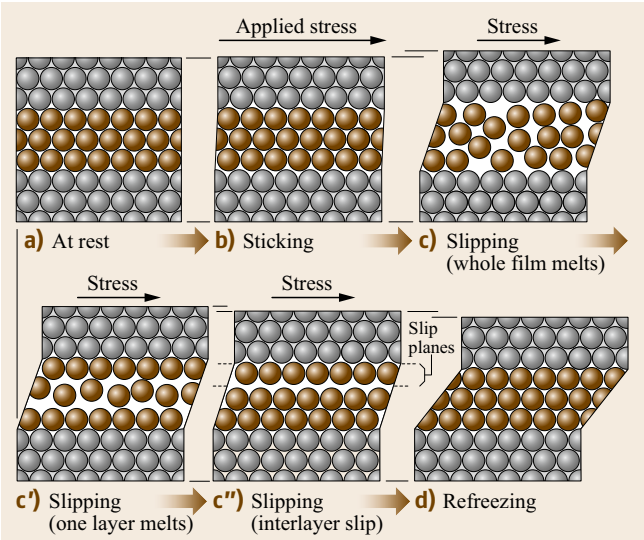

Fig. 28.23a–d Idealized schematic illustration of molecular rearrangements occurring in a molecularly thin film of spherical or simple chain molecules between two solid surfaces during shear. **(a)** At rest, and **(b)** when sticking. Depending on the system, a number of different molecular configurations within the film are possible during slipping and sliding, shown here as stages **(c)** – total disorder as the whole film melts; **(c′)** – partial disorder; and **(c″)** – order persists even during sliding with slip occurring at a single slip plane either within the film or at the walls. A dilation is predicted in the direction normal to the surfaces. **(d)** Refreezing (after [28.142], with permission)

Other sliding modes, for example involving the movement of dislocations or disclinations, are also possible, and it is unlikely that one single mechanism applies in all cases.

Both friction and adhesion hysteresis vary nonlinearly with temperature, often peaking at some particular temperature T_0. The temperature dependence of these forces can, therefore, be represented on a friction phase diagram such as the one shown in Fig. 28.25. Experiments have shown that T_0, and the whole bell-shaped curve, are shifted along the temperature axis (as well as in the vertical direction) in a systematic way when the load, sliding velocity, etc., are varied. These shifts also appear to be highly correlated with one another.

Such effects are also commonly observed in other energy-dissipating phenomena such as polymer viscoelasticity [28.194]. A possible molecular process underlying the energy dissipation of chain molecules during boundary-layer sliding is illustrated in Fig. 28.26, which shows the three main dynamic phase states of boundary monolayers.

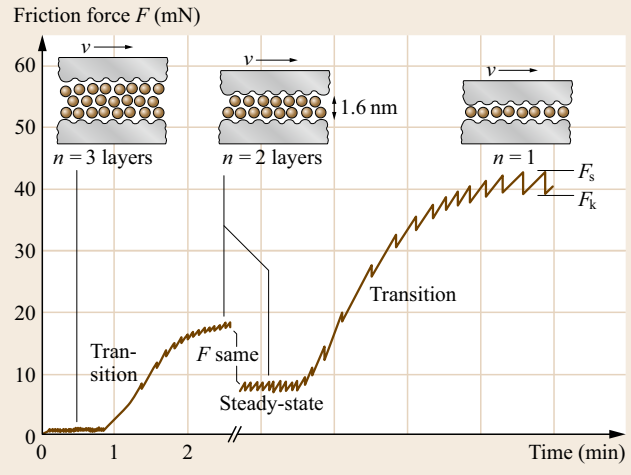

Fig. 28.24 Measured change in friction during interlayer transitions of the silicone liquid OMCTS, an inert liquid whose quasispherical molecules have a diameter of 0.8 nm. In this system, the shear stress $S_c = F/A$ was found to be constant as long as the number of layers, n, remained constant. Qualitatively similar results have been obtained with other quasispherical molecules such as cyclohexane (after [28.187]). The shear stresses are only weakly dependent on the sliding velocity v. However, for sliding velocities above some critical value, v_c, the stick–slip disappears and sliding proceeds smoothly at the kinetic value (after [28.141], with permission)

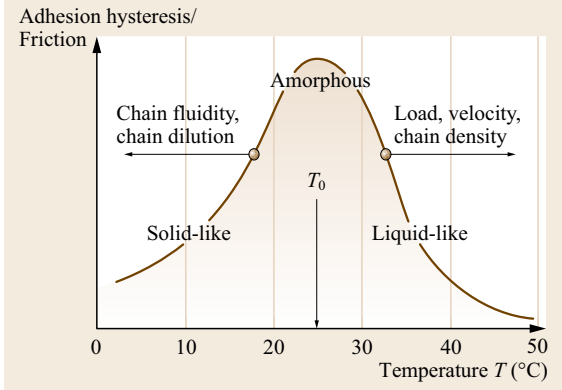

Fig. 28.25 Schematic friction phase diagram representing the trends observed in the boundary friction of a variety of different surfactant monolayers. The characteristic *bell-shaped curve* also correlates with the adhesion energy hysteresis of the monolayers. The *arrows* indicate the direction in which the whole curve is dragged when the load, velocity, etc. is increased (after [28.155], with permission)

Abrupt versus Continuous Transitions Between Smooth and Stick–Slip Sliding

An understanding of stick–slip is of great practical importance in tribology [28.195], since these spikes are the major cause of damage and wear of moving parts. stick–slip motion is a very common phenomenon and is also the cause of sound generation (the sound of a violin string, a squeaking door, or the chatter of machinery), sensory perception (taste texture and feel), earthquakes, granular flow, nonuniform fluid flow such as the spurting flow of polymeric liquids, etc. In the previous section, the stick–slip motion arising from freezing-melting transitions in thin interfacial films was described. There are other mechanisms that can give rise to stick–slip friction, which will now be considered.

Rough Surfaces or Surface Topology Model

Rapid slips can occur whenever an asperity on one surface goes over the top of an asperity on the other surface. The extent of the slip will depend on asperity heights and slopes, on the speed of sliding, and on the elastic compliance of the surfaces and the moving stage. As in all cases of stick–slip motion, the driving velocity v may be constant, but the resulting motion at the surfaces v_0 will display large slips. This type of stick–slip [28.195] will not be of much concern here since it is essentially a noise-type fluctuation, resulting from surface imperfections rather than from the intrinsic interaction between two surfaces.

Distance-Dependent or Creep Model

Another theory of stick–slip, observed in solid-on-solid sliding, is one that involves a characteristic distance, but also a characteristic time τ_s, this being the characteristic time required for two asperities to increase their adhesion strength after coming into contact. Originally proposed by *Rabinowicz* [28.195, 196], this model suggests that two rough macroscopic surfaces adhere through their microscopic asperities of a characteristic length. During shearing, each surface must first creep this distance (the size of the contacting junctions) after which the surfaces continue to slide, but with a lower (kinetic) friction force than the original (static) value. The reason for the decrease in the friction force is that even though, on average, new asperity junctions should form as rapidly as the old ones break, the time-dependent adhesion and friction of the new ones will be lower than the old ones.

The friction force, therefore, remains high during the creep stage of the slip. However, once the surfaces have moved the characteristic distance, the friction rapidly drops to the kinetic value. Any system where the kinetic friction is less than the static force (or one that has a negative slope over some part of its curve of F_0 versus v_0) will exhibit regular stick–slip sliding motion for certain values of K, m, and driving velocity v.

This type of friction has been observed in a variety of dry (unlubricated) systems such as paper-on-paper [28.197] and steel-on-steel [28.196, 198]. This model is also used extensively in geologic systems to analyze rock-on-rock sliding [28.199]. While originally described for adhering macroscopic asperity junctions, the distance-dependent model may also apply to molecularly smooth surfaces. For example, for polymer lubricant films, the characteristic length would now be the chain-chain entanglement length, which could be much larger in a confined geometry than in the bulk.

Velocity-Dependent Friction Model

In contrast to the two friction models mentioned above, which apply mainly to unlubricated, solid-on-solid contacts, the stick–slip of surfaces with thin liquid films between them is better described by other mechanisms. The velocity-dependent friction model is the most studied mechanism of stick–slip and, until recently, was considered to be the only cause of intrinsic stick–slip. If a friction force decreases with increasing sliding velocity, as occurs with boundary films exhibiting shear thinning, the force (F_s) needed to initiate motion will be higher than the force (F_k) needed to maintain motion.

A decreasing intrinsic friction force F_0 with sliding velocity v_0 results in the sliding surface or stage moving in a periodic fashion, where during each cycle rapid acceleration is followed by rapid deceleration. As long as the drive continues to move at a fixed velocity v, the surfaces will continue to move in a periodic fashion punctuated by abrupt stops and starts whose frequency and amplitude depend not only on the function $F_0(v_0)$, but also on the stiffness K and mass m of the moving stage, and on the starting conditions at $t = 0$.

More precisely, the motion of the sliding surface or stage can be determined by solving the differential equation

$$m\ddot{x} = (F_0 - F) = F_0 - (x_0 - x)K$$
$$\text{or} \quad m\ddot{x} + (x_0 - x)K - F_0 = 0\,, \tag{28.45}$$

where $F_0 = F_0(x_0,\ v_0,\ t)$ is the intrinsic or real friction force at the shearing surfaces, F is the force on the spring (the externally applied or measured force), and $(F_0 - F)$ is the force on the stage. To solve (28.45) fully, one must also know the initial (starting) conditions at $t = 0$, and the driving or steady-state conditions at finite t. Commonly, the driving condition is $x = 0$ for $t < 0$ and $x = vt$ for $t > 0$, where $v =$ constant. In other systems, the appropriate driving condition may be $F =$ constant.

Various, mainly phenomenological, forms for $F_0 = F_0(x_0, v_0, t)$ have been proposed to explain various kinds of stick–slip phenomena. These models generally assume a particular functional form for the friction as a function of velocity only, $F_0 = F_0(v_0)$, and they may also contain a number of mechanically coupled elements comprising the stage [28.200, 201]. One version is a two-state model characterized by two friction forces, F_s and F_k, which is a simplified version of the phase transitions model described below. More complicated versions can have a rich F–v spectrum [28.202]. Unless the experimental data are very detailed and extensive, these models cannot generally distinguish between different types of mechanisms. Neither do they address the basic question of the origin of the friction force, since this is assumed to begin with.

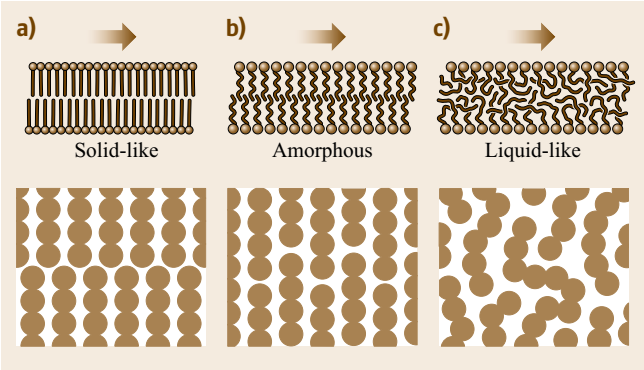

Fig. 28.26a–c Different dynamic phase states of boundary monolayers during adhesive contact and/or frictional sliding. Solid-like **(a)**, amorphous **(b)** and liquid-like monolayers **(c)** exhibit low adhesion hysteresis and friction. Increasing the temperature generally shifts a system from the left to the right. Changing the load, sliding velocity, or other experimental conditions can also change the dynamic phase state of surface layers, as shown in Fig. 28.25 (after [28.26, 155], with permission)

Experimental data has been used to calculate the friction force as a function of velocity within an individual stick–slip cycle [28.203]. For a macroscopic granular material confined between solid surfaces, the data show a velocity-weakening friction force during the first half of the slip. However, the data also show a hysteresis loop in the friction-velocity plot, with a different behavior in the deceleration half of the slip phase. Similar results were observed for a 1–2 nm liquid lubricant film between mica surfaces [28.193]. These results indicate that a purely velocity-dependent friction law is insufficient to describe such systems, and an additional element such as the state of the confined material must be considered.

Phase Transitions Model

In molecular dynamics computer simulations it has been found that thin interfacial films undergo first-

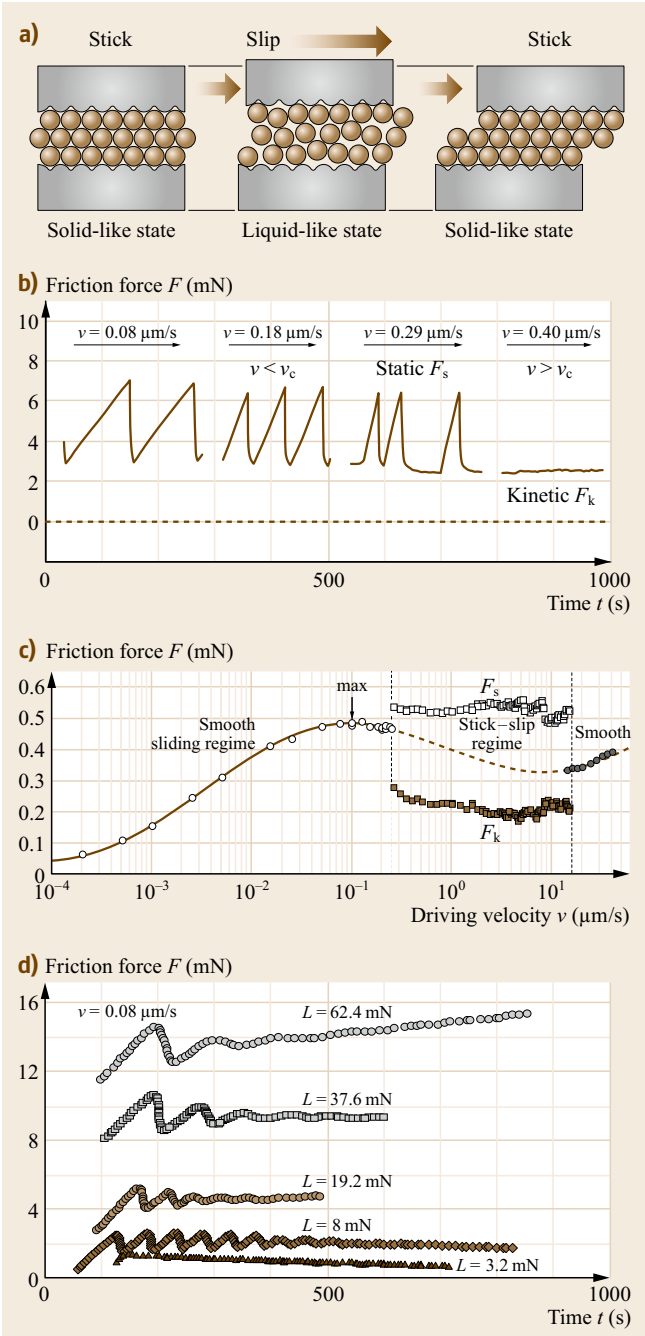

Fig. 28.27 **(a)** *Phase transitions* model of stick–slip where a thin liquid film alternately freezes and melts as it shears, shown here for 22 spherical molecules confined between two solid crystalline surfaces. In contrast to the velocity-dependent friction model, the intrinsic friction force is assumed to change abruptly (at the transitions), rather than smoothly or continuously. The resulting stick–slip is also different, for example the peaks are sharper and the stick–slip disappears above some critical velocity v_c. Note that while the slip displacement is here shown to be only two lattice spacings, in most practical situations it is much larger, and that freezing and melting transitions at surfaces or in thin films may not be the same as freezing or melting transitions between the bulk solid and liquid phases. **(b)** Exact reproduction of a chart-recorder trace of the friction force for hexadecane between two untreated mica surfaces at increasing sliding velocity v, plotted as a function of time. In general, with increasing sliding speed, the stick–slip spikes increase in frequency and decrease in magnitude. As the critical sliding velocity v_c is approached, the spikes become erratic, eventually disappearing altogether at $v = v_c$. At higher sliding velocities the sliding continues smoothly in the kinetic state. Such friction traces are fairly typical for simple liquid lubricants and dry boundary lubricant systems (Fig. 28.28a) and may be referred to as the *conventional* type of static-kinetic friction (in contrast to panel **(c)**). Experimental conditions: contact area $A = 4\times10^{-9}$ m^2, load $L = 10$ mN, film thickness $D = 0.4$–0.8 nm, $v = 0.08$–$0.4\,\mu\mathrm{m\,s^{-1}}$, $v_c \approx 0.3\,\mu\mathrm{m\,s^{-1}}$, atmosphere = dry N_2 gas, $T = 18\,^\circ$C. (**(a,b)** after [28.204] with permission, American Chemical Society). **(c)** Transition from smooth sliding to *inverted* stick–slip and to a second smooth-sliding regime with increasing driving velocity during shear of two adsorbed surfactant monolayers in aqueous solution at a load of $L = 4.5$ mN and $T = 20\,^\circ$C. The smooth sliding (*open circles*) to inverted stick–slip (*squares*) transition occurs at $v_c \approx 0.3\,\mu$m/s. Prior to the transition, the kinetic stress levels off after a logarithmic dependence on velocity. The quasismooth regime persists up to the transition at v_c. At high driving velocities (*filled circles*), a new transition to a smooth sliding regime is observed between 14 and 17 μm/s (after [28.191] with permission). **(d)** Friction response of a thin squalane (a branched hydrocarbon) film at different loads and a constant sliding velocity $v = 0.08\,\mu\mathrm{m\,s^{-1}}$, slightly above the critical velocity for this system at low loads. Initially, with increasing load, the stick–slip amplitude and the mean friction force decrease with sliding time or sliding distance. However, at high loads or pressures, the mean friction force increases with time, and the stick–slip takes on a more symmetrical, sinusoidal shape. At all loads investigated, the stick–slip component gradually decayed as the friction proceeded towards smooth sliding (after [28.149] with permission, American Physical Society) ◀

order phase transitions between solid-like and liquid-like states during sliding [28.128, 205], as illustrated in Fig. 28.27. It has been suggested that this is responsible for the observed stick–slip behavior of simple isotropic liquids between two solid crystalline surfaces. With this interpretation, stick–slip is seen to arise because of the abrupt change in the flow properties of a film at a transition [28.142, 143, 183], rather than the gradual or continuous change, as occurs in the previous example. Other computer simulations indicate that it is the stick–slip that induces a disorder (*shear melting*) in the film, not the other way around [28.206].

An interpretation of the well-known phenomenon of decreasing coefficient of friction with increasing sliding velocity has been proposed based on computer simulation [28.128]. This postulates that it is not the friction that changes with sliding speed v, but rather the time various parts of the system spend in the sticking and sliding modes. In other words, at any instant during sliding, the friction at any local region is always F_s or F_k, corresponding to the static or kinetic values. The measured frictional force, however, is the sum of all these discrete values averaged over the whole contact area. Since as v increases each local region spends more time in the sliding regime (F_k) and less in the sticking regime (F_s), the overall friction coefficient falls. One may note that this interpretation reverses the traditional way that stick–slip has been explained. Rather than invoking a decreasing friction with velocity to explain stick–slip, it is now the more fundamental stick–slip phenomenon that is producing the apparent decrease in the friction force with increasing sliding velocity. This approach has been studied analytically [28.207], with a comprehensive rate- and state-dependent friction force law. This model includes an analytic description of the freezing-melting transitions of a film, resulting in a friction force that is a function of sliding velocity in a natural way. This model predicts a full range of stick–slip behavior observed experimentally.

An example of the rate- and state-dependent model is observed when shearing thin films of OMCTS between mica surfaces [28.208, 209]. In this case, the static friction between the surfaces is dependent on the time that the surfaces are at rest with respect to each other, while the intrinsic kinetic friction $F_{k,0}$ is relatively constant over the range of velocities. At slow driving velocities, the system responds with stick–slip sliding with the surfaces reaching maximum static friction before each slip event, and the amplitude of the stick–slip, $F_s - F_k$, is relatively constant. As the driving velocity increases, the static friction decreases as the time at relative rest becomes shorter with respect to the characteristic time of the lubricant film. As the static friction decreases with increasing drive velocity, it eventually equals the intrinsic kinetic friction $F_{k,0}$, which defines the critical velocity v_c, above which the surfaces slide smoothly without the jerky stick–slip motion.

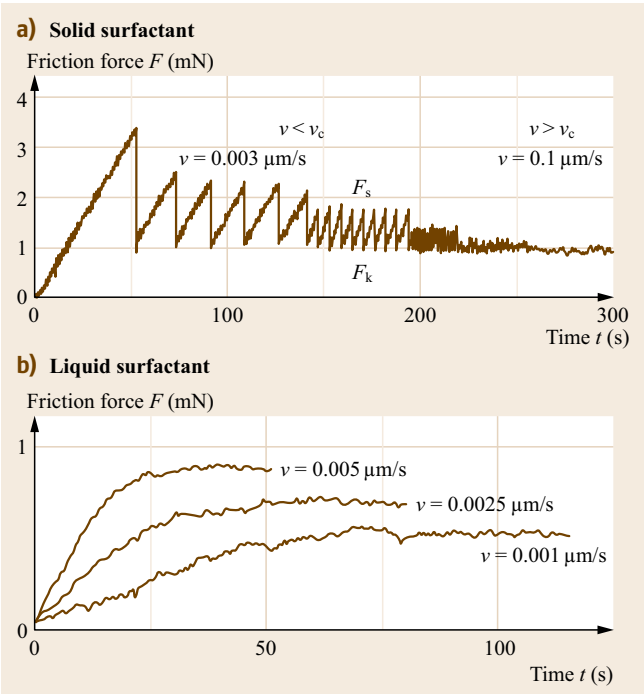

Fig. 28.28 **(a)** Exact reproduction of chart-recorder trace for the friction of closely packed surfactant monolayers (l-α-dimirystoylphosphatidyl-ethanolamine, DMPE) on mica (dry boundary friction) showing qualitatively similar behavior to that obtained with a liquid hexadecane film (Fig. 28.27b). In this case, $L = 0$, $v_c \approx 0.1\,\mu m\,s^{-1}$, atmosphere = dry N_2 gas, $T = 25\,°C$. **(b)** Sliding typical of liquid-like monolayers, here shown for calcium alkylbenzene sulfonate in dry N_2 gas at $T = 25\,°C$ and $L = 0$ (after [28.133], with permission, American Chemical Society)

The above classifications of stick–slip are not exclusive, and molecular mechanisms of real systems may exhibit aspects of different models simultaneously. They do, however, provide a convenient classification of existing models and indicate which experimental parameters should be varied to test the different models.

Critical Velocity for Stick–Slip

For any given set of conditions, stick–slip disappears above some critical sliding velocity v_c (Fig. 28.28), above which the motion continues smoothly in the liquid-like or kinetic state [28.133, 149, 191, 193, 204]. The critical velocity is well described by two simple equations. Both are based on the phase transition model, and both include some parameter associated with the inertia of the measuring instrument. The first equation is

based on both experiments and simple theoretical modeling [28.204]

$$v_c = \frac{(F_s - F_k)}{5k\tau_0} , \qquad (28.46)$$

where τ_0 is the characteristic nucleation time or freezing time of the film. For example, inserting the following typically measured values for $a \approx 1$ nm thick hexadecane film between mica $(F_s - F_k) \approx 5$ mN, spring constant $k \approx 500\,\mathrm{N\,m^{-1}}$, and nucleation time [28.204] $\tau_0 \approx 5$ s, we obtain $v_c \approx 0.4\,\mu\mathrm{m\,s^{-1}}$, which is close to typically measured values (Fig. 28.27b).

The second equation is based on computer simulations [28.205]

$$v_c \approx 0.1\sqrt{\frac{F_s\sigma}{m}} , \qquad (28.47)$$

where σ is a molecular dimension and m is the mass of the stage. Again, inserting typical experimental values into this equation, that is, $m \approx 20$ g, $\sigma \approx 0.5$ nm, and $(F_s - F_k) \approx 5$ mN as before, we obtain $v_c \approx 0.3\,\mu\mathrm{m\,s^{-1}}$, which is also close to measured values.

Stick–slip also disappears above some critical temperature T_c, which is not the same as the melting temperature of the bulk fluid [28.149]. Certain correlations have been found between v_c and T_c and between various other tribological parameters that appear to be consistent with the principle of time-temperature superposition (Sect. 28.8.3), similar to that occurring in viscoelastic polymer fluids [28.194, 210, 211].

Work on the coupling between the mechanical resonances of the sliding system and molecular-scale relaxations [28.189, 190] has resulted in a better understanding of a phenomenon previously noted in various engineering applications: the vibration of one of the sliding surfaces perpendicularly to the sliding direction can lead to a significant reduction of the friction. At certain oscillation amplitudes and a frequency higher than the molecular-scale relaxation frequency, stick–slip friction can be eliminated and replaced by an ultralow kinetic-friction state.

28.9 Effects of Nanoscale Texture on Friction

The above scenario is already quite complicated, and yet this is the situation for the simplest type of experimental system. The factors that appear to determine the critical velocity v_c depend on the type of liquid between the surfaces, as well as on the surface lattice structure.

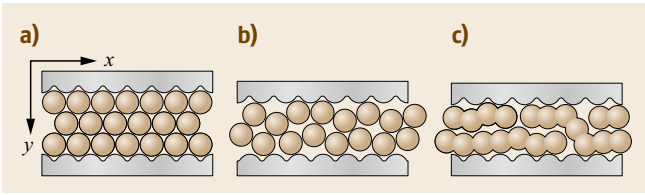

Fig. 28.29a–c Schematic view of an interfacial film composed of spherical molecules under a compressive pressure between two solid crystalline surfaces. **(a)** If the two surface lattices are free to move in the x–y–z directions, so as to attain the lowest energy state, they could equilibrate at values of x, y, and z, which induce the trapped molecules to become *epitaxially* ordered into a *solid-like* film. **(b)** Similar view of trapped molecules between two solid surfaces that are not free to adjust their positions, for example as occurs in capillary pores or in brittle cracks. **(c)** Similar to **(a)**, but with chain molecules replacing the spherical molecules in the gap. These may not be able to order as easily as do spherical molecules even if x, y, and z can adjust, resulting in a situation that is more akin to **(b)** (after [28.204] with permission, American Chemical Society)

28.9.1 Role of the Shape of Confined Molecules

Small spherical molecules such as cyclohexane and OMCTS have been found to have very high v_c, which indicates that these molecules can rearrange relatively quickly in thin films. Chain molecules and especially branched-chain molecules have been found to have much lower v_c, which is to be expected, and such liquids tend to slide smoothly or with erratic stick–slip [28.193], rather than in a stick–slip fashion (Table 28.5). With highly asymmetric molecules, such as multiply branched isoparaffins and polymer melts, no regular spikes or stick–slip behavior occurs at any speed, since these molecules can never order themselves sufficiently to solidify. Examples of such liquids are some perfluoropolyethers and PDMS.

Computer simulations [28.55, 57, 151] of the structure, interaction forces, and tribological behavior of chain molecules between two shearing surfaces indicate that both linear and singly or doubly branched-chain molecules order between two flat surfaces by aligning into discrete layers parallel to the surfaces. However, in the case of the weakly branched molecules, the expected oscillatory forces do not appear because of a complex cancellation of entropic and enthalpic contributions to the interaction free energy, which results in

a monotonically smooth interaction, exhibiting a weak energy minimum rather than the oscillatory force profile that is characteristic of linear molecules. During sliding, however, these molecules can be induced to further align, which can result in a transition from smooth to stick–slip sliding.

Table 28.5 shows the trends observed with some organic and polymeric liquids between smooth mica surfaces. Also listed are the bulk viscosities of the liquids. From the data of Table 28.5 it appears that there is a direct correlation between the shapes of molecules and their coefficients of friction or effectiveness as lubricants (at least at low shear rates). Small spherical or chain molecules have high friction with stick–slip because they can pack into ordered solid-like layers. In contrast, longer chained and irregularly shaped molecules remain in an entangled, disordered, fluid-like state even in very thin films, and these give low friction and smoother sliding. It is probably for this reason that irregularly shaped branched chain molecules are usually better lubricants. It is interesting to note that the friction coefficient generally decreases as the bulk viscosity of the liquids increases. This unexpected trend occurs because the factors that are conducive to low friction are generally conducive to high viscosity. Thus molecules with side groups such as branched alkanes and polymer melts usually have higher bulk viscosities than their linear homologues for obvious reasons. However, in thin films the linear molecules have higher shear stresses, because of their ability to become ordered. The only exception to the above correlations is water, which has been found to exhibit both low viscosity and low friction (Fig. 28.18a, and Sect. 28.7.3). In addition, the presence of water can drastically lower the friction and eliminate the stick–slip of hydrocarbon liquids when the sliding surfaces are hydrophilic.

If an *effective* viscosity, η_{eff}, were to be calculated for the liquids of Table 28.5, the values would be many orders of magnitude higher than those of the bulk liquids. This can be demonstrated by the following simple calculation based on the usual equation for Couette flow (28.42)

$$\eta_{\text{eff}} = \frac{F_{\text{k}} D}{A v} , \qquad (28.48)$$

where F_{k} is the kinetic friction force, D is the film thickness, A the contact area, and v the sliding velocity. Using typical values for experiments with hexadecane [28.204] – $F_{\text{k}} = 5\,\text{mN}$, $D = 1\,\text{nm}$, $A = 3 \times 10^{-9}\,\text{m}^2$, and $v = 1\,\mu\text{m}\,\text{s}^{-1}$ – one gets $\eta_{\text{eff}} \approx 2000\,\text{N}\,\text{s}\,\text{m}^{-2}$, or 20 000 P, which is ≈ 106 times higher than the bulk viscosity, η_{bulk}, of the liquid. It is instructive to consider that this very high effective viscosity nevertheless still produces a low friction force or friction coefficient μ of about 0.25. It is interesting to speculate that, if a 1 nm film were to exhibit bulk viscous behavior, the friction coefficient under the same sliding conditions would be as low as 0.000 001. While such a low value has never been reported for any tribological system, one may consider it a theoretical lower limit that could conceivably be attained under certain experimental conditions.

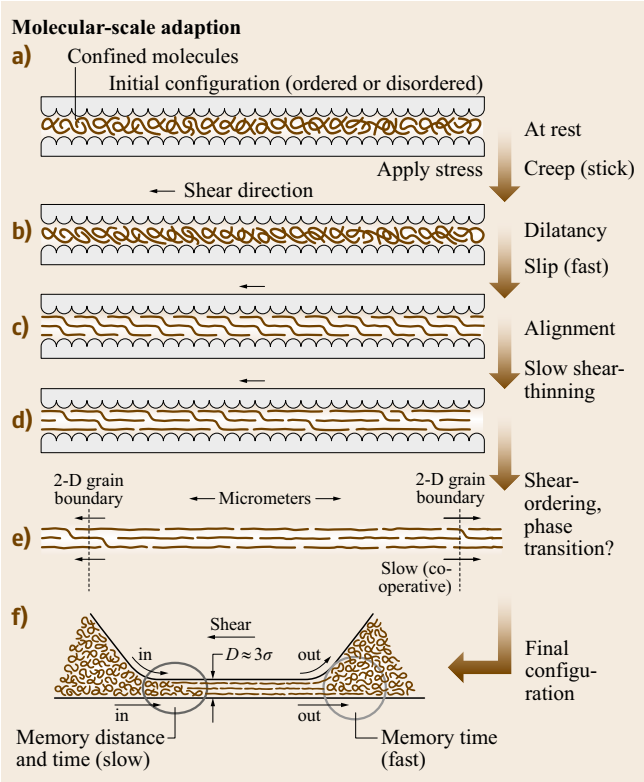

Fig. 28.30a–f Schematic representation of the film under shear. **(a)** The lubricant molecules are just confined, but not oriented in any particular direction. Because of the need to shear, the film dilates **(b)**. The molecules disentangle **(c)** and get oriented in a certain direction related to the shear direction **(d)**. **(e)** Slowly evolving domains grow inside the contact region. These macroscopic domains are responsible for the long relaxation times. **(f)** At the steady state, a continuous gradient of confinement time and molecular order is established in the contact region, which is different for molecules adsorbed on the upper and lower surfaces. Molecules entering into the contact are not oriented or ordered. The required sliding distance to modify their state defines a characteristic distance. Molecules leaving the contact region need some (short) characteristic time to regain their bulk, unconfined configuration (after [28.212], with permission, American Chemical Society)

28.9.2 Effects of Surface Structure

Various studies [28.33, 139, 140, 148–150] have shown that confinement and load generally increase the effective viscosity and/or relaxation times of molecules, suggestive of an increased glassiness or solid-like behavior (Figs. 28.29 and 28.30). This is in marked contrast to studies of liquids in small confining capillaries where the opposite effects have been observed [28.213, 214]. The reason for this is probably because the two modes of confinement are different. In the former case (confinement of molecules between two structured solid surfaces), there is generally little opposition to any lateral or vertical displacement of the two surface lattices relative to each other. This means that the two lattices can shift in the $x-y-z$ planes (Fig. 28.29a) to accommodate the trapped molecules in the most crystallographically commensurate or epitaxial way, which would favor an ordered, solid-like state. In contrast, the walls of capillaries are rigid and cannot easily move or adjust to accommodate the confined molecules (Fig. 28.29b), which will therefore be forced into a more disordered, liquid-like state (unless the capillary wall geometry and lattice are exactly commensurate with the liquid molecules, as occurs in certain zeolites [28.214]).

Experiments have demonstrated the effects of surface lattice mismatch on the friction between surfaces [28.129, 130, 215]. Similar to the effects of lattice mismatch on adhesion (Fig. 28.10), the static friction of a confined liquid film is maximum when the lattices of the confining surfaces are aligned. For OMCTS confined between mica surfaces [28.130] the static friction was found to vary by more than a factor of four, while for bare mica surfaces the variation was by a factor of 3.5 [28.215]. In contrast to the sharp variations in adhesion energy over small twist angles, the variations in friction as a function of twist angle were much broader both in magnitude and angular spread. Similar variations in friction as a function of twist or misfit angles have also been observed in computer simulations [28.216].

Robbins et al. [28.217] computed the friction forces of two clean crystalline surfaces as a function of the angle between their surface lattices. They found that, for all nonzero angles (finite twist angles), the friction forces fell to zero due to incommensurability effects. They further found that submonolayer amounts of organic or other impurities trapped between two incommensurate surfaces can generate a finite friction force. They therefore concluded that any finite friction force measured between incommensurate surfaces is probably due to such *third-body* effects.

The reason why surface texture (lattice structure, roughness, granularity, topography, etc.) has a larger effect on the lateral (shear or friction) forces between two surfaces than on their normal (adhesion) forces is because friction is proportional to the adhesion hysteresis (Sect. 28.7.2), which can be low even when the adhesion force is high. It is also important to recognize that a system might be defined by more than one length scale. Some systems have well-defined dimensions or size (e.g., a perfect lattice, monodisperse nanoparticles), while others have different lateral and vertical dimensions and macroscopic curvature [28.122]. Furthermore, the morphology or texture of many systems, such as asperities that are randomly distributed over a surface, affects adhesion and tribological properties [28.118, 122, 151, 218, 219].

With rough surfaces, i. e., those that have *random* protrusions rather than being periodically structured, we expect a smearing out of the correlated intermolecular interactions that are involved in film freezing and melting (and in phase transitions in general). This should effectively eliminate the highly regular stick–slip and may also affect the location of the slipping planes [28.57, 151, 175]. The stick–slip friction of real surfaces, which are generally rough, may therefore be quite different from those of perfectly smooth surfaces composed of the same material. We should note, however, that even between rough surfaces, most of the contacts occur between the tips of microscopic asperities, which may be smooth over their microscopic contact area [28.220].

29. Atomic Scale Friction Phenomena

Enrico Gnecco, Rémy Pawlak, Marcin Kisiel, Thilo Glatzel, Ernst Meyer

Friction has long been the subject of research: the empirical da Vinci–Amontons friction laws have been common knowledge for centuries. Macroscopic experiments performed by the school of *Bowden* and *Tabor* revealed that macroscopic friction can be related to the collective action of small asperities. Over the last 25 years, experiments performed with the atomic force microscope have provided new insights into the physics of single asperities sliding over surfaces. This development, together with the results from complementary experiments using surface force apparatus and the quartz microbalance, have led to the new field of *nanotribology*. At the same time, increasing computing power has permitted the simulation of processes that occur during sliding contact involving several hundreds of atoms. It has become clear that atomic processes cannot be neglected when interpreting nanotribology experiments. Even on well-defined surfaces, experiments have revealed that atomic structure is directly linked to friction force. This chapter will describe friction force microscopy (FFM) experiments that reveal, more or less directly, atomic processes during sliding contact.

We will begin by introducing friction force microscopy, including the calibration of cantilever force sensors and special aspects of the ultrahigh vacuum environment. The empirical Prandtl–Tomlinson model often used to describe atomic stick–slip results is therefore presented in detail. We review experimental results regarding atomic friction, including thermal activation, velocity dependence, and temperature dependence. The geometry of the contact is crucial to the interpretation of experimental results, such as the calculation of the lateral contact stiffness. The onset of wear on the atomic scale has recently been studied experimentally and it is described here. The chapter ends with a discussion of recent experiments aimed at detecting the dissipative forces acting when a sharp tip is moved parallel and very close to a solid surface without being in contact with it, or when small entities such as single polymer chains, graphene nanoribbons, or large organic molecules are manipulated.

29.1 Friction Force Microscopy in Selected Environments

The *friction force microscope* (FFM, also called the *lateral force microscope*, LFM) is used to record the torsion deformation of an elastic cantilever driving a sharp tip on a solid surface and to investigate dissipative processes occurring in a sliding contact down to the atomic scale (Fig. 29.1). The relative motion of tip and surface is realized by a *scanner* made by piezoelectric elements, which moves the surface below the tip at a certain rate. The scanner can also be extended or retracted to vary the normal force F_N applied to the surface. This force is responsible for the deflection of the flexible cantilever supporting the tip. If the normal force F_N increases while scanning due to local topographic variations, the scanner is retracted by a feedback loop. Conversely, if F_N decreases, the surface is brought closer to the tip by extending the scanner. In this way, the surface topography can be determined line-by-line from the vertical displacement of the scanner. Accurate control of such movement is made possible by a light beam reflected from the rear of the lever into a photodetector. When the cantilever bends, the light spot on the detector moves up or down and causes the photocurrent to vary, when in turn triggers a corresponding change in the normal force F_N applied.

The relative sliding of tip and surface is usually also accompanied by *friction*. A lateral force F_L, which acts in the opposite direction to the scan velocity v hinders the motion of the tip. This force causes torsion in the cantilever, which can be observed along with the topography if the photodetector can detect not only the normal deflection but also the lateral movement of the lever while scanning. In practice this is achieved using four-quadrant photodetectors, as shown in Fig. 29.1. We should note that friction forces also cause lateral bending of the cantilever, but this effect is negligible if the thickness of the lever is much less than the width.

The FFM was first used by *Mate* et al. in 1987 to study the friction associated with atomic features [29.1]. In their experiment, Mate used a tungsten wire and a slightly different technique (nonfiber interferometry) to detect lateral forces. Optical beam deflection was introduced later by *Marti* et al. [29.2] and *Meyer* et al. [29.3]. Other methods of measuring the forces between tip and surface include capacitance detection [29.4], dual fiber interferometry [29.5], and piezolevers [29.6]. In the first method, two plates close to the cantilever reveal the capacitance while scanning. The second technique uses two optical fibers to detect the cantilever deflection along two orthogonal directions aligned 45° with respect to the surface normal. Finally, in the third method, cantilevers with two Wheatstone bridges at their bases reveal normal and lateral forces, which are respectively proportional to the sum and the difference of both bridge signals.

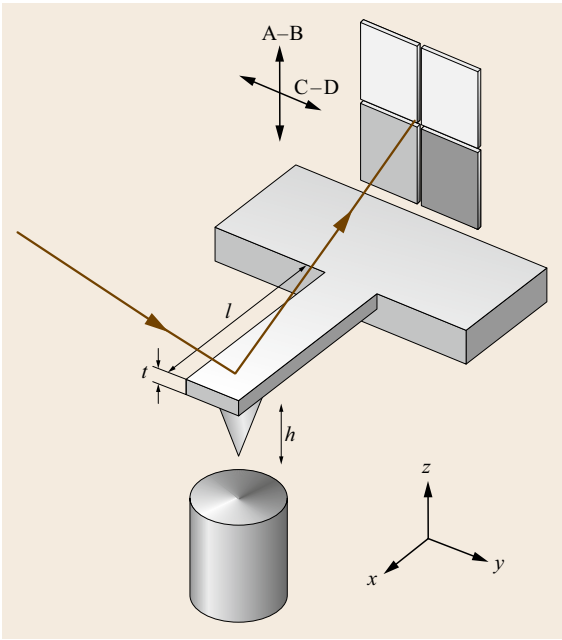

Fig. 29.1 Schematic diagram of a beam-deflection friction force microscope

29.1.1 Force Calibration

Force calibration is relatively simple if rectangular cantilevers are used. Because of possible discrepancies with the geometric values provided by manufacturers, one should use optical and electron microscopes to determine the width, thickness, and length of the cantilever (w, t, l), the tip height h, and the position of the tip with respect to the cantilever. The thickness of the cantilever can also be determined from the resonance frequency of the lever f_0 using the relation [29.7]

$$t = \frac{2\sqrt{12}\pi}{1.875^2}\sqrt{\frac{\rho}{E}}f_0 l^2 \,, \tag{29.1}$$

where ρ is the density of the cantilever and E is its Young's modulus. The normal spring constant (c_N) and the lateral spring constant (c_L) of the lever are given by

$$c_N = \frac{Ewt^3}{4l^3}, \quad c_L = \frac{Gwt^3}{3h^2 l} \,, \tag{29.2}$$

where G is the shear modulus. Figure 29.2 shows some SEM (scanning electron microscope) images of rectangular silicon cantilevers used for FFM. In the case of silicon $\rho = 2.33 \times 10^3\,\mathrm{kg/m^3}$, $E = 1.69 \times 10^{11}\,\mathrm{N/m^2}$, and

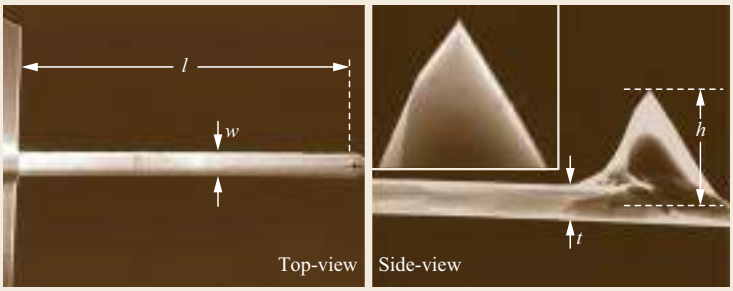

Fig. 29.2 SEM images of a rectangular cantilever. The relevant dimensions are $l = 445\,\mu\text{m}$, $w = 43\,\mu\text{m}$, $t = 4.5\,\mu\text{m}$, $h = 14.75\,\mu\text{m}$. Note that h is given by the sum of the tip height and half of the cantilever thickness

$G = 0.5 \times 10^{11}\,\text{N/m}^2$. Thus, for the cantilever shown in Fig. 29.2, $c_\text{N} = 1.9\,\text{N/m}$ and $c_\text{L} = 675\,\text{N/m}$.

The next step consists of measuring the sensitivity of the photodetector S_z (nm/V). For beam-deflection FFMs, the sensitivity S_z can be determined by force versus distance curves measured on hard surfaces (e.g., Al_2O_3), where elastic deformations are negligible and the vertical movement of the scanner equals the deflection of the cantilever. A typical dependence of the vertical signal recorded by the four-quadrant detector V_N in ambient conditions on the tip–surface distance is sketched in Fig. 29.3. When the tip is approached towards the surface, no signal is revealed until the tip jumps into contact at $z = z_1$. Further extension and successive retraction of the scanner result in elastic behavior until the tip jumps out of contact again at a distance $z_2 > z_1$ (when $V_\text{N} = V_\text{off}$). The slope of the elastic part of the curve gives the required sensitivity S_z.

The normal and lateral forces depend on the voltage V_N and the horizontal signals V_L as

$$F_\text{N} = c_\text{N} S_\text{z} V_\text{N}, \quad F_\text{L} = \frac{3}{2} c_\text{L} \frac{h}{l} S_\text{z} V_\text{L} \,. \tag{29.3}$$

It is assumed here that the light beam is positioned precisely above the probing tip, which may not always be the case in practice.

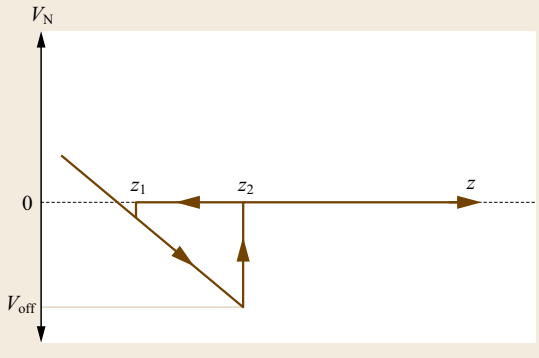

Fig. 29.3 Sketch of a typical force versus distance curve

The normal spring constant c_N can also be calibrated using other methods. *Cleveland* et al. [29.8] attached tungsten spheres to the tip, which changes the resonance frequency f_0 according to the formula

$$f_0 = \frac{1}{2\pi} \sqrt{\frac{c_\text{N}}{M + m^*}} \,. \tag{29.4}$$

M is the mass of the added object and m^* is an effective mass of the cantilever, which depends on its geometry. The spring constant can be extrapolated from the frequency shifts corresponding to the different masses attached. As an alternative, *Hutter* et al. observed that the spring constant c_N can be related to the area of the power spectrum of the thermal fluctuations of the cantilever P [29.9]. The correct relation is $c_\text{N} = 4k_\text{B}T/(3P)$, where $k_\text{B} \approx 1.38 \times 10^{-23}\,\text{J/K}$ is Boltzmann's constant and T is the temperature [29.10]. Cantilevers with different shapes require finite element analysis, although analytical formulas can be derived in a few cases. For V-shaped cantilevers, *Neumeister* et al. derived the following approximation for the lateral spring constant c_L [29.11]

$$c_\text{L} = \frac{Et^2}{3(1+\upsilon)h^2} \times \left(\frac{1}{\tan\alpha} \ln \frac{w}{d \sin\alpha} + \frac{L\cos\alpha}{w} - \frac{3\sin 2\alpha}{8} \right)^{-1} . \tag{29.5}$$

The geometrical quantities L, w, α, d, t, and h are defined in Fig. 29.4. The expression for the normal constant is more complex and can be found in the cited reference.

Surfaces with well-defined profiles permit an alternative in situ calibration of lateral forces [29.12]. As an example, Fig. 29.5 shows a commercial grating formed by alternate faces with opposite inclinations with respect to the scan direction. When the tip slides on the inclined planes, the normal force F_N and the lateral force F_L with respect to the surface are different from the two components $F_\perp$ and $F_\parallel$, which are separated by the photodiode (Fig. 29.6a).

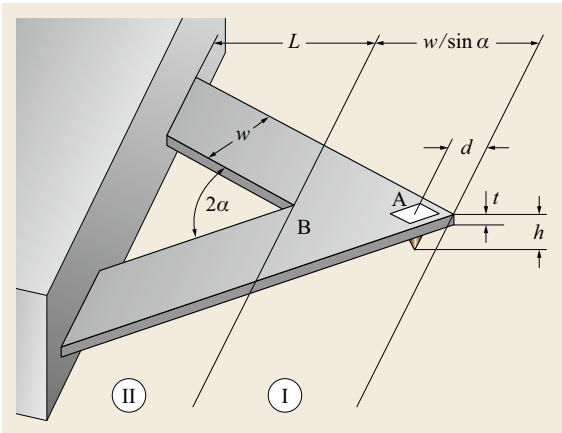

Fig. 29.4 Geometry of a V-shaped cantilever (after [29.11])

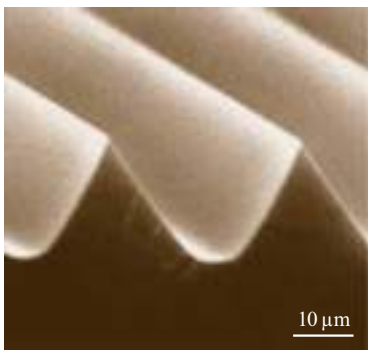

Fig. 29.5 Silicon grating formed by alternating faces angled at ±55° from the surface (Courtesy of Silicon-MDT Ltd., Moscow)

If Amontons' relation $F_L = \mu F_N$ holds, the component $F_\parallel$ can be expressed in terms of $F_\perp$

$$F_1 = \frac{\mu + \tan\theta}{1 - \mu\tan\theta} F_\perp \,. \tag{29.6}$$

The component $F_\perp$ is kept constant by the feedback loop. The sum of and the difference between the $F_\parallel$ values for the two planes (1) and (2) are given by

$$F_+ \equiv F_\parallel^{(1)} + Ff_\parallel^{(2)} = \frac{2\mu(1+\tan^2\theta)}{1-\mu^2\tan^2\theta} F_\perp \,,$$
$$F_- \equiv F_\parallel^{(1)} - F_\parallel^{(2)} = \frac{2(1+\mu^2)\tan\theta}{1-\mu^2\tan^2\theta} F_\perp \,. \tag{29.7}$$

The values of F_+ and F_- (in volts) can be measured by scanning the profile back and forth (Fig. 29.6b). If F_+ and F_- are recorded with different values of $F_\perp$, one can determine the conversion ratio between volts and nanonewtons as well as the coefficient of friction (COF) μ.

An accurate error analysis of lateral force calibration was provided by *Schwarz* et al., who discussed the importance of cantilever oscillations induced by the feedback loop and of geometrical positioning of the laser beam onto the cantilever [29.13]. Other sources of error (in-plane deformation and cantilever tilt) were discussed by *Sader* et al. [29.14, 15].

An adequate estimation of the radius of curvature of the tip R is also important. This quantity can be directly measured with a scanning electron microscope. If high-aspect structures such as step sites or whiskers are scanned, the resulting images are convolutions of those surfaces with the tip shape. A deconvolution algorithm that allows for the extraction of the probe tip's radius of curvature was proposed by *Villarrubia* [29.16].

29.1.2 Friction Force Microscopy in Ultra High Vacuum

Atomic friction studies require well-defined surfaces and – whenever possible – tips. For the surfaces, established methods of surface science performed in ultrahigh vacuum (UHV) can be employed. Ionic crystals such as NaCl have become standard materials for friction force microscopy on the atomic scale. Atomically clean and flat surfaces can be prepared by cleavage in UHV. The crystal has to be heated to $\approx 150\,^\circ$C for 1 h in order to remove charge after the cleavage process. Metal surfaces can be cleaned and flattened by cycles of sputtering with argon ions and annealing. Even surfaces prepared in air or liquids, such as self-assembled molecular monolayers, can be transferred into the vacuum and studied after careful heating procedures that remove water layers.

Tip preparation in UHV is more difficult. Most force sensors for friction studies have silicon nitride (Si_3N_4) or pure silicon tips. Tips can be cleaned and oxide layers removed by sputtering with argon ions. However, the sharpness of the tip is normally reduced by sputtering. As an alternative, tips can be etched in fluoric acid directly before transfer to the UHV. The significance of tip preparation is limited by the fact that the chemical and geometrical structure of the tip can undergo significant changes when sliding over the surface.

Using FFM in UHV conditions requires some additional effort. First of all, only materials with low vapor pressures can be used, which excludes most plastics and lubricants. Beam-deflection FFMs employ either a light source in the vacuum chamber or an optical fiber guiding the light into the chamber. The positioning of the light beam on the cantilever and the reflected beam on the position-sensitive detector is achieved by motorized mirrors or by moving the light source or detector. Furthermore, a motorized sample approach must be realized.

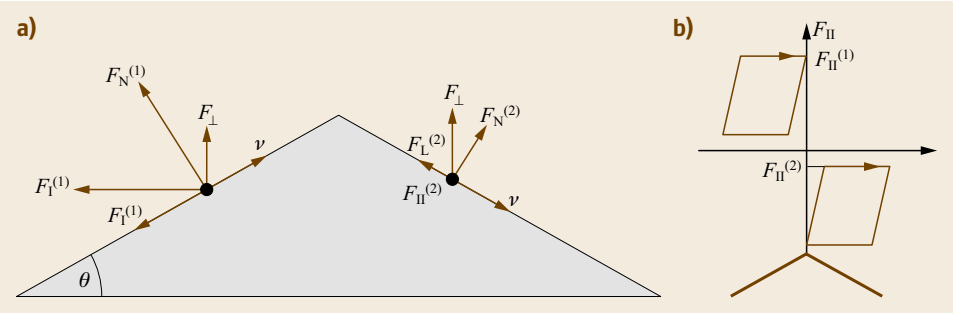

Fig. 29.6 **(a)** Forces acting on an FFM tip sliding on the grating shown in Fig. 29.5; **(b)** friction loops acquired on the two faces

The quality of the force sensor's electrical signal can seriously deteriorate when it is transferred out of the vacuum chamber. Low noise and high bandwidth can be preserved using a preamplifier in the vacuum. Again, the choice of materials for printing and devices is limited by the need for low vapor pressure. Stronger heating of the electrical circuitry in vacuum, therefore, may be needed.

A typical atomic force microscope (AFM) used in UHV is shown in Fig. 29.7. The housing (1) contains the light source and a set of lenses that focus the light onto the cantilever. Alternatively, the light can be guided via an optical fiber into the vacuum. By using light emitting diodes with low coherency it is possible to avoid interference effects often found in instruments that use a laser as the light source. A plane mirror fixed on the spherical rotor of a first stepping motor (2) can be rotated around vertical and horizontal axes in order to guide the light beam onto the rear of the cantilever, which is mounted on a removable carrier plate (3). The light is reflected off the cantilever toward a second motorized mirror (4) that guides the beam to the center of the quadrant photodiode (5), where the light is then converted into four photocurrents. Four preamplifiers in close vicinity to the photodiode allow low-noise measurements with a bandwidth of 3 MHz.

The two motors with spherical rotors, used to realign the light path after the cantilever has been exchanged, work as *inertial stepping motors*: the sphere rests on three piezoelectric legs that can be moved in small amounts tangentially to the sphere. Each step of the motor consists of the slow forward motion of two legs followed by an abrupt jump backwards. During the slow forward motion, the sphere follows the legs due to friction, whereas it cannot follow the sudden jump due to its inertia. A series of these tiny steps rotates the sphere macroscopically. The sample, which is also placed on an exchangeable carrier plate, is mounted at the end of a tube scanner (6), which can move the sample in three dimensions over several micrometers. The whole scanning head (7) is the slider of a third inertial stepping motor for coarse positioning of the

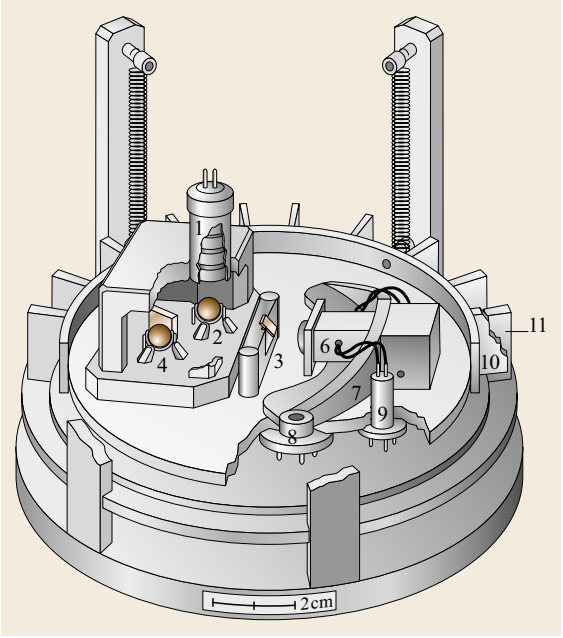

Fig. 29.7 Schematic view of the UHV-FFM realized at the University of Basel. *1*: light source, *2, 4*: mirrors, *3*: cantilever holders, *5*: photodetector, *6*: scanner, *7*: slider, *8*: driving piezo, *9*: fixed post, *10, 11*: eddy current damping (after [29.17])

sample. It rests with its flat and polished bottom on three supports. Two of them are symmetrically placed piezoelectric legs (8), whereas the third central support is passive. The slider (7) can be moved in two dimensions and rotated about a vertical axis by several millimeters (rotation is achieved by antiparallel operation of the two legs). The slider is held down by two magnets, close to the active supports, and its travel is limited by two fixed posts (9) that also serve as cable attachments. The whole platform is suspended by four springs. A ring of radial copper lamellae (10), floating between a ring of permanent magnets (11) on the base flange, acts to efficiently damp eddy currents.

29.1.3 Energy Dissipation in Noncontact Atomic Force Microscopy

Historically, the measurement of energy dissipation induced by tip–sample interaction has been the domain of FFM. In a typical stick–slip experiment, the energy dissipated in a single atomic slip event is of the order of 1 eV and the lateral resolution is limited by the contact area, which is usually formed by several atoms. These limitations can be overcome using noncontact (NC) AFM. In this case, the tip oscillates with constant amplitude A of typically 1−20 nm at the eigenfrequency f of the cantilever, which shifts by Δf due to interaction forces between tip and sample. In NC-AFM, power dissipation P_0 caused by internal friction of the freely oscillating cantilever is observed. This dissipation is proportional to the eigenfrequency f_0 and to the square of the amplitude A and is inversely proportional to the known Q value of the cantilever. When the tip–sample distance is reduced, the tip interacts with the sample and therefore additional damping of the oscillation is encountered. The extra dissipation P_{ts} caused by the tip–sample interaction can be calculated from the excitation signal A_{exc} [29.18]. The observed energy losses per oscillation cycle (in the order of 100 meV) [29.20] are comparable to the 1 eV energy loss in the contact slip process observing that in that a few atoms are involved in the contact. The origins of dissipation in NC-AFM are manifold: phonon excitation, Joule dissipation, and van der Waals friction, as schematized in Fig. 29.8.

A recent improvement in force measurements on the nanoscale using NC-AFM came from the introduction of q-plus sensors and vertically suspended ultrasensitive cantilevers as scanning probes (Fig. 29.9). Both configurations, namely *tuning fork AFM* and *pendulum AFM* hold two opposite positions in terms of force sensitivity and amplitude stability. The tuning fork AFM is in fact a combination of STM (scanning tunneling microscope) and AFM and is dedicated to performing high-resolution imaging. The measurements are typically conducted at a temperature $T = 5$ K and in UHV. STM characterizations are done in constant-current mode with a bias voltage applied to the tungsten tip whereas AFM is performed in noncontact mode using a phase lock loop (PLL). The spring constant k of the q-plus sensor is large, typically of about 2 kN/m. Although not extremely force sensitive the probe provides outstanding atomic-scale resolution due to small amplitudes of oscillation. Amplitude stability and high stiffness of the q-plus sensor also allow one to perform quantitative measurements of molecular friction. This possibility relies on the fact that the variation Δf of the natural contact resonance f_0 of the cantilever are related to the *normal* force F_N on the tip by

$$\frac{\Delta f}{f_0} = -\frac{1}{2k}\frac{dF_N}{dz} ,$$

(provided that the oscillation amplitude is small compared to the characteristic decay length of F_N) [29.21].

The pendulum UHV-AFM is a unique design dedicated to the measurement of extremely small forces. In this geometry the cantilever is hovering perpendicularly to the sample surface, shearing a nanometer vacuum gap between tip and sample. In this way, the

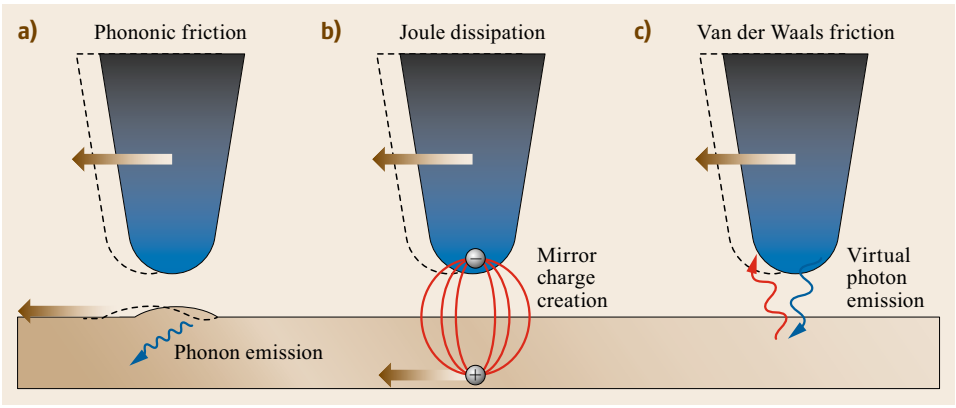

Fig. 29.8 **(a)** Phononic friction occurs when due to attractive tip–sample interactions the surface is deformed following the tip movement and, the strain energy is eventually dissipated into phonons. **(b)** Joule dissipation takes place when noncompensated charges beneath the surface move through a resistive medium. The tip oscillation causes the displacement current and Joule heating. **(c)** The van der Waals friction is initiated by the emission of a virtual photon towards the surface. The reflected photon is adsorbed back in the tip. The friction rises because the two photons are Doppler shifted in the moving reference frame of the oscillating tip (after [29.19])

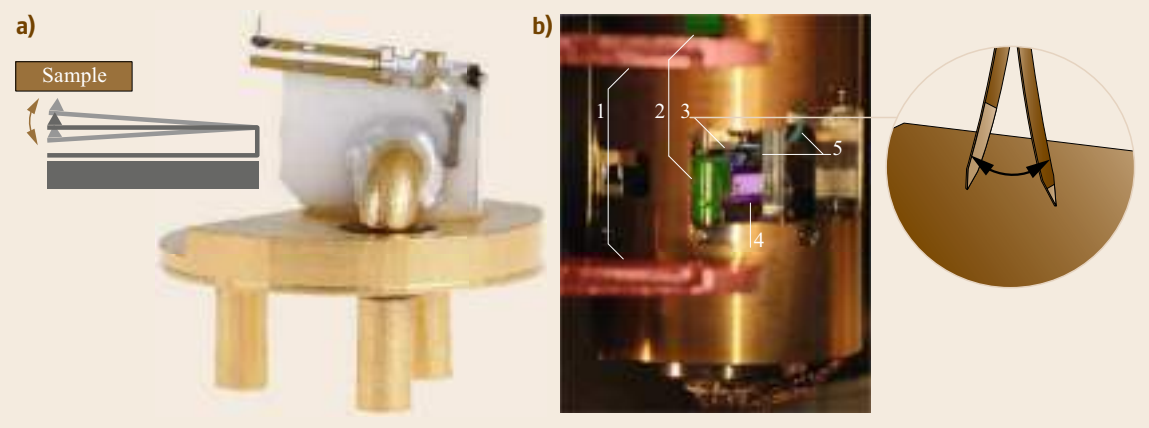

Fig. 29.9 **(a)** Schematic drawing of a tuning fork sensor in q-plus configuration. **(b)** Pendulum AFM configuration where 1 is the microscope, 2 are the mirrors of the beam deflection detection system, 3 is the cantilever suspended in pendulum geometry, 4 is the sample holder, and 5 is the STM line

so-called *noncontact friction* can be measured. In the pendulum AFM very soft cantilevers with spring constants k in the order of 10^{-5} to 10^{-3} N/m are used, which avoids snapping into contact with the sample. In contrast to contact friction measurements, where the slider is usually moved at constant velocity, in the pendulum AFM the tip oscillates above the sample surface with a constant frequency. The pendulum AFM operates at cryogenic temperatures and typical quality factors are in the order of $Q \approx 10^5$–10^6. Such high Q together with extremely small k values (both at the limit for silicon cantilevers) imply that the minimal detectable energy dissipation is a few orders of magnitude lower as compared to standard AFM configuration.

29.1.4 Friction Force Microscopy in Water

A robust alternative to UHV is measuring friction with the tip completely embedded in water or aqueous solution. Here, capillary condensation effects are completely removed and lattice resolution is easily obtained in standard FFM maps. This possibility is achieved using dedicated liquid cells, and is particularly interesting for studying dissolution and growth of mineral surfaces, but also the molecular arrangement of self-assembled monolayers when UHV-AFM is not available. A detailed molecular dynamics (MD) investigation of atomic-scale stick–slip on a (hydrophobic) graphite surface in water, considering collisions of single H_2O molecules with the probing tip, has recently been presented by *Vilhena* et al. [29.22]. The main conclusion is that, for small forces in the nN regime, friction in water is almost indistinguishable from friction in UHV except for a slightly enhanced background noise due to molecular collisions. Although this result cannot be generalized to hydrophilic materials, it is reasonable to expect that tip-water collisions do not play a pivotal role also in that case.

29.2 The Prandtl–Tomlinson Model

The contrast obtained in FFM images of crystal surfaces on the atomic scale is ultimately determined by the *stick–slip* motion of the probing tip. This process was described by *Prandtl* well before modern scanning probe techniques were introduced [29.23] and, for historical reasons, it is usually known as the Prandtl–Tomlinson (PT) mechanism. In combination with Kramer's theory for thermally activated processes, the PT model also explains the temperature and velocity dependence of atomic-scale friction.

29.2.1 One-Dimensional Prandtl–Tomlinson Model

In the PT model, the motion of the tip is determined by both the repulsive interaction with the atomic lattice of the surface and the elastic deformations of the driving support and the contact region. The shape of the tip–surface potential $U(\mathbf{r})$ depends on several factors, such as the chemical composition of the materials in contact and the atomic arrangement on the crystal

surface and the tip apex. For the sake of simplicity, we will start the analysis in the one-dimensional case considering a simple sinusoidal profile with a periodicity a and an amplitude U_0 increasing with the applied load. If the cantilever support moves with a constant velocity v along the x-direction, as usually occurs in FFM measurements, the total energy of the system is

$$U_{\mathrm{tot}}(x,t) = -U_0 \cos\frac{2\pi x}{a} + \frac{1}{2}k_{\mathrm{eff}}(vt-x)^2 \,, \quad (29.8)$$

where k_{eff} is an effective lateral stiffness (Sect. 29.5.3). Figure 29.10a shows the energy profile $U_{\mathrm{tot}}(x,t)$ at two different times t. When $t=0$, the tip is pinned in the absolute minimum of U_{tot}. This minimum becomes less and less pronounced with time, and, at a critical time $t=t^*$, this position becomes unstable and the tip suddenly slips into the next minimum of the potential profile. Correspondingly, the lateral force $F_{\mathrm{L}} = k(vt-x)$ takes the value [29.24]

$$F_{\mathrm{s}} = \frac{k_{\mathrm{eff}}a}{2\pi}\sqrt{\eta^2-1} \,, \quad (29.9)$$

where $\eta = 4\pi^2 U_0/(k_{\mathrm{eff}}a^2)$. In this way, (29.9) defines the *static friction* force acting on the tip, and stick–slip is observed only if $\eta > 1$, i. e., when the system is not too stiff or the tip–surface interaction is not too weak.

The lower curve in Fig. 29.10b shows the variation of the lateral force F_{L} when the cantilever is moved to the right. If, at a certain point, the direction of motion is suddenly inverted, the force follows the profile corresponding to the upper part of the curve. The area of the *friction loop* obtained by scanning back and forth gives the total energy dissipated in the process. Conversely, when $\eta < 1$, the tip slides continuously on the surface and the lateral force oscillates between negative and positive values. Elastic instabilities are suppressed, which leads to disappearance of lateral force hysteresis (so-called *superlubricity*: see also Sect. 29.2.3).

The average *kinetic friction* can be directly estimated from the energy drop ΔU accompanying the slip as $F_{\mathrm{k}} = \Delta U/a$. It increases linearly with the parameter η when the latter is high enough and it approaches the superlubric transition as $(\eta-1)^2$ [29.25].

Note that all previous considerations are valid in the so-called *quasistatic* limit, assuming that the tip, once unpinned from the surface, immediately rebinds to it. This approximation is acceptable if the damping coefficient γ describing dissipative processes due to tip-substrate coupling is high enough. If this is not the case *long* jumps of several lattice constants are possible and, if γ is very low, a chaotic regime of motion is established [29.25].

29.2.2 Two-Dimensional Prandtl–Tomlinson Model

In two dimensions, (29.8) is replaced by

$$U_{\mathrm{tot}}(\boldsymbol{r},t) = U(r) + \frac{k_{\mathrm{eff}}}{2}(\boldsymbol{v}t-\boldsymbol{r})^2 \,, \quad (29.10)$$

where $\boldsymbol{r} \equiv (x,y)$ gives the tip position and the velocity vector $\boldsymbol{v}$ is arbitrarily oriented on the surface (note that $\boldsymbol{v} \neq \mathrm{d}\boldsymbol{r}/\mathrm{d}t$). Figure 29.11a shows the total energy corresponding to a periodic potential of the form

$$U(x,y,t) = -\frac{U_0}{2}\left(\cos\frac{2\pi x}{a} + \cos\frac{2\pi y}{a}\right) + U_1 \cos\frac{2\pi x}{a}\cos\frac{2\pi y}{a} \,. \quad (29.11)$$

In general, the equilibrium condition becomes

$$\nabla U_{\mathrm{tot}}(\boldsymbol{r},t) = \nabla U(\boldsymbol{r}) + k_{\mathrm{eff}}(\boldsymbol{r}-\boldsymbol{v}t) = 0 \quad (29.12)$$

and the stability is described by the Hessian matrix

$$H = \begin{pmatrix} \frac{\partial^2 U}{\partial x^2} + k_{\mathrm{eff}} & \frac{\partial^2 U}{\partial x \partial y} \\ \frac{\partial U}{\partial y \partial x} & \frac{\partial^2 U}{\partial y^2} + k_{\mathrm{eff}} \end{pmatrix} . \quad (29.13)$$

When both eigenvalues $\lambda_{1,2}$ of the Hessian are positive, the position of the tip is stable. Figure 29.11b shows these regions for a potential of the form (29.11).

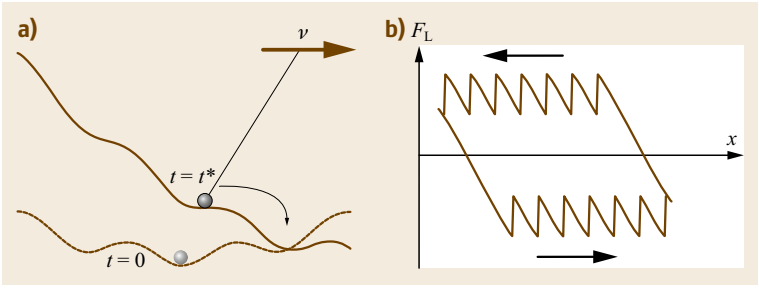

Fig. 29.10 **(a)** Energy profile experienced by the FFM tip (*black circle*) at $t=0$ (*dotted line*) and $t=t^*$ (*continuous line*). **(b)** Friction loop obtained by scanning back and forth in the one-dimensional (1-D) PT model. The effective spring constant k_{eff} is the slope of the sticking part of the loop (if $\eta \gg 1$)

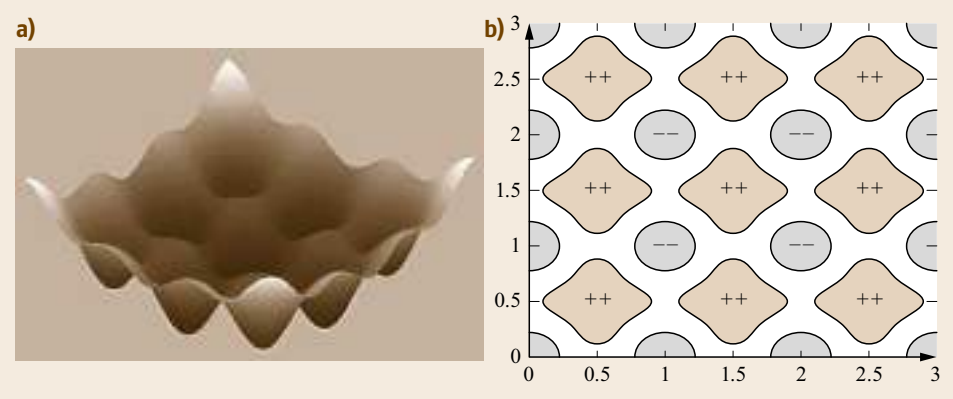

Fig. 29.11 **(a)** Energy landscape experienced by the FFM tip in two-dimensional (2-D) PT model. **(b)** Regions on the tip plane labeled according to the signs of the eigenvalues of the Hessian matrix (after [29.26])

The tip follows the cantilever adiabatically as long as it remains in the (++)-region. When the tip reaches the border of this region, it slips into a neighboring (++)-region and, as a result of several repetitions of this process, the tip is expected to follow a zigzag pathway. Analytical expressions for the static friction F_s and the kinetic friction F_k can be derived on simple square [29.27] and hexagonal [29.28] potentials.

29.2.3 Friction Between Atomically Flat Surfaces

Thus far we have implicitly assumed that the tip is ideally terminated by only one atom. It is also instructive to consider the case of a periodic surface sliding on another periodic surface. In the *Frenkel–Kontorova–Tomlinson* (FKT) *model*, the atoms of one surface are harmonically coupled with their nearest neighbors. In this context, the role of *commensurability* is essential. In 1-D, *Weiss* and *Elmer* predicted that friction should decrease with decreasing commensurability, the minimum friction being reached when the ratio between the two lattice constants is equal to the *golden mean* [29.30]

$$\bar{z} = 1 + \frac{1}{1 + \frac{1}{1+\ldots}} = \frac{\sqrt{5}-1}{2} \,. \tag{29.14}$$

In 2-D, *Gyalog* and *Thomas* studied the case of two square lattices with $a_1 = a_2$, and a misalignment given by an angle θ (Fig. 29.12a). When the sliding direction changes, friction also varies from a minimum value (corresponding to the sliding angle $\varphi = \theta/2$) to a maximum value (which is reached when $\varphi = \theta/2 + \pi/4$; Fig. 29.12b). The misfit angle θ is related to the commensurability. Since the misfit angles that give rise to commensurate structure form a dense subset, the dependence of friction on θ is expected to be discontinuous as indeed confirmed by additional numerical simulations.

In general, if the contact is incommensurate, the lateral forces of single atoms tend to cancel out if the load decreases or the stiffness increases and a transition from stick–slip to negligible friction is expected [29.31]. This situation may be called *superlubricity* or, as suggested by *Müser*, *structural lubricity* [29.32].

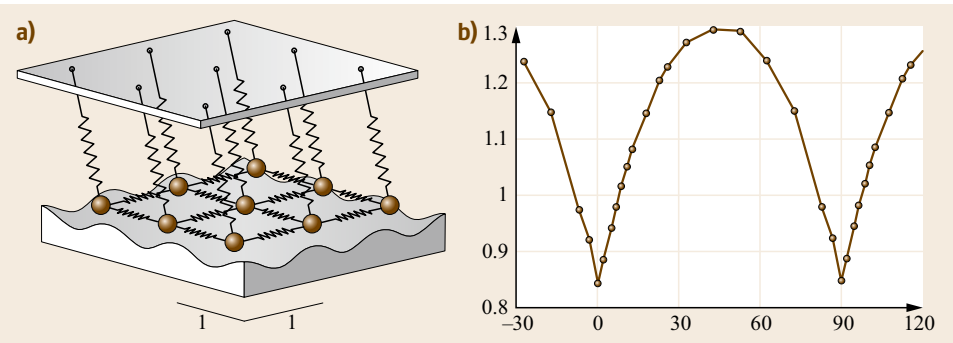

Fig. 29.12 **(a)** The FKT model in 2-D. **(b)** Friction as a function of the sliding angle φ in the 2-D FKT model (after [29.29])

29.3 Friction Experiments on the Atomic Scale

In the first lattice-resolved FFM measurements, *Mate* et al. scanned a graphite surface in ambient conditions with normal forces up to few tens of μN [29.1]. According to continuum mechanics, these values correspond to contact diameters of about 100 nm suggesting that a graphite flake may have detached from the surface and adhered to the tip. A rather linear load dependence of friction was also observed with a small friction coefficient $\mu = 0.01$. More precise and reproducible results are obtained in UHV, where the surface cleanness is better controlled than in ambient conditions. An atomic-scale friction map, acquired with the setup described in Sect. 29.1.2, is shown in Fig. 29.13. Here the lateral force F_L recorded on a sodium chloride surface periodically increases up to values $F_s \approx 0.4$ nN, when a slip event occurs and the tip promptly rebinds to the surface. The process is repeated several times, and the resulting FFM map perfectly reproduces the symmetry of the surface lattice. Using (29.9) the values $U_0 \approx 0.22$ eV and $k \approx 1$ N/m are estimated for the amplitude of the interaction potential and the effective lateral stiffness of the system. Note that the duration of the slip event, which is related to damping coefficient γ of the tip oscillations, remains beyond the time resolution of state-of-the-art FFMs [29.33]. However, this parameter may be indirectly estimated from statistical analysis of the slip length at different loading, as suggested by *Roth* et al. [29.34]. By applying subnanonewton loads to an NaCl surface, *Socoliuc* et al. were able to observe the transition from stick–slip to continuous sliding discussed in Sect. 29.2.1 [29.24] In other experiments, the transition was induced *dynamically* by exciting flexural or torsional resonance modes of the cantilever in contact with the surface [29.35, 36].

Note that no individual defects are seen in Fig. 29.13. This is expected if the contact between tip and surface is formed by several atoms. The availability of ultrasharp tips with curvature radius below 2 nm has recently allowed this limitation to be overcome. High-resolution FFM imaging of the moiré pattern formed by an ultrathin KBr film epitaxially grown on NaCl is demonstrated in Fig. 29.14a. This pattern results from the lattice mismatch between the two surfaces, with a substrate versus adsorbate lattice constant ratio of about 6 : 7. It is not observed if the load is close to the pull-off value. Hexagonal moiré patterns have also been reported by *Filleter* et al. using FFM on a graphene film on SiC(0001) [29.38]. Reconstruction domains on semiconducting surfaces [29.39], and friction variations across surface step edges of sodium chloride and germanium (Fig. 29.14b) have also been observed with *quasiatomic* resolution using FFM.

The anisotropy of friction and the zigzag walk of the tip predicted by the 2-D PT model (Sect. 29.2.2) was first observed by *Fujisawa* et al. [29.42] and *Kawakatsu* et al. [29.43] on mica and on MoS_2 using original 2-D FFM with two laser beams and two quadrant photodetectors. With another dedicated *Tribolever Dienwiebel* et al. were able to track friction forces with arbitrary scan orientations [29.44]. In this way, stick–slip and a significant energy dissipation were only observed at angles of rotation corresponding to a commensurate contact between a graphite surface and graphene flakes picked up by the tip. More recently, friction anisotropy has also been demonstrated by *Fessler* et al. on organic crystal surfaces [29.45]. The chemical structure of the used benzylammonium-terminated crystalline surface is presented in Fig. 29.15a. The FFM maps in UHV revealed a significant contrast between different molecular orientations yielding molecular rows which differ from their neighboring ones in dependence of the applied load (Fig. 29.15b). These maps could be repro-

duced introducing the empirical potential

$$U(x, y) = -U_0 \cos \frac{2\pi x}{a} \left(\cos \frac{2\pi y}{b} + c \right)$$

in the 2-D PT model, where a and b are the lattice constants and the parameter c gives rise to two different energy barriers $\Delta E^+ = U_0(1 + c)$ and $\Delta E^- = U_0(1 - c)$. Two examples of measurements and corresponding simulations are shown in Fig. 29.15b–e. The good agreement between them is demonstrated by the alternate contrast of a row with almost smooth sliding and the neighboring ones with considerably larger friction corresponding to the energy barriers ΔE^- and ΔE^+, respectively.

The potential of liquid environments for high-resolution FFM is also well established. Figure 29.16 shows

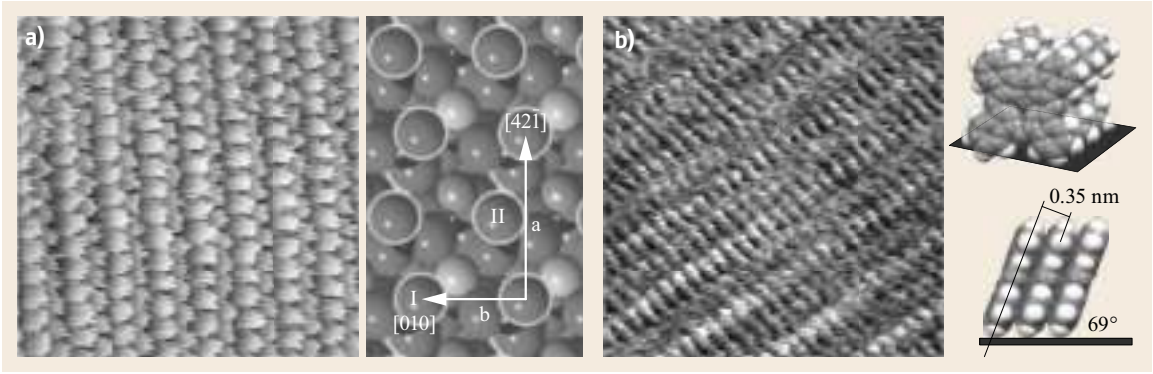

Fig. 29.16a,b FFM maps of **(a)** a dolomite cleavage surface (after [29.46]) and **(b)** of a Cu phthalocyanine ultrathin film grown on it (after [29.47])

a friction map of a dolomite cleavage surface and of a thin film of Cu phthalocyanine (PC) molecules previously deposited on it. On the dolomite surface two pinning sites per unit cell are resolved, corresponding to protruding carbonate groups. The contrast of each group varies with the scan direction, which can also be explained by the 2-D PT model. A comparison with the structure of PC crystals, as obtained by X-ray diffraction, clearly reveals that the molecules are stacked perpendicular to the substrate. This information could not be obtained in ambient conditions, where, due to capillary condensation, lattice resolution was not achieved.

29.4 Thermal Effects on Atomic Friction

Although the PT model gives a good interpretation of the basic mechanism of the atomic stick–slip discussed in Sect. 29.3, it cannot explain some important features observed in the friction maps. For example, the peaks in the sawtooth profile in Fig. 29.13b have different heights, which is in contrast to the result in Fig. 29.10b. Another effect is observed if the scan velocity v is varied: the mean friction force increases with the logarithm of v [29.37]. This effect cannot be understood within the mechanism discussed in Sect. 29.2 without further assumptions.

29.4.1 The Prandtl–Tomlinson Model at Finite Temperature

Let us focus again on the energy profile discussed in Sect. 29.2.1. For the sake of simplicity, we will suppose that $\eta \gg 1$. At a given time $t < t^*$, the tip jump is prevented by the energy barrier $\Delta E = U(x_{\max}, t) - U(x_{\min}, t)$, where $x_{\max}$ corresponds to the first maximum observed in the energy profile and $x_{\min}$ is the actual position of the tip (Fig. 29.17a). The quantity ΔE decreases with time or, equivalently, with the frictional force F_{L} until it vanishes when $F_{\mathrm{L}} \approx F^*$ (Fig. 29.17b).

At finite temperature T, the lateral force required to induce a jump is lower than F^*. To estimate the most probable value of F_{L} at this point, we first consider the probability p that the tip does *not* jump. The probability p changes with time t according to the master equation

$$\frac{\mathrm{d}p(t)}{\mathrm{d}t} = -f_0 \exp\left(-\frac{\Delta E(t)}{k_{\mathrm{B}}T}\right) p(t)\,, \qquad (29.15)$$

where f_0 is a characteristic attempt frequency in the order of fewtens of kHz (for typical FFM measurements on the atomic scale). Note that the probability of a reverse slip is neglected, since in this case the energy barrier that must be overcome is much higher than ΔE. Assuming a linear dependence of ΔE on the lateral force, a logarithmic dependence of friction on the scan velocity is obtained

$$F_{\mathrm{L}}(v) = F^* - \frac{k_{\mathrm{B}}T}{\lambda} \ln \frac{v_{\mathrm{c}}}{v}\,, \qquad (29.16)$$

where λ is in the order of the lattice constant.

However, the linear approximation for ΔE does not hold when the slip occurs very close to the critical point $x = x^*$, which is the case at high velocities. In this case thermal activation does not play any role and friction (due to stick–slip motion) becomes constant, in agreement with the classical Coulomb's law of friction. We

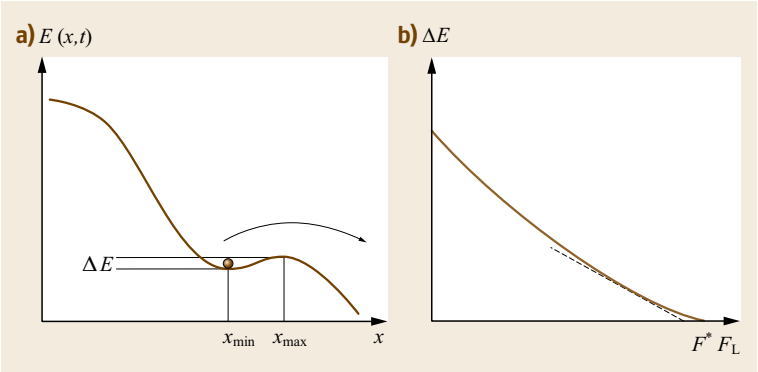

Fig. 29.17 **(a)** Energy barrier that hinders the tip jump in the PT model. **(b)** Energy barrier ΔE as a function of the lateral force F_L. The *dashed line* close to the critical value corresponds to the linear approximation (29.16)

should also mention that a better approximation for the energy barrier is $\Delta E \propto (F^* - F_L)^{3/2}$ [29.48]. The corresponding relations for the velocity dependence of friction are more complex and difficult to distinguish from the experimental results. Furthermore, the logarithmic law (29.15) becomes invalid at very low values of v. In this case reverse slip cannot be excluded, and, as a result, static friction is found to be proportional to v [29.49]. At room temperature such a *thermolubric* regime would be observed for unrealistic velocity values well below 1 pm/s (but the critical value increases rapidly with temperature). The thermally activated PT model has also been discussed in 2-D [29.50].

29.4.2 Velocity and Temperature Dependence of Atomic-Scale Friction

The first velocity-dependent atomic-scale FFM measurements in UHV were performed by *Bennewitz* et al. [29.51] and *Gnecco* et al. [29.37] with surfaces on copper and sodium chloride; in both cases a logarithmic increase of friction with the sliding velocity was observed up to $v < 1\,\mu$m/s in perfect agreement with (29.16). It is worth noting that a similar logarithmic dependence was also reported by *Bouhacina* et al. in polymer layers grafted on silicon oxide and interpreted as the result of stress-aided thermal activation of viscous flow [29.52]. We should also emphasize that the so-called *velocity strengthening* of friction can be masked by *velocity weakening* in FFM measurements performed in a humid environment. Here the nucleation of capillary bridges can be assisted by thermal activation and lead to friction forces logarithmically increasing with the sliding velocity [29.53].

Thus far we have used thermal activation to explain the velocity dependence of friction. The same mechanism also predicts that friction should change with temperature. The master equation (29.15) shows indeed that the probability of a tip slip is reduced at low temperatures T until it vanishes when $T = 0$. In this case thermal activation is excluded, and the lateral force F_L is equal to F^*, independent of the scanning velocity v.

Zhao et al. [29.54] observed that friction on graphite decreases as $1/T$ over a wide temperature range (140–750 K), supporting the hypothesis of thermal activation of the stick–slip process. However, it was only recently that the group of *Schirmeisen* reported atomic-scale FFM measurements in UHV at different temperatures [29.55]. When silicon, SiC, ionic crystals, and graphite surfaces were cooled from room temperature to cryogenic conditions, a good agreement with the thermally activated PT model was found down to a peak or a plateau, appearing between 50 and 200 K. Below these values, the friction was found to decrease with temperature, which the authors attributed to the competition between thermally activated rupture and formation of chemical bonds [29.56].

29.5 Friction on the Nanometer Scale

Friction is ultimately related to the real shape of the contact between the sliding surfaces. On the macroscopic scale, the contact between two bodies is studied within the context of continuum mechanics, which is based on the elasticity theory developed by Hertz in the nineteenth century. Various FFM experiments have shown that continuum mechanics is still valid down to contact areas just a few nanometers in size. Only when contact is reduced to a few atoms does the continuum frame become unsuitable, and other approaches like molecular dynamics become necessary.

29.5.1 Continuum Mechanics of Single Asperities

The lateral force F_L between two surfaces in reciprocal motion depends on the size of the real area of contact A, which can be a few orders of magnitude smaller than the apparent area of contact. The simplest assumption is that friction is proportional to A; the proportionality factor is called the *shear strength* τ [29.57]

$$F_L = \tau A \,. \tag{29.17}$$

For plastic deformation, the asperities are compressed until the pressure p equals a certain yield value p^*. The resulting contact area is thus $A = F_N/p^*$, and the well-known Amonton's law is obtained: $F_L = \mu F_N$, where $\mu = \tau/p^*$ is the *coefficient of friction*. The same idea can be extended to contacts formed by many asperities, and it leads again to Amonton's law. The simplicity of this analysis explains why most friction processes were related to plastic deformation for a long time. Such a mechanism, however, should provoke quick disruption of surfaces, which is not observed in practice.

Elastic deformation can be easily studied in the case of a sphere of radius R pressed against a flat surface. In this case, the contact area is

$$A(F_N) = \pi \left(\frac{R}{K}\right)^{2/3} F_N^{2/3} \,, \tag{29.18}$$

where $K = 3E^*/4$ and E^* is an effective Young's modulus, related to the Young's moduli (E_1 and E_2) and the Poisson numbers (ν_1 and ν_2) of the sphere and plane, by the following relation [29.58]

$$\frac{1}{E^*} = \frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2} \,. \tag{29.19}$$

The result $A \propto F_N^{2/3}$ contrasts with Amonton's law. However, a linear relation between F_L and F_N can be obtained for contacts formed from several asperities in particular cases. For example, the area of contact between a flat surface and a set of asperities with an exponential height distribution and the same radius of curvature R depends linearly on the normal force F_N [29.59]. The same conclusion holds approximately even for a Gaussian height distribution. However, the hypothesis that the radii of curvature are the same for all asperities is not realistic. A general model was recently proposed by *Persson*, who analytically derived the proportionality between contact area and load for a large variety of elasto-plastic contacts formed by surfaces with arbitrary roughness [29.60]. However, the discussion of this theory is not straightforward and goes beyond the purpose of this section.

Further effects are observed if adhesive forces between the asperities are taken into account. If the range of action of these forces is smaller than the elastic deformation, (29.18) is extended to the Johnson–Kendall–Roberts (JKR) relation

$$A(F_N) = \pi \left(\frac{R}{K}\right)^{2/3} \left(F_N + 3\pi\gamma R + \sqrt{6\pi R F_N + (3\pi\gamma R)^2}\right)^{2/3} , \tag{29.20}$$

where γ is the surface tension of the sphere and plane [29.61]. The real contact area at zero load is finite and the sphere can be detached only by pulling it away with a certain force. This is also true in the opposite case, in which the range of action of adhesive forces is larger than the elastic deformation. In this case, the relation between contact area and load takes the simple form

$$A(F_N) = \pi \left(\frac{R}{K}\right)^{2/3} (F_N - F_{off})^{2/3} \,, \tag{29.21}$$

where F_{off} is the negative load required to break the contact. The *Hertz-plus-offset* relation (29.21) can be derived from the Derjaguin–Muller–Toporov (DMT) model [29.62]. To discriminate between the JKR or DMT models, *Tabor* introduced a nondimensional parameter

$$\Phi = \left(\frac{9R\gamma^2}{4K^2 z_0^3}\right)^{1/3} , \tag{29.22}$$

where z_0 is the equilibrium distance during contact. The JKR model can be applied if $\Phi > 5$; the DMT model holds when $\Phi < 0.1$ [29.63]. For intermediate values of Φ, the Maugis–Dugdale model [29.64] can reasonably explain experimental results.

29.5.2 Dependence of Friction on Load

The FFM tip represents a single asperity sliding on a surface. The previous discussion suggests a nonlinear dependence of friction on the applied load, provided that continuum mechanics is applicable. *Schwarz* et al. [29.65] observed the Hertz-plus-offset relation (29.21) on graphite, diamond, amorphous carbon, and C_{60} in an argon atmosphere (Fig. 29.18). In their measurements, they used well-defined spherical tips with radii of curvature of tens of nanometers, obtained by contaminating silicon tips with amorphous carbon in a transmission electron microscope.

A good agreement with JKR theory has been reported in earlier UHV-FFM measurements on ionic crystals, mica, and metals [29.66–68]. In order to correlate the lateral and normal forces with improved statistics, *Meyer* et al. [29.66] applied an original 2-D histogram technique (Fig. 29.19). *Carpick* et al. extended the JKR relation (29.19) to include nonspherical tips [29.67]. In the case of an axisymmetric tip profile $z \propto r^{2n}$ $(n > 1)$, it can be proven analytically that the increase in friction becomes less pronounced with increasing n.

29.5.3 Estimation of the Contact Area

In contrast to other tribological instruments, such as the surface force apparatus [29.69], the contact area cannot be measured directly by FFM. Indirect methods are provided by contact stiffness measurements. The contact between the FFM tip and the sample can be modeled by a series of two springs (Fig. 29.20). The effective constant k^z_{eff} of the series is given by

$$\frac{1}{k^z_{\text{eff}}} = \frac{1}{k^z_{\text{contact}}} + \frac{1}{c_{\text{N}}} , \qquad (29.23)$$

where c_{N} is the normal spring constant of the cantilever and k^z_{contact} is the normal stiffness of the contact. This quantity is related to the radius of the contact area (a) by the simple relation [29.70]

$$k^z_{\text{contact}} = 2aE^* , \qquad (29.24)$$

where E^* is the effective Young's modulus introduced previously. However, typical values of k^z_{contact} are 1–2 orders of magnitude larger than c_{N} and a direct application of (29.23) is difficult. Alternatively, one can measure the normal resonance frequency f_{N} of the cantilever contacting the surface while scanning. *Steiner* et al. reported atomically resolved measurements of f_{N} on a sodium chloride surface [29.71]. Corresponding variations of the lateral force were simultaneously acquired. The normal stiffness k_{N} could be estimated from continuum mechanics relations, which were modified to account for the inclination of the cantilever with respect to the sample surface.

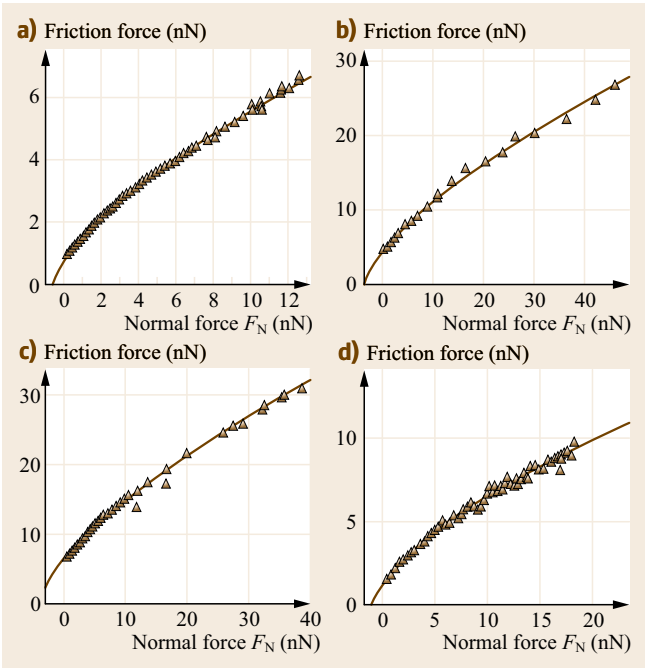

Fig. 29.18a–d Friction versus load curve on amorphous carbon in argon atmosphere. Curves **(a,b)** refer to tips with different radii of curvature (after [29.65])

The *lateral* contact stiffness of the contact between a sphere and a flat surface is [29.70]

$$k^x_{\text{contact}} = 8aG^* , \qquad (29.25)$$

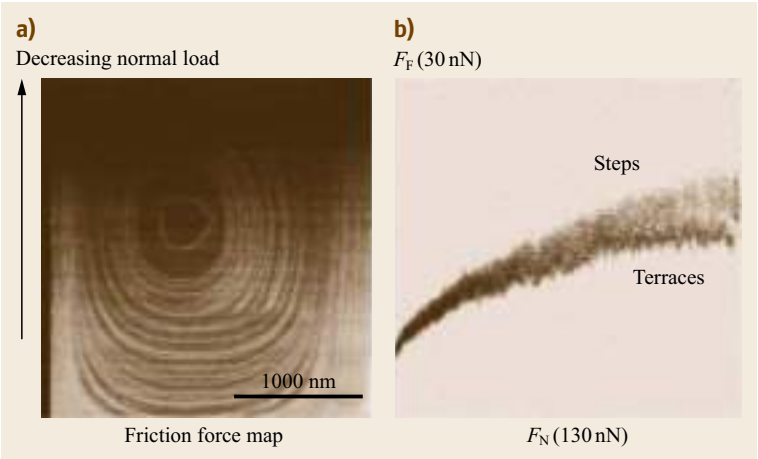

Fig. 29.19 **(a)** Friction force map on NaCl(100). The load is decreased from 140 to 0 nN (jump-off point) during imaging. **(b)** 2-D histogram of **(a)** (after [29.66])

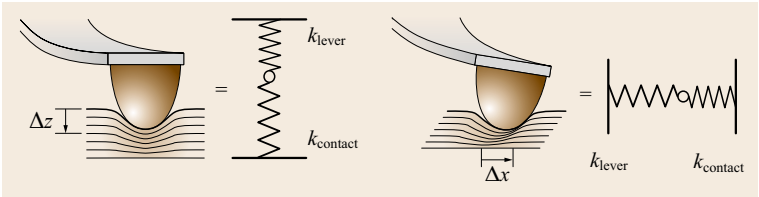

Fig. 29.20 Sketch of normal and lateral stiffness of the contact between tip and surface (after [29.72])

where the effective shear stress G^* is defined by

$$\frac{1}{G^*} = \frac{2-\nu_1^2}{G_1} + \frac{2-\nu_2^2}{G_2} \,. \tag{29.26}$$

G_1, G_2 are the shear moduli of the sphere and the plane, respectively. The contact between the FFM tip and the sample can again be modeled by a series of springs (Fig. 29.20). The effective constant k^x_{eff} of the series is given by

$$\frac{1}{k^x_{\text{eff}}} = \frac{1}{k^x_{\text{contact}}} + \frac{1}{k^x_{\text{tip}}} + \frac{1}{c_{\text{L}}} \,, \tag{29.27}$$

where c_{L} is the lateral spring constant of the cantilever and k^x_{contact} is the lateral stiffness of the contact. As suggested by *Lantz* et al., (29.27) also includes the lateral stiffness of the tip k^x_{tip} which can be comparable to the lateral spring constant [29.73]. The effective spring constant k^x_{eff} is simply given by the slope of the friction loop (Sect. 29.2.1). Once k^x_{contact} is determined, the contact radius a is easily estimated by (29.25).

The lateral stiffness method was applied to contacts between silicon nitride and muscovite mica in air and between $NbSe_2$ and graphite in UHV. The dependences of both the spring constant k^x_{eff} and the lateral force F_{L} on the load F_{N} were explained within the same models (JKR and Maugis–Dugdale, respectively), which confirms that friction is proportional to the contact area for the range of loads applied (up to $F_{\text{N}} = 40\,\text{nN}$ in both experiments).

Enachescu et al. estimated the contact area by measuring the contact conductance on diamond as a function of the applied load [29.74, 75]. Their experimental data were fitted with the DMT model, which was also used to explain the dependence of friction on load. Since the contact conductance is proportional to the contact area, the validity of the hypothesis (29.17) was confirmed again.

29.6 Wear on the Atomic Scale

If the normal force F_{N} applied by the FFM exceeds a critical value, which depends on the tip shape and on the material under investigation, the surface topography is permanently modified by abrasive wear and related processes. On the nanoscale wear may result in patterns with well-defined shapes. Here we will focus on the few experiments which demonstrated the unique ability of the FFM to both scratch and image surfaces down to the atomic scale.

In Fig. 29.21a, a small mound piled up at the end of a groove on KBr(100) is shown at different magnifications. The groove (800 nm long) was produced by repeated scratching with a normal force F_{N} of about 20 nN. When the groove was formed (in about 20 min) a rather continuous increase of friction with time was observed, which is well fitted by the exponential law

$$F_{\text{L}} = F_0 + F_1(1 - \text{e}^{-t/\tau}). \tag{29.28}$$

If $t \gg \tau$ a saturation of the contact area (proportional to friction) is expected, corresponding to the limit value at which the applied load can be perfectly balanced by the tip. In spite of the apparent continuity of the process on long time scales, the friction loops acquired while scraping (not shown) suggest that the atoms (or ion pairs) are removed one by one. Note that this kind of *atom-by-atom attrition* process has been observed recently in TEM images of nanotips getting worn when

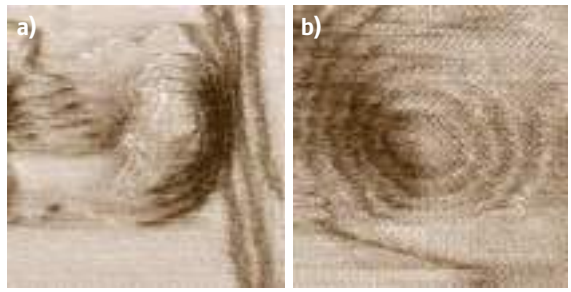

Fig. 29.21 **(a)** Lateral force image acquired at the end of a groove scratched 256 times with a normal force $F_{\text{N}} = 21\,\text{nN}$. Frame sizes: 39 nm. **(b)** Lateral force image of a pit produced with $F_{\text{N}} = 22.8\,\text{nN}$. Frame size: 20 nm (after [29.76])

scraped on harder surfaces [29.77]. No fracture or plastic deformation was found when Si volumes up to few tens of nm^3 were progressively removed from the tip.

Another example is given in Fig. 29.21b, where a pit produced by repeated low-frequency tip oscillations on a 5 nm long line is shown. From a comparison of the number of missing atoms (extracted from the figure) and the energy dissipated during scanning (extracted from the friction loops) it could be estimated that only 30% of the energy dissipation went into rupture of ionic bonds. Furthermore, the damage was observed to increase with the applied load, but did not vary significantly with the scan velocity.

In another study on KBr films on Cu(100) *Filleter* et al. [29.78] reported significant wear at intrinsic step edges of the films, where atomic coordination is lower. In contrast, low friction and no wear were observed across metal steps covered by KBr, which indicates a stabilizing effect of the alkali halide coating on the metal surface.

A different kind of wear is observed on layered materials. *Kopta* et al. [29.79] removed layers from a mica surface by scraping it with large normal forces of few hundreds of nN. Fourier-filtered images acquired on very small areas revealed the different periodicities of the underlying layers, which reflect the complex structure of the substrate. To interpret their results, *Kopta* et al. assumed that wear is initiated by atomic defects. When the defects accumulate beyond a critical concentration, they grow to form the scars observed by AFM. This process can be once again thermally activated. The number of defects created in the contact area $A(F_N)$ is

$$N_{def}(F_N) = t_{res} n_0 A(F_N) f_0 \exp\left(-\frac{\Delta E}{k_B T}\right), \qquad (29.29)$$

where t_{res} is the residence time of the tip, n_0 is the surface density of atoms, and f_0 is the frequency of attempts to overcome the energy barrier ΔE to break a Si−O bond, which depends on the applied load. When the defect density reaches a critical value, a hole is nucleated.

29.7 Noncontact Friction

As discussed in Sect. 29.1.3 forces and dissipation can be measured by recording Δf and A_{exc} simultaneously while scanning a surface by NC-AFM. Earlier experiments showed true atomic contrast in topography in the dissipation signal A_{exc} [29.80–83]. Figure 29.22a shows the border of an ultrathin NaCl island grown on Cu(111).

The strongly enhanced contrast of the step edges and kink sites could be attributed to a slower decay of the electric field and to easier relaxation of the positions of the ions at these locations. The dissipation image shown in Fig. 29.22b was recorded at the same time. Depending on the structure of the tip apex, the topography and damping signal were found to be in phase, partially shifted, or even in antiphase. This is impressively confirmed by the tip change observed in the experimental images in Fig. 29.22b. The dissipation contrast is seriously enhanced, while the topography contrast remains almost unchanged.

More directly related to friction measurements, where the tip is sliding in contact with the sample, are NC-AFM experiments in the pendulum geometry (Sect. 29.1.3). In the first measurements of this kind *Stowe* et al. [29.84] could image the dopant density for n- and p-type silicon samples with 150 nm spatial resolution. The damping turned out to scale as U_{ts}^2 with the tip–sample voltage as expected for electric field Joule dissipation [29.85]. *Stipe* et al. [29.86] measured the noncontact friction between a Au(111) surface and a gold-coated tip using the same setup. They observed the same U_{ts}^2 dependence of the bias voltage and a distance dependence that follows the power law $1/d^n$, where n is between 1.3 and 3. Note that a considerable electric field was present even with zero external bias voltage, which is frequently the case in this kind of measurement.

In order to distinguish phononic and electronic contribution to friction *Kisiel* et al. [29.87] oscillated

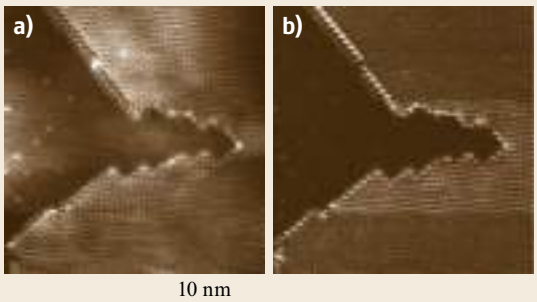

Fig. 29.22 (a) Topography and (b) damping images of an NaCl island on Cu(111). The tip changed after 1/4 of the scan, thereby enhancing the contrast in A_{exc}. After 2/3 of the scan, the contrast in the lower part of the image was restored, indicating a reversible tip change (after [29.82])

a pendulum cantilever over a 150 nm thick niobium film. The measurement was performed at two different temperatures, thus allowing them to investigate both the superconducting state of Nb, where the phononic channel of energy dissipation prevails, as well as the normal metal state where an electronic contribution to friction is superimposed. The dependence of the damping on the temperature is shown in Fig. 29.23a. During the measurement the tip–sample distance was kept constant. The noncontact friction coefficient rose by a factor of three when the critical temperature $T_c = 9.2$ K was approached from below and leveled off in the normal state. The variation of the friction coefficient in the vicinity of T_c is smooth as predicted by the Bardeen–Cooper–Schrieffer (BCS) theory of superconductivity [29.89]. In the superconducting phase, the electrons lose their identity and form Cooper pairs. Therefore, the energy is lost only in the emission of phonons. Close to the transition temperature the gradually growing normal electron population causes acoustic wave attenuation rises due to electron-phonon scattering, which ultimately results in dissipation. Further measurements of voltage V and distance d dependent friction support the hypothesis of separation of phononic and electronic channels.

The idea of replacing a passive substrate with an *active* material undergoing a phase transition for the purpose of friction study was further accomplished on an $SrTiO_3$ sample. According to *Benassi* et al. [29.90] the friction coefficient is peaking when a sliding object undergoes a phase transition. In this context $SrTiO_3$ is a perfect candidate, because of the presence of a structural second-order phase transition at $T = 110$ K. A recent pendulum AFM experiment [29.88] showed that the critical fluctuations in a bulk crystal may affect the dissipation of mechanical probes even if completely external to the crystal surface. NC-AFM dissipation bears clear evidence of a most classic bulk transition, that to the antiferrodistortive state of $SrTiO_3$, as is shown in Fig. 29.23b. It also showed that the friction coefficient peaks at temperatures of 110–130 K. In this range the system becomes very *soft* owing to proliferation of domain walls, defects, and disorder in the distortive part of the crystal structure. Moreover, the frictional response close to the transition was governed by critical exponents characteristic for the three-dimensional (3-D) Ising model.

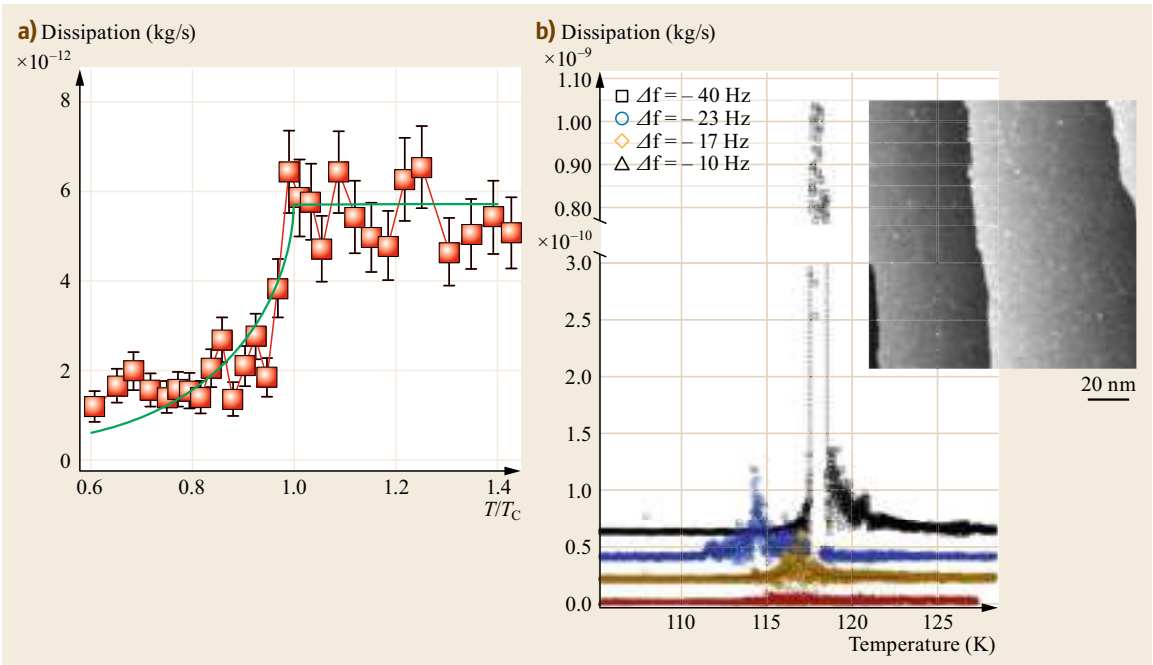

Fig. 29.23 **(a)** Temperature dependence of noncontact friction across the critical temperature of an Nb sample. The *green line* is a BCS theory fit to the measured data (*red squares*) (after [29.87]). **(b)** Experimental AFM dissipation as a function of temperature and tip–$SrTiO_3$ sample distance. The *black color* corresponds to the closest approach and the sharp peak is located at the critical temperature of $SrTiO_3$ in the bulk region under the tip. *Inset* shows a low-temperature ($T = 5$ K) STM image of the $SrTiO_3$ surface. Fig. 29.24 **(a)** STM image of an $NbSe_2$ surface at $T = 6\,K$ and **(b)** Energy dissipation as a function of tip–sample distance. Three giant dissipation peaks are visible (after [29.91])

Pendulum AFM experiments have also addressed the coupling of a mechanical oscillator to *charge-density-waves* (CDWs) on an $NbSe_2$ sample, an elusively subtle long-range property of matter [29.91]. Figure 29.21a shows an atomically resolved surface topography with the additional CDW-induced moiré pattern, which is incommensurate with the underlying lattice. The distance dependence of the friction coefficient $\Gamma(d)$ shows striking multiple dissipation peaks at a few nm distance from the surface (Fig. 29.24b). The temperature evolution of the peaks suggested a strong connection with CDWs. In order to understand the origin of the dissipation spikes a theoretical model was proposed, where a CDW is considered to be an elastic medium, whose phase is perturbed locally by the attractive potential of the cantilever tip [29.92]. This is shown in Fig. 29.24c. For a given perturbation the charge peak below the tip displaces (red solid line) and the resulting CDW phase is getting distorted (red dashed line). As the force reaches a critical value the central peak disappears and an extra 2π phase is pumped locally below the cantilever tip (green line). The energies for the two discussed phase deformations ($N = 0$ and $N = 1$) are shown by the red and green solid lines and a crossover energy is marked by a circle. Oscillations close to a crossover point will cause pumping in and out of an extra 2π phase and thus be accompanied by a hysteresis cycle in the tip mechanics. The hysteresis explains the giant size of dissipation peaks and approaching the tip further down, might produce another phase slip explaining multiple dissipation peaks.

Lateral oscillations can also be excited in normal AFM geometry when exciting the torsional oscillation of commercial, rectangular AFM cantilevers. Also in this case the tip is oscillating approximately parallel to the surface. This mode, although much less force sensitive than the pendulum AFM, allowed one to measure lateral forces acting on the tip at step edges and near impurities quantitatively [29.93]. Enhanced energy dissipation was also observed at the impurities. When the tip was moved further toward the sample, the contact formation transformed the nearly free torsional oscillation of the cantilever into a different mode, with the tip–sample contact acting as a hinge. This caused a rapid increase in the power required to maintain a constant tip oscillation amplitude and a positive frequency shift.

29.8 Single Molecule Friction

The experiments described so far focused on the friction forces between a sharp tip and a crystal surface either in contact or in close proximity to each other. In this section we will address the problem of the frictional response of a nano-object as small as a single molecule sliding on a surface. Such experiments require us to intentionally pick up the molecule previously deposited on a solid surface with the apex of an AFM tip and to manipulate it laterally or vertically. This can be also done using quartz tuning forks as a force

sensor (QPlus) operated in NC mode. The high stiffness ($\approx 2\,\mathrm{kN/m}$) of the sensor allows one to achieve subangstrom oscillation amplitudes. Furthermore, low-temperature conditions are mandatory to ensure the stability of the molecule–surface junction while performing the friction experiments.

Ternes et al. first succeeded in measuring *the force to move an adatom on a surface* by means of force spectroscopy [29.94, 95]. First attempts to measure the force accompanying the lifting of a PTCDA (perylenetetracarboxylic dianhydride) molecule on Au(111) were conducted by the group of *Temirov* [29.96, 97]. Systematic vertical manipulations demonstrated reproducible features of the force curves which were related to the detachment of the molecule, i. e., adhesion, as well as to the mechanics of the molecular junction.

To investigate the mechanical degrees of freedom of a molecular structure during vertical displacements, *Kawai* et al. performed pulling manipulation experiments of long polymeric chains [29.98]. The chains were synthesized on a Au(111) surface by Ullmann-coupling of several dibromoterfluorene (DBTF) molecules previously adsorbed on the surface. A single chain, having a length of a few nm and lying flat on the surface, is bound to the tip of an AFM as shown in Fig. 29.25a. Tip retraction results in vertical manipulation of the molecular chain. During such lifting, force–distance $\Delta f(z)$ curves (Sect. 29.1.3) were acquired (Fig. 29.25b). The effective stiffness, calculated as the derivative of the curve, is indicated on the right scale. A periodic variation is observed, with each period terminated by an abrupt jump. The number of periods (24) exactly corresponds to the number of the fluorene units forming the chain, as previously estimated by STM, and the periodicity of about 0.9 nm corresponds to the length of a single unit. The chain thus detached step-wise from the surface during pulling. The experimental results were interpreted within an *edge-driven Frenkel–Kontorova* (FK) model. The polymer chain was schematized as a series of particles connected by springs of stiffness k and equilibrium length b. Each particle interacts with the substrate via a periodic potential reproducing the symmetry of the Au(111) surface and expressed by a formula introduced by Steele to describe gas-atoms solid interaction [29.99]. As shown in Fig. 29.25c, the main features of the experimental $\Delta f(z)$ curves were satisfactorily reproduced in such a way. Simulations also pointed out the fact that the effective stiffness of the pulled segments must be large compared to the stiffness of the chemical bond formed between tip and chain. Remarkably, they also allowed one to estimate the normal force required to detach one unit, which cannot be directly measured in the experiment. This force (in the order of 0.25 nN) is nearly independent of the length of the chain as well as of the unit position in the chain.

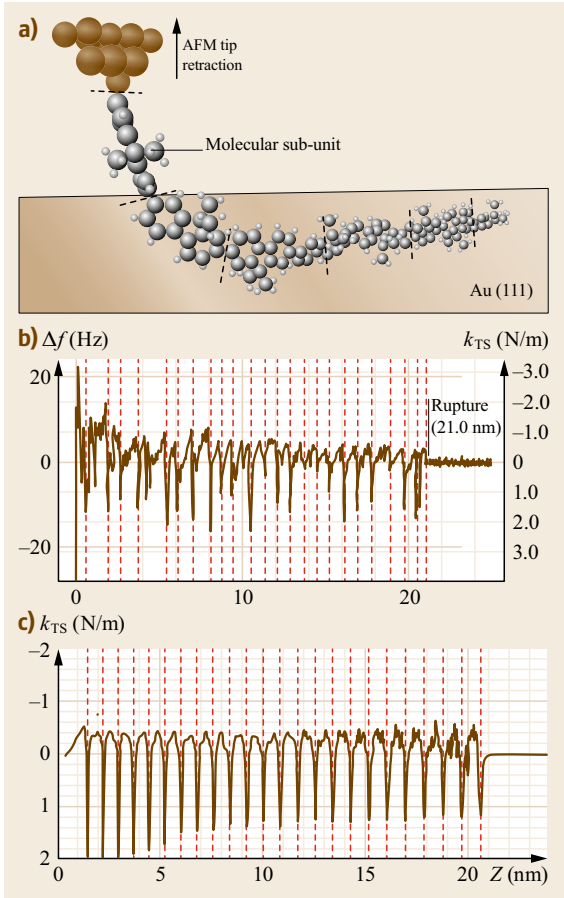

Fig. 29.25 **(a)** On-surface Ullmann coupling of DBTF molecules leads to long polymeric chains on Au(111). The end of the chain can be attached to the AFM tip and then retracted from the surface while acquiring interaction forces. **(b)** Experimental $\Delta f(z)$ spectra obtained during the lifting of the macromolecule (f_0 is the free resonance frequency of the tuning fork and k, its spring constant). The detachment is marked by the arrow. **(c)** Calculated dependence of the normal force gradient k_{TS} versus tip–surface distance z according the extended Frenkel–Kontorova model (Reprinted from [29.98]. Copyright 2014 National Academy of Sciences)

In another investigation *Kawai* et al. were able to measure the friction force acting on graphene nanoribbons (GNRs) sliding on a Au(111) surface using a similar approach [29.100]. The GNRs were again produced by Ullmann-coupling, and first manipulated without attaching them to the tip. The GNRs started to move in correspondence to exceptionally low friction force values of a few 100 pN. The static friction

per unit length was found to decrease with increasing GNR length, consistently with a strong superlubric behavior of graphene when forming an incommensurate contact. As a next step, the ends of selected GNRs were anchored to the tip and dragged back and forth in a controlled way (Fig. 29.26a). The corresponding variations of $\Delta f(x)$ are shown in Fig. 29.26c,d for increasing values of the tip–sample separation z. The frequency shift oscillates with a periodicity of 0.28 nm, except when the GNR was driven backward with $z = 5$ nm. The amplitude of the Δf oscillations is not constant along x but is modulated on distances of a few nm. Molecular dynamics (MD) simulations were also employed to reproduce the manipulation process. In this way the herringbone reconstruction of Au(111) was found to be responsible not only for the modulation of $\Delta f(x)$, but also for a significant reduction of commensurability between GNR and substrate. As a consequence, the GNR-Au(111) contact is almost superlubric, with both static and kinetic friction force values in the range of 100 pN.

The frictional response of a single organic molecule sliding on a metal surface was recently investigated by *Pawlak* et al. [29.101]. In this experiment, a porphyrin molecule was attached to the AFM tip via its core as shown in Fig 29.27a. The surface–molecule junction was formed by a single carbonitrile end-group of the porphyrin structure resulting in a single-point contact with a Cu(111) surface. While dragging the molecule, the junction was robust enough to maintain the contact although mechanical deformation of the molecular spring was expected. A friction $\Delta f(x, y)$ map of the Cu(111) surface obtained in such conditions is shown in Fig. 29.27b. The atomic-scale contrast resembles the frictional patterns obtained by conventional FFM on Cu(111) [29.51]. A dark depression corresponding to a Cu vacancy in the bottom right part of the image was also observed. In the line profiles of the tip–sample stiffness $k_{TS}(x)$ extracted from the Δf data (Fig. 29.21c) a clear saw-tooth modulation is detected resembling the standard atomic-scale friction pattern in FFM. Here, the hysteresis of the friction loop between forward and backward traces is small suggesting superlubric sliding. To verify this assumption, a generalized PT model including the Steele potential was used to simulate the friction process [29.99]. The intrinsic parameters characterizing the relevant stretching and bending rigidities of the molecule structure were extracted from first-principles calculations and used to parameterize the simulations. The calculations demonstrated that the variation of the normal force gradient during sliding is coupled to the friction force acting on the cyano end-group via the molecular entity thus supporting the experimental hypothesis.

29.9 Conclusion

Over the last 25 years, the establishment of friction force microscopy has led to exceptional development in the field of nanotribology. The sliding motion of single asperities with only a few atoms forming the contact can be precisely investigated, and the friction forces accompanying the motion can be studied as a function of time, but also of load, velocity, and temperature. Stick–slip motion on the atomic scale is properly described by the Prandtl–Tomlinson model. Extensions of this model predict superlubric transitions and thermally activated slip, both of which have been experimentally verified. Friction force microscopy can also be applied to investigate initial stages of abrasive wear. Conversely, noncontact friction has recently become an active topic of research thanks to instrumental refinements such as pendulum AFM and tuning fork sensors. Distinguishing phononic and electronic contributions to noncontact friction is nowadays possible, as well as estimating the friction forces acting on polymer chains, graphene ribbons, and even single molecules dragged or lifted off a solid surface.

30. Computer Simulations of Nanometer-Scale Indentation and Friction

Susan B. Sinnott, Seong-Jun Heo, Donald W. Brenner, Judith A. Harrison, Douglas L. Irving

Engines and other machines with moving parts are often limited in their design and operational lifetime by friction and wear. This limitation has motivated the study of fundamental tribological processes with the ultimate aim of controlling and minimizing their impact. The recent development of miniature apparatus, such as microelectromechanical systems (MEMSs) and nanometer-scale devices, has increased interest in atomic-scale friction, which has been found to, in some cases, be due to mechanisms that are distinct from the mechanisms that dominate in macroscale friction.

Presented in this chapter is a review of computational studies of tribological processes at the atomic and nanometer scale. In particular, a review of the findings of computational studies of nanometer-scale indentation, friction and lubrication is presented, along with a review of the salient computational methods that are used in these studies, and the conditions under which they are best applied.

Engines and other machines with moving parts are often limited in their design and operational lifetime by friction and wear. This limitation has motivated the study of tribological processes with the aim of controlling and minimizing the impact of these processes. There are numerous historical examples that illustrate the importance of friction to the development of civilizations, including the ancient Egyptians who invented technologies to move the stones used to build the pyramids [30.1]; Coulomb, who was motivated to study friction by the need to move ships easily and without wear from land to the water [30.1]; and *Johnson* et al. [30.2], who developed an improved understanding of contact mechanics and surface energies through the study of automobile windshield wipers. At present, substantial research and development is aimed at microscale and nanoscale machines with moving parts that at times challenge our fundamental understanding of friction and wear. This has motivated the study of atomic-scale friction and has, consequently, led to new discoveries such as self-lubricating surfaces and wear-resistant materials. While there are similarities between friction at the macroscale and the atomic scale, in many instances the mechanisms that lead to friction at these two scales are quite different. Thus, as devices such as magnetic storage disks and microelectromechanical systems (MEMS) [30.3] continue to shrink in size, it is expected that new phenomena associated with atomic-scale friction, adhesion and wear will dominate the functioning of these devices.

The last two decades have seen considerable scientific effort expended on the study of atomic-scale friction [30.4–17]. This effort has been facilitated by the development of new advanced experimental tools to measure friction over nanometer-scale distances at low loads, rapid improvements in computer power, and the maturation of computational methodologies for the modeling of materials at the atomic scale. For example, friction-force and atomic-force microscopes (FFMs and AFMs) allow the frictional properties of solids to be characterized with atomic-scale resolution under single-asperity indentation and sliding condi-

B. Bhushan (Ed.), *Springer Handbook of Nanotechnology*, DOI 10.1007/978-3-319-49347-3_30

tions [30.18–21]. In addition, the surface force apparatus (SFA) provides data about the tribological and lubrication responses of many liquid and solid systems with atomic resolution [30.22], and the quartz crystal microbalance (QCM) provides information about the atomic-scale origins of friction [30.4, 23]. These and related experimental methods allow researchers to study sliding surfaces at the atomic scale and relate the observed phenomena to macroscopically observed friction, lubrication and wear.

Analytic models and computational simulations have played an important role in characterizing and understanding friction. They can, for example, assist in the interpretation of experimental data or provide predictions that subsequent experiments can confirm or refute. Analytic models have long been used to study friction, including early studies by *Tomlinson* [30.24] and *Frenkel* and *Kontorova* [30.25] and more recent studies by *McClelland* and *Glosli* [30.26], *Sokoloff* [30.13, 27–33], *Persson* et al. [30.34–37] and others [30.38–44]. Most of these idealized models divide the complex motions that create friction into more fundamental components defined by quantities such as spring constants, the curvature and magnitude of potential wells, and bulk phonon frequencies. While these simplifications provide these approaches with some predictive capabilities, many assumptions must be made in order to be able to apply these models to study friction, which may lead to incorrect or incomplete results.

In atomic-scale molecular dynamics (MD) simulations, atom trajectories are calculated by numerically integrating coupled classical equations of motion. Interatomic forces that enter these equations are typically calculated either from total energy methods that include electronic degrees of freedom, or from simplified mathematical expressions that give the potential energy as a function of interatomic displacements. MD simulations can be considered numerical experiments that provide a link between analytic models and experiments. The main strength of MD simulations is that they can reveal unanticipated phenomena or unexpected mechanisms for well-known observations. Weaknesses include a lack of quantum effects in classical atomistic dynamics, and perhaps more importantly, the fact that meaningless results can be obtained if the simulation conditions are chosen incorrectly. The next section contains a review of MD simulations, including the approximations that are inherent in their application to the study of friction, and the conditions under which they should and should not be applied.

30.1 Computational Details

Molecular dynamics simulations are straightforward to describe: given a set of initial conditions and a way of mathematically modeling interatomic forces, Newton's (or equivalent) classical equation of motion is numerically integrated [30.45]

$$\boldsymbol{F} = m\boldsymbol{a}\,, \tag{30.1a}$$

$$-\nabla E = m\left(\frac{\partial^2 \boldsymbol{r}}{\partial t^2}\right)\,, \tag{30.1b}$$

where F is the force on each atom, m is the atomic mass, a is the atomic acceleration, E is the potential energy felt by each atom, r is the atomic position, and t is time. The forces acting on any given atom are calculated, and then the atoms move a short increment ∂t (called a time step) forward in time in response to these applied forces. This is accompanied by a change in atomic positions, velocities and accelerations. The process is then repeated for some specified number of time steps.

The output of these simulations includes new atomic positions, velocities, and forces that allow additional quantities such as temperature and pressure to be determined. As the size of the system increases, it is useful to render the atomic positions in animated movies that reveal the responses of the system in a qualitative manner. Quantitative data can be obtained by analyzing the numerical output directly.

The following sections review the way in which energies and forces are calculated in MD simulations and the important approximations that are used to realistically model the friction that occurs in experiments with smaller systems of only a few tens of thousands of atoms in simulations. The reader is referred to additional sources [30.46–52] for a more comprehensive overview of MD simulations (including computer algorithms), analysis methods, and the potentials that are used to calculate energies and forces in MD simulations.

30.1.1 Energies and Forces

There are several different approaches by which interatomic energies and forces are determined in MD simulations. The most theoretically rigorous methods are those that are classified as ab initio or first principles. These techniques, which include density functional theory [30.53, 54] and quantum chemical ab initio [30.55]

methods, are derived from quantum mechanical principles and are generally both the most accurate and the most computationally intensive. They are therefore limited to a small number of atoms (< 500), which has limited their use in the study of friction. Alternatively, empirical methods are functions containing parameters that are determined by fitting to experimental data or the results of ab initio calculations [30.50]. These techniques can usually be relied on to correctly describe qualitative trends and are often the only choice available for modeling systems containing tens of thousands, millions, or billions of atoms. Empirical methods have therefore been widely used in studies of friction. Semiempirical methods, including tight-binding methods, include some elements of both empirical methods and ab initio methods. For instance, they require quantum mechanical information in the form of, for example, on-site and hopping matrix elements, and include fits to experimental data [30.56].

Empirical methods simplify the modeling of materials by treating the atoms as spheres that interact with each other via repulsive and attractive terms that can be either pairwise additive or many-body in nature. In this approach, electrons are not treated explicitly, although it is understood that the interatomic interactions are ultimately dependent on them. As discussed in this section, some empirical methods explicitly include charge through classical electrostatic interactions, although most methods assume charge-neutral systems. The repulsive and attractive functional forms generally depend on interatomic distances and/or angles and contain adjustable parameters that are fit to ab initio results and/or experimental data.

The main strength of empirical potentials is their computational speed. Recent simulations with these approaches have modeled billions of atoms [30.57], something that is not possible with ab initio or semiempirical approaches at this time. The main weakness of empirical potentials is their lack of quantitative accuracy, especially if they are poorly formulated or applied to systems that are too far removed from the fitting database used in their construction. Furthermore, because of the differences in the nature of chemical bonding in various materials, such as covalent bonding in carbon versus metallic bonding in gold, empirical methods have been historically derived for particular classes of materials. They are therefore generally nontransferable, although some methods have been shown to be theoretically equivalent [30.51, 58], and in recent years there has been progress towards the development of empirical methods that can model heterogeneous material systems [30.59–64].

Several of the most important and common general classes of empirical methods used for calculating interatomic energies and forces in materials, the so-called potentials, are reviewed here. The first to be considered are the potentials that are used to model covalently bound materials, including the bond-order potential and the Stillinger–Weber potential.

The bond-order potential was first formulated by *Abell* [30.65] and subsequently developed and parameterized by *Tersoff* for silicon and germanium [30.66, 67], *Brenner* and coworkers for hydrocarbons [30.52, 68, 69], *Dyson* and *Smith* for carbon-silicon-hydrogen systems [30.70], *Sinnott* and coworkers for carbon-oxygen-hydrogen systems [30.71], and *Graves* and coworkers [30.72] and *Sinnott* and coworkers [30.73] for fluorocarbons, *Schall* and coworkers for pure Si [30.74], and *Hu* and coworkers on C-N-O-H [30.75].

The bond-order potential has the general functional form

$$E = \sum_i \sum_{j(>i)} [V_R(r_{ij}) - b_{ij} V_A(r_{ij})] \qquad (30.2)$$

where $V_R(r)$ and $V_A(r)$ are pair-additive interactions that model the interatomic repulsion and electron–nuclear attraction, respectively. The quantity r_{ij} is the distance between pairs of nearest-neighbor atoms i and j, and b_{ij} is a bond-order term that takes into account the many-body interactions between atoms i and j, including those due to nearest neighbors and angle effects. The potential is short-ranged and only considers nearest neighbor bonds. To model long-range nonbonded interactions, the bond-order potential is combined with pair-wise potentials either directly through splines [30.76] or indirectly with more sophisticated functions [30.77].

The *Stillinger–Weber* potential [30.78] potential was formulated to model silicon, with a particular emphasis on the liquid phases of silicon. It includes many-body interactions in the form of a sum of two- and three-body interactions

$$E = \sum_{ij} V_{ij}^2(r_{ij}) + \sum_{jik} V_{jik}^3(r_{ij}, r_{ik}) \,, \qquad (30.3)$$

where V^2 is a pair-additive interaction and V^3 is a three-body term. The three-body term includes an angular interaction that minimizes the potential energy for tetrahedral angles. This term favors the formation of open structures, such as the diamond cubic crystal structure.

The second potential is the embedded atom method (EAM) approach [30.79, 80] and related methods [30.81], which were initially developed for model-

ing metals and alloys. The functional form in the EAM is

$$E = \sum_i F(\rho_i) + \sum_{i>j} \Phi(r_{ij}) \,, \tag{30.4}$$

where F is called the embedding energy. This term models the energy due to embedding an atom into a uniform electron gas with a uniform compensating positive background (jellium) of density ρ_i that is equal to the actual electron density of the system. The term $\Phi(r_{ij})$ is a pairwise functional form that corrects for the jellium approximation. Several parameterizations of the EAM exist (see, for example, [30.79, 80, 82–84]) and it has recently been extended to model nonmetallic systems. For example, the modified EAM (MEAM) approach [30.64, 85, 86] was developed so that EAM could be applied to metal oxides [30.60] and covalently bound materials [30.86].

The third method is the general class of Coulomb or multipole interaction potentials used to model charged ionic materials or molecules [30.87]. In this formalism, an energy term is given as

$$E = \sum_i \sum_{j(>i)} \left(\frac{q(r_i)q(r_j)}{r_{ij}} \right) , \tag{30.5}$$

where $q(r_i)$ is the charge on atom i and r_{ij} is the distance between atoms i and j. More complex formalisms that take into account, say, the Madelung constant in the case of ionic crystals, are used in practice. In general, the charges are held fixed, but methods that allow charge to vary in a realistic manner have been developed [30.61, 88].

Lastly, long-range van der Waals or related forces are typically modeled with pairwise additive potentials. A widely used approximation is the Lennard-Jones (LJ) potential [30.89], which has the following functional form

$$E = 4\varepsilon \sum_i \sum_{j(>i)} \left[\left(\frac{\sigma}{r_{ij}} \right)^{12} - \left(\frac{\sigma}{r_{ij}} \right)^{6} \right] . \tag{30.6}$$

In this approach ε and σ are parameters and r_{ij} is the distance between atoms i and j.

All of these potentials are widely used in MD simulations of materials, including studies of friction, lubrication, and wear.

30.1.2 Important Approximations

Several approximations are typically used in MD simulations of friction. The first is the use of periodic boundary conditions (PBCs) and the minimum image convention for interatomic interactions [30.48]. In both cases the simulation supercell is surrounded by replicas of itself so that atoms (or phonons, etc.) that exit one side of the supercell remerge into the simulation through the opposite side of the supercell. In the minimum image convention an atom interacts either with another atom in the supercell or its equivalent atom in a surrounding cell depending on which distance to the atom is shortest. This process is illustrated in Fig. 30.1. In this convention supercells must be large enough that atoms do not interact with themselves over the periodic boundaries. In computational studies of friction and wear, PBCs are usually applied in the two dimensions within the plane(s) of the sliding surface(s). The strength of this approach is that it allows a finite number of atoms to model an infinite system. However, the influence of boundaries on system dynamics is not completely eliminated; for example, phonon scattering due to the periodic boundaries can influence heat transport and therefore frictional properties of sliding interfaces.

Another important tool that is often used in MD simulations of friction is thermostats to regulate system temperature. In macroscopic systems, heat that is generated from friction is dissipated rapidly from the surface to the bulk phonon modes. Because atomistic computer simulations are limited systems that are many orders of magnitude smaller than systems that are generally studied experimentally, thermostats are needed to prevent the system temperature from rising

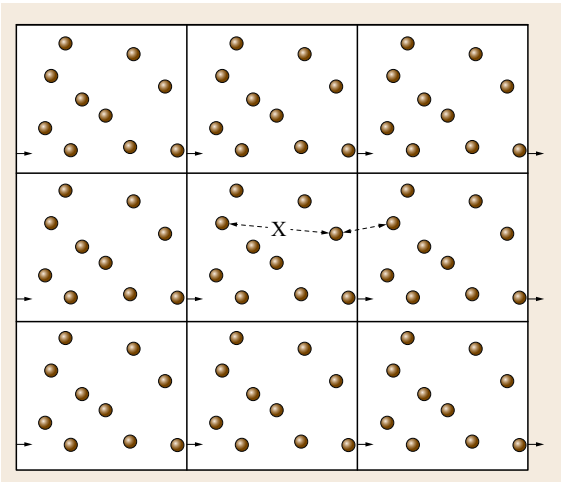

Fig. 30.1 Illustration of periodic boundary conditions consisting of a central simulation cell surrounded by replica systems. The *solid arrows* indicate an atom leaving the central box and reentering on the opposite side. The *dotted arrows* illustrate the minimum image convention

in a nonphysical manner. Typically in simulations of indentation or friction, the thermostat is applied to a region of the simulation cell that is well removed from the interface where friction and indentation is taking place. In this way, local heating of the interface that occurs as work is done on the system, but excess heat is efficiently dissipated from the system as a whole. In this manner the adjustment of atomic temperatures occurs away from the processes of interest, and simplified approximations for the friction term can be used without unduly influencing the dynamics produced by the interatomic forces.

There are several different formalisms for atomistic thermostats. The simplest of these controls the temperature by intermittently rescaling the atomic velocities to values corresponding to the desired temperature [30.90] such that

$$\left(\frac{\boldsymbol{v}_{\text{new}}}{\boldsymbol{v}_{\text{old}}}\right)^2 = \frac{T}{T_{\text{ins}}} , \tag{30.7}$$

where $\boldsymbol{v}_{\text{new}}$ is the rescaled velocity, and $\boldsymbol{v}_{\text{old}}$ is the velocity before the rescaling. This approach, which is called the velocity rescaling method, is both simple to implement and effective at maintaining a given temperature over the course of an MD simulation. It was consequently widely used in early MD simulations. The velocity rescaling approach does have some significant disadvantages, however. First, there is little theoretical basis for the adjustment of atomic velocities, and the system dynamics are not time-reversible, which is inconsistent with classical mechanics. Second, the rate and mode of heat dissipation are disconnected from system properties, which may affect system dynamics. Lastly, for typical MD simulation system sizes, the averaged quantities that are obtained, such as pressure for instance, do not correspond to values in any thermodynamic ensemble.

For these reasons, more sophisticated methods for maintaining system temperatures in MD simulations have been developed. The Langevin dynamics approach [30.48], which was originally developed from the theory of Brownian motion, falls into this category. In this approach, terms are added to the interatomic forces that correspond to a random force and a frictional term [30.46, 91, 92]. Therefore, Newton's equation of motion for atoms subjected to Langevin thermostats is given by the following equation rather than (30.1a) and (30.1b)

$$m\boldsymbol{a} = \boldsymbol{F} - m\xi\boldsymbol{v} + R(t) , \tag{30.8}$$

where $\boldsymbol{F}$ are the forces due to the interatomic potential, ξ is a friction coefficient, m and $\boldsymbol{v}$ are the particle's mass and velocity, respectively, and $R(t)$ is a random force that acts as *white noise*. The friction term can be formulated in terms of a memory kernal, typically for harmonic solids [30.93–95], or a friction coefficient can be approximated using the Debye frequency. The random force can be given by a Gaussian distribution where the width, which is chosen to satisfy the fluctuation-dissipation theorem, is determined from the equation

$$\langle R(0)R(t)\rangle = 2mk_{\text{B}}T\xi\delta(t) . \tag{30.9}$$

Here, the function R is the random force in (30.8), m is the particle mass, T is the desired temperature, k_{B} is Boltzmann's constant, t is time, and ξ is the friction coefficient. It should be noted that the random forces are uncoupled from those at previous steps, which is denoted by the delta function. Additionally, the width of the Gaussian distribution from which the random force is obtained varies with temperature. Thus, the Langevin approach does not require any feedback from the current temperature of the system as the random forces are determined solely from (30.9).

In the early 1980s, *Nosé* developed a new thermostat that corresponds directly to a canonical ensemble (system with constant temperature, volume and number of atoms) [30.96, 97], which is a significant advance from the methods described so far. In this approach, Nosé introduces a degree of freedom s that corresponds to the heat bath and acts as a time scaling factor, and adds a parameter Q that may be regarded as the heat bath *mass*. A simplified form of Nosé's method was subsequently implemented by *Hoover* [30.46] that eliminated the time scaling factor whilst introducing a thermodynamic friction coefficient ζ. Hoover's formulation of Nosé's method is therefore easy to use and is commonly referred to as the Nosé–Hoover thermostat.

When this thermostat is applied to a system containing N atoms, the equations of motion are written as (dots denote time derivatives)

$$\begin{aligned}
\dot{\boldsymbol{r}}_i &= \frac{\boldsymbol{p}_i}{m_i} , \\
\dot{\boldsymbol{p}}_i &= \boldsymbol{F}_i - \zeta\boldsymbol{p}_i , \\
\dot{\zeta} &= \frac{1}{Q}\left(\sum_{i=1}^{N}\frac{p_i^2}{m_i} - N_{\text{f}}k_{\text{B}}T\right) ,
\end{aligned} \tag{30.10}$$

where $\boldsymbol{r}_i$ is the position of atom i, $\boldsymbol{p}_i$ is the momentum and $\boldsymbol{F}_i$ is the force applied to each atom. The last equation in (30.10) contains the temperature control mechanism in the Nosé–Hoover thermostat. In particular, the term between the parentheses on the right-hand

side of this equation is the difference between the system's instantaneous kinetic energy and the kinetic energy at the desired temperature. If the instantaneous value is higher than the desired one, the friction force will increase to lower it and vice versa.

It should be pointed out that the choice of the heat bath *mass* Q is arbitrary but crucial to the successful performance of the thermostat. For example, a small value of Q leads to rapid temperature fluctuation while large Q values result in inefficient sampling of phase space. Nosé recommended that Q should be proportional to $N_f k_B T$ and should allow the added degree of freedom s to oscillate around its averaged value at a frequency of the same order as the characteristic frequency of the physical system [30.96, 97]. If ergodic dynamic behavior is assumed, the Nosé–Hoover thermostat will maintain a well-defined canonical distribution in both momentum and coordinate space. However, for small systems where the dynamic is not ergodic, the Nosé–Hoover thermostat fails to generate a canonical distribution. Therefore, more sophisticated algorithms based on the Nosé–Hoover thermostat have been proposed to fix its ergodicity problem; for example, the *Nosé–Hoover chain* method of *Martyna* et al. [30.98]. However, these complex thermostats are not as easy to apply as the Nosé–Hoover thermostat due to the difficult evaluation of the coupling parameters for each different case and the significant computational cost [30.99]. From a practical point of view, if the molecular system is large enough that the movements of the atoms are sufficiently chaotic, ergodicity is guaranteed and the performance of the Nosé–Hoover thermostat is satisfactory [30.25].

In an alternative approach, *Schall* et al. recently introduced a hybrid continuum-atomistic thermostat [30.100]. In this method, an MD system is divided into grid regions, and the average kinetic energy in the atomistic simulation is used to define a temperature for each region. A continuum heat transfer equation is then solved stepwise on the grid using a finite difference approximation, and the velocities of the atoms in each grid region are scaled to match the solution of the continuum equation. To help account for a time lag in the transfer of kinetic to potential energy, Hoover constraining forces are added to those from the interatomic potential. This process is continued, leading to an ad hoc feedback between the continuum and atomistic simulations. The main advantage of this approach is that the experimental thermal diffusivity can be used in the continuum expression, leading to heat transfer behavior that matches experimental data. For example, in metals the majority of the thermal properties at room temperature arise from electronic degrees of freedom that are neglected with strictly classical potentials. This thermostat is relatively straightforward to implement, and requires only the interatomic potential and the bulk thermal diffusivity as input. It is also appropriate for nonequilibrium heat transfer, such as occurs as heat is dissipated from sliding surfaces moving at high relative velocities. Other localized phenomena, such as Joule heating and melting in current carrying applications, can also be simulated by using a recent extension to the hybrid thermostat [30.101]. This modification allows the ability to model degradation of interfaces under high electrical load at the atomic level. Relevant examples are hot switched radio frequency MEMS and metal/metal contacts in electromagnetic launchers.

Cushman et al. [30.102, 103] developed a unique alternative to the grand canonical ensemble by performing a series of grand canonical Monte Carlo simulations [30.48, 104] at various points along a hypothetical sliding trajectory. The results from these simulations are then used to calculate the correct particle numbers at a fixed chemical potential, which are then used as inputs to nonsliding, constant-*NVE* MD simulations at each of the chosen trajectory points. The sliding speed can be assumed to be infinitely slow because the system is fully equilibrated at each step along the sliding trajectory. This approach offers a useful alternative to continuous MD simulations that are restricted to sliding speeds that are orders of magnitude larger than most experimental studies (about 1 m/s or greater).

To summarize, this section provides a brief review and description of components that are used in atomistic, molecular dynamics simulation of many of the processes related to friction, such as indentation, sliding, and wear. The components discussed here include the potential energy expression used to calculate energies and forces in the simulations, periodic boundary conditions and thermostats. Each of these components has their own strengths and weaknesses that should be well-understood both prior to their use and in the interpretation of results. For example, general principles related to liquid lubrication in confined areas may be most easily understood and generalized from simulations that use pair potentials and may not require a thermostat. On the other hand, if one wants to study the wear or indentation of a surface of a particular metal, then EAM or other semiempirical potentials, together with a thermostat, would be expected to yield more reliable results. If one requires information on electronic effects, ab initio or semi-empirical approaches that include the evaluation of electronic degrees of freedom must be used. Thus, the best combination of components for a particular study depends on the chemical nature of the system of interest, the processes being simulated, the type of information desired, and the available computational resources.

30.2 Indentation

It is critical to understand the nanometer-scale properties of materials that are being considered for use as new coatings with specific friction and wear behavior. Experimental determination of these properties is most frequently done with the AFM, which provides a variety of data related to the interaction of the microscope tips with the sample surface [30.105–107]. In AFM experiments, the tip has a radius of about 1−100 nm and is pressed against the surface under ambient conditions (in air), ultrahigh vacuum (UHV) conditions, or in a liquid. The microscope tip can either move in the direction normal to the surface, which is the case in nanoindentation studies, or raster across the surface, which is the case in surface imaging or friction studies. Sliding rates of 1 nm/s–1 μm/s are typically used, which are many orders of magnitude slower than the rates used in MD simulations of sliding or indentation of around 1−100 m/s. As discussed in the previous section, the higher rates used in computational simulations are a consequence of modeling full atomic motion, which occurs on a femto- to picosecond timescale, and the stepwise solution of the classical equations of motion, which makes the large number of simulation steps needed to reach experimental timescales computationally impossible with current processor speeds.

As the tip moves either normal to or across the surface, the forces acting upon it as a result of its interactions with the surface are measured. When the tip is moved in the surface normal direction, it can penetrate the surface on the nanometer scale and provide information on the nanometer-scale mechanical properties of the surface [30.108, 109]. The indentation process also causes the force on the tip to increase, and the rate of increase is related to both the depth of indentation and the properties of the surface. The region of the force curve that reflects this high force is known as the repulsive wall region [30.105], or, when considered without any lateral motion of the tip, an indentation curve. When the tip is retracted after indentation, enhanced adhesion between the tip and surface relative to the initial contact can result. This phenomenon is indicated by hysteresis in the force curve.

Tip–surface adhesion can result from the formation of chemical bonds between the tip and the sample, or from the formation of liquid capillaries between the microscope tip and the surface caused by the interaction of the tip with a layer of liquid contamination on the surface. The latter case is especially prevalent in AFM studies conducted in ambient environments. In the case of clean metallic systems, the sample can wet the tip or the tip can wet the sample in the form of a connective *neck* of metal atoms between the surface and the tip that can lead to adhesion. In the case of polymeric or molecular systems, entanglement of molecules that are anchored on the tip with molecules anchored on the sample can be responsible for force curve hysteresis.

In the case of horizontal rastering of AFM tips across surfaces, the force curve data provide a map of the surface that is indicative of the surface topography [30.110]. If the deflection of the tip in the lateral direction is recorded while the tip is being rastered, a friction map of the surface [30.20] is produced.

The rest of this section discusses some of the important insights and findings that have been obtained from MD simulations of nanoindentation. These studies have not only provided insight into the physical phenomena responsible for the qualitative shapes of AFM force curves, they have also revealed a wealth of atomic-scale phenomena that occur during nanoindentation that was not previously known.

30.2.1 Surfaces

The nature of adhesive interactions between clean, deformable metal tips indenting metal surfaces have been identified and clarified over the course of the last decade through the use of MD simulations [30.107, 111–115]. In particular, the high surface energies associated with clean metal surfaces can lead to strongly attractive interactions between surfaces in contact. The strength of this attraction can be so large that when the tip gets close enough to the surface to interact with it, surface atoms *jump* upwards to wet the tip in a phenomena known as jump-to-contact (JC). This wetting mechanism was first discovered in MD simulations [30.114] and has been confirmed experimentally [30.108, 116–118] using the AFM, as shown in Fig. 30.2.

The MD simulations of *Landman* et al. [30.114, 119–121] using EAM potentials revealed that the JC phenomenon in metallic systems is driven by the need of the atoms at the tip–surface interface to optimize their interaction energies while maintaining their individual material cohesive binding. When the tip advances past the JC point it indents the surface, which causes the force to increase. This behavior is indicated in Fig. 30.3, points D to M. This region of the computer-generated force curve has a maximum not present in the force curve generated from experimental data (Fig. 30.3, point L). This is due to tip-induced flow of the metal atoms in the surface that causes *pile-up* of the surface atoms around the edges of the indenter. Hysteresis on the withdrawal of the tip, shown in Fig. 30.3, points M to X, is present due to adhesion between the tip and the substrate. In particular, as the tip re-

tracts from the sample, a connective *neck* or nanowire of atoms forms between the tip and the substrate that is primarily composed of metal atoms from the surface with some atoms from the metal indenter that have diffused into the structure. A snapshot from the MD simulations that illustrates this behavior is shown in Fig. 30.4.

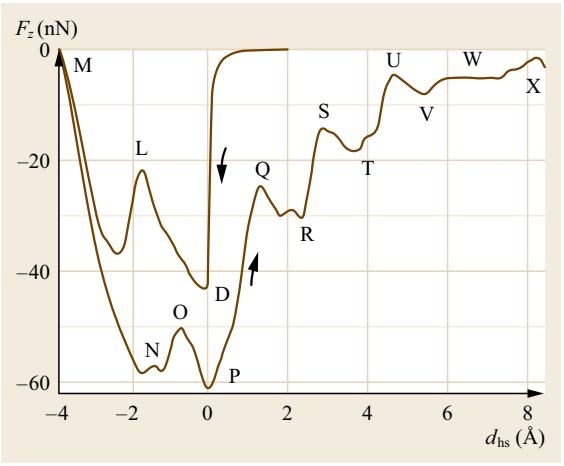

Fig. 30.3 Computationally derived force F_z versus tip-to-sample distance d_{hs} curves for approach, contact, indentation, then separation using the same tip–sample system shown in Fig. 30.4. These data were calculated from an MD simulation (after [30.114], © AAAS 1990)

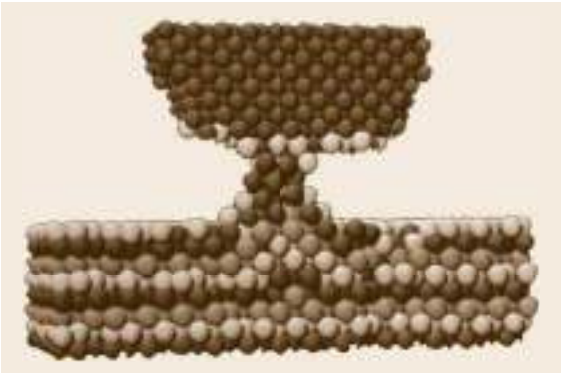

Fig. 30.4 Illustration of atoms in the MD simulation of a Ni tip being pulled back from an Au substrate. This causes the formation of a connective neck of atoms between the tip and the surface (after [30.114], © AAAS 1990)

As the tip is withdrawn farther, the magnitude of the force increases (becomes more negative) until, at a critical force, the atoms in adjacent layers of the connective nanowire rearrange so that an additional row of atoms is created. This process causes elongation of the connective nanowire and is responsible for the fine structure (apparent as a series of maxima) present in the retraction portion of the force curve. These elongation and rearrangement steps are repeated until the connection between the tip and the surface is broken. Similar elongation events have been observed experimentally. For example, scanning tunneling microscopy (STM) experiments demonstrate that the metal nanowires between

metal tips and surfaces can elongate ≈ 2500 Å without breaking [30.122].

The JC process has been shown to affect the temperature at the tip–surface interface. For instance, the constant-energy MD simulations of *Tomagnini* et al. [30.123] predicted that the energy released due to the wetting of the tip by surface atoms increases the temperature of the tip by about 15 K at room temperature and is accompanied by significant structural rearrangement. At temperatures high enough to cause the first few metal surface layers to be liquid, the distance at which the JC occurs increases, as does the contact area between the tip and the surface and the amount of nanowire elongation prior to breakage.

Simulations by *Komvopoulos* and *Yan* [30.124] using LJ potentials showed how metallic surfaces respond to single and repeated indentation by metallic, or covalently bound, rigid tips. The simulations predicted that a single indentation event produces hysteresis in the force curve as a result of surface plastic deformation and heating. The repulsive force decreases abruptly during surface penetration by the tip and surface plastic deformation. Repeated indentation results in the continuous decrease of the elastic stiffness, surface heating, and mean contact pressures at maximum penetration depths to produce behaviors that are similar to cyclic work hardening and softening by annealing observed in metals at the macroscale.

When the tip is much stiffer than the surface, pile-up of surface atoms around the tip occurs to relieve the stresses induced by nanoindentation. In contrast, when the surface is much stiffer than the tip, the tip can be damaged or destroyed. Simulations by *Belak* and *Stowers* [30.126] using perfectly rigid tips showed the mechanism by which the surface yields plastically after its elastic threshold is exceeded. The simulations showed how nanoindentation causes surface atoms to move on to the surface but under the tip and thus cause atomic pile-up. In this study, variations in the indentation rate reveal that point defects created as a result of nanoindentation relax by moving through the surface if the rate of indentation is slow enough. If the indentation rate is too high, there is no time for the point defects to relax and move away from the indentation area and so strain builds up more rapidly. The rigid indenters considered in these MD simulations are analogous to experiments that use surface passivation to prevent JC between the tip and the surface [30.125, 127], the results of which agree with the predicted results of pile-up and crater formation, as shown in Fig. 30.5 [30.125].

In short, MD simulations are able to explain the atomic-scale mechanisms behind measured experimental force curves produced when metal tips indent homogeneous metal surfaces to nanometer-scale depths. This preliminary work has spawned much of the current interest in using the JC to produce metal nanowires [30.128–130].

MD simulations have also been used to examine the relationship between nanoindentation and surface structure. This is most apparent in a series of computational studies that consider the indentation of a surface with a *virtual* hard-sphere indenter in a manner that is independent of the rate of indentation, as shown in Fig. 30.6. The virtual indenter is modeled through the application of a repulsive force to the surface rather than through the presence of an actual atomic tip. *Kelchner* et al. [30.131], rather than use MD, pushed the indenter against the surface a short distance and then allowed the system to relax using standard energy minimization methods in combination with EAM potentials. The

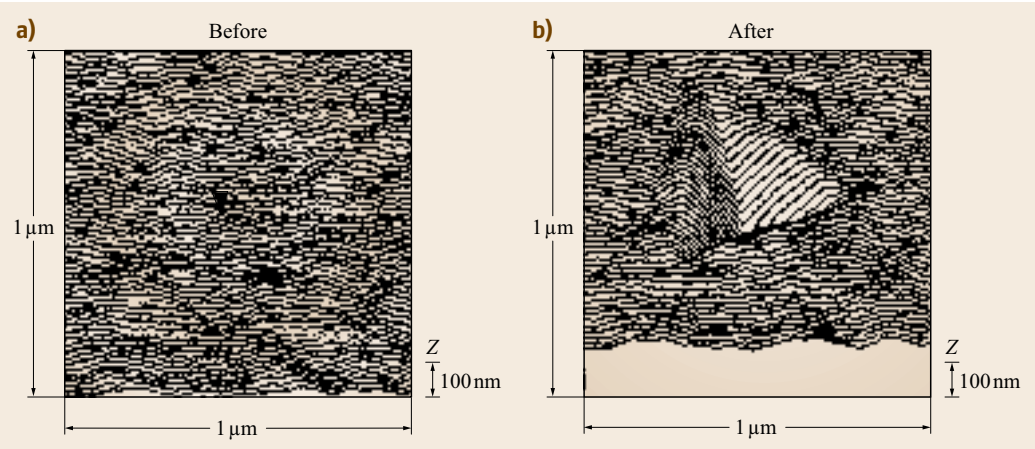

Fig. 30.5a,b Images of a gold surface *before* (**a**) and *after* (**b**) being indented with a pyramidal shaped diamond tip in air. The indentation created a surface crater. Note the pile-up around the crater edges (after [30.125], © Elsevier 1993)

system is fully relaxed when the energy of the surface system is minimized. After relaxation, the tip is pushed further into the surface and the process is repeated. As the tip generates more stresses in the surface, dislocations are generated and plastic deformation occurs. If the tip is pulled back after indenting less than a specific critical value, the atoms that were plastically deformed are healed during the retraction and the surface recovers its original structure. In contrast, if the tip is indented past the critical depth, additional dislocations are created that interfere with the surface healing process on tip withdrawal. In this case, a surface crater is left on the surface following nanoindentation.

A similar study by *Lilleodden* et al. [30.132] considered the generation of dislocations in perfect crystals and near grain boundaries in gold. Analysis of the relationship between the load and the tip displacement in the perfect crystal shows discrete load drops followed by elastic behavior. These load drops are shown to correspond to the homogeneous nucleation of dislocations, as illustrated in Fig. 30.7, which is a snapshot taken just after the load drop. When nanoindentation occurs close to a grain boundary, similar relationships between the load and tip displacement are predicted to occur as were seen for the perfect crystal. However, the dislocations responsible for the load drop are preferentially emitted from the grain boundaries, as illustrated in Fig. 30.8.

Simulations can also show how atomic structure and stresses are affected by nanoindentation. For instance, MD simulations with a virtual indenter by *Hasnaoui* et al. [30.133] using semi-empirical tight-binding methods showed the interaction between the grain boundaries under the indenter and the dislocations generated by the indentation, as illustrated in Fig. 30.9. This study shows that if the size of the indenter is smaller than the grain size, the grain boundaries can emit, absorb, and reflect the dislocations in a manner that depends on atomic structure and the distribution of stresses.

Fig. 30.7 Snapshot of two partial dislocations separated by a stacking fault. The *dark spheres in the center* of the structure indicate atoms in perfect crystal positions after both partial dislocations have passed (after [30.132], © Elsevier 1993)

Fig. 30.8 Snapshot of the high-energy atoms only after a load drop caused by dislocation generation during the nanoindentation of gold near a grain boundary (after [30.132], © Elsevier 1993)

Zimmerman et al. considered the indentation of a single-crystal gold substrate both near and far from a surface step [30.134]. The results of these simulations, which used EAM potentials, showed that the onset of plastic deformation depends to a significant degree on the distance of indentation from the step, and whether the indentation is on the plane above or below the step. In a related set of simulations, *Shenderova* et al. [30.135] examined whether ultrashallow elastic nanoindentation can nondestructively probe surface stress distributions associated with surface structures

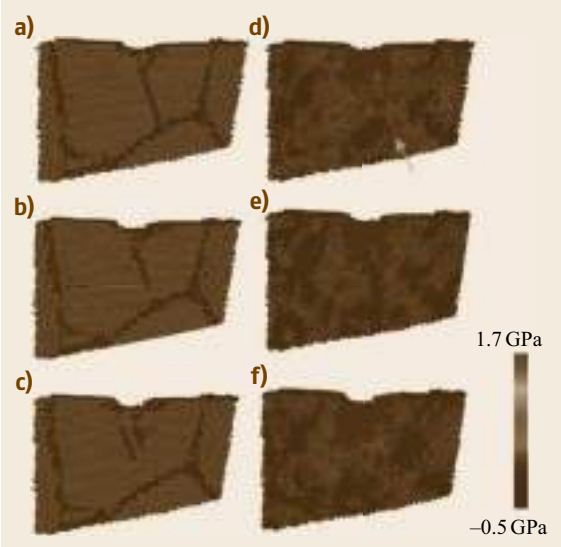

Fig. 30.9a–d Snapshots showing the atomic stress distribution and atomic structures in a gold surface. Figures **(a–c)** show the atomic structure at indentation depths of 7.9, 8.6, and 9.6 Å, respectively, with a virtual spherical indenter. A dislocation is represented by the two parallel {111} planes (*two dark lines*) that show the stacking fault left behind after the leading partial dislocation has passed. Figures **(d–f)** show the atomic stress distribution of the same system at the same indentation depths. Here the *dark color* indicates compressive hydrostatic pressures of 1.7 GPa and higher while the *gray* color indicates tensile pressures of -0.5 GPa and lower. Fig. 30.10a,b Data and system illustration from a simulation of a gold surface containing a dislocation. **(a)** Maximum load for simulated shallow indentation at several points along the *dotted line* in the bottom illustration. **(b)** Top view of the simulated surface. The dislocation is denoted by the *solid black lines*

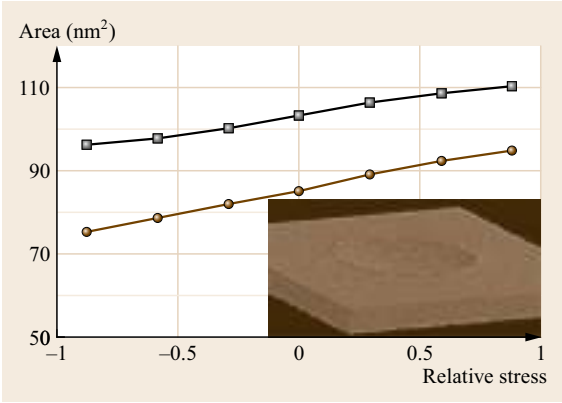
such as a trench and a dislocation intersecting a surface. The simulations carried out the nanoindentation to a constant depth. They predicted maximum loads that reflect the in-plane stresses at the point of contact between the indenter and the substrate, as illustrated in Fig. 30.10.

Since the 1930s, studies have been performed using hardness measurement techniques [30.136–139] and indentation methods [30.140] that suggest that the hardness of a material depends on applied in-plane uni- and bi-axial strain. In general, tensile strain appeared to decrease hardness while increases in hardness under compressive in-plane strain were reported. This behavior had traditionally been attributed to the contribution of stresses from the local strain from the indentation to the resolved shear stresses and the in-plane strain [30.137, 139]. However, in 1996, *Pharr* and coworkers determined that changes in elastic modulus determined from unloading curves of strained substrates using contact areas estimated via an elastic model are too large to have physical significance, a result that brought into question the interpretation of prior hardness data [30.140, 141]. They hypothesized that the apparent change in modulus (and hardness) with in-plane strain is mainly due to changes in contact area that are not typically taken into consideration in elastic half-space models. This hypothesis was based on experimental nanoindentation studies of a strained polycrystalline aluminum alloy and finite element calculations on an isotropic solid [30.140, 141]. They further suggested that in-plane compression increases pile-up around the indenter that, when not taken into account in the analysis of unloading curves, implies a nonphysical increase in modulus. Likewise, they suggested that in-plane tensile strain reduces the amount of material that is piled up around an indenter, which leads to a corresponding reduced (nonphysical) modulus when interpreting unloading curves using elastic models.

To explore in more detail the issue of pile-up and its influence on the interpretation of loading curves, *Schall* and *Brenner* used MD simulations and EAM potentials to model the plastic nanoindentation of a single-crystal



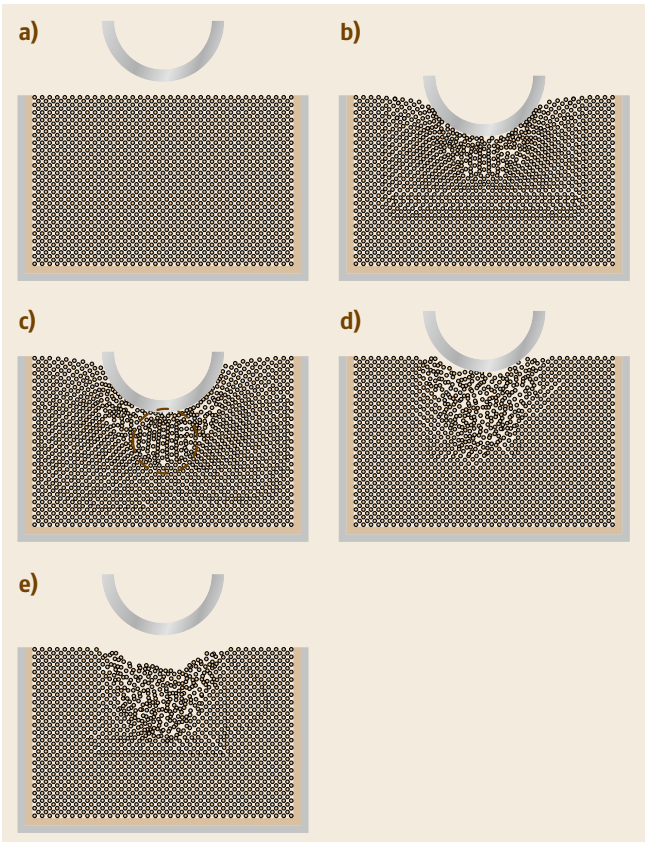


Fig. 30.11 Contact area projected in the plane at a maximum load for simulated indention of a gold surface as a function of in-plane biaxial stress. The stress is normalized to the theoretical yield stress. The *top curve* is from an atomistic simulation; the *bottom curve* is from an elastic model. *Inset*: Illustration of the region near the indention from the simulation. The tip is not shown for clarity. Initial formation of pile-up around the edge of the indentation is apparent

gold surface under an applied in-plane strain [30.142]. These simulations predicted that the mean pressure, calculated from true contact areas that take into account plastic pile-up around the indenter, varies only slightly with applied pre-stress. They also predicted that the higher values occur in compression rather than in tension, and that the modulus calculated from the true contact area is essentially independent of the pre-stress level in the substrate. In contrast, if the contact area is estimated from approximate elastic formulae, the contact area is underestimated, which leads to a strong, incorrect dependence of apparent modulus on the pre-stress level. The simulations also showed larger pile-up in compression than in tension, in agreement with the Pharr model, and both regimes produced contact areas larger than those typically assumed in elastic analyses. These findings are illustrated in Fig. 30.11.

Nanometer-scale indentation of ceramic systems has also been investigated with MD simulations. Ceramics are stiffer and more brittle than metals at the macroscale and examining the nanoindentation of ceramic surfaces provides information about the nanometer-scale properties. They also reveal the manner by which defects form in covalent and ionic materials. For example, *Landman* et al. [30.113, 143] considered the interaction of a CaF_2 tip with a CaF_2 substrate in MD simulations using empirical potentials. As the tip approaches the surface, the attractive force between them steadily increases. This attractive force increases dramatically at the critical distance of 2.3 Å as the interlayer spacing of the tip increases (the tip is elongated) in a process that is similar to the JC phenomenon observed in metals. An important difference, however, is the amount of elongation, which is 0.35 Å in the case of the ionic ceramics and several angstroms in the case of metals. As the distance between the tip and the surface decreases further, the attractive nature of their interaction increases until a maximum value is reached. Indentation beyond this point results in a repulsive tip–substrate interaction, compression of the tip, and ionic bonding between the tip and substrate. These bonds are responsible for the hysteresis predicted to occur in

the force curve on retraction, which ultimately leads to plastic deformation of the tip followed by fracture.

The responses of covalently bound ceramics such as diamond and silicon to nanoindentation have been heavily studied with MD simulations. One of the first of these computational studies was carried out by *Kallman* et al. who used the Stillinger–Weber potential to examine the indentation of amorphous and crystalline silicon [30.144]. The motivation for this study came from experimental data that indicated a large change in electrical resistivity during indentation of silicon, which led to the suggestion of a load-induced phase transition below the indenter. *Clarke* et al., for example, reported forming an Ohmic contact under load, and using transmission electron microscopy they observed an amorphous phase at the point of contact after indentation [30.147]. Using micro-Raman microscopy, *Kailer* et al. identified a metallic β-Sn phase in silicon near the interface of a diamond indenter during hardness loading [30.148]. Furthermore, upon rapid unloading they detected amorphous silicon as in the *Clarke* et al. [30.147] experiments, while slow unloading resulted in a mixture of high-pressure polymorphs near the indent point. At the highest indentation rate and the lowest temperature, the simulations by *Kallman* et al. [30.144] showed that amorphous and crystalline silicon have similar yield strengths of 138 and 179 kbar, respectively. In contrast, at temperatures near the melting temperature and at the slowest indentation rate, both amorphous and crystalline silicon are predicted to have lower yield strengths of 30 kbar. The simulations thus show how the predicted yield strength of silicon at the

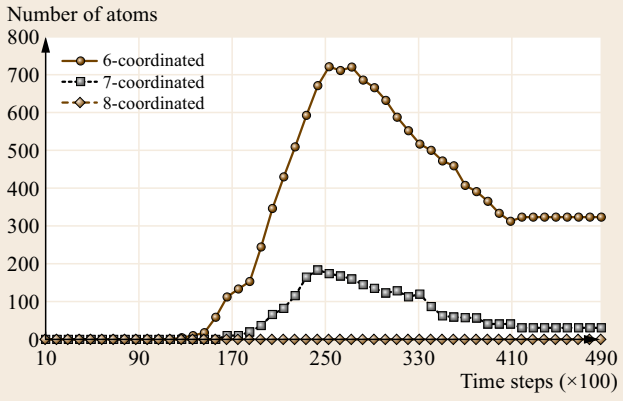

Fig. 30.13 The coordination of the silicon atoms shown in Fig. 30.12 as a function of time during nanoindentation (after [30.145], © IOP 2000)

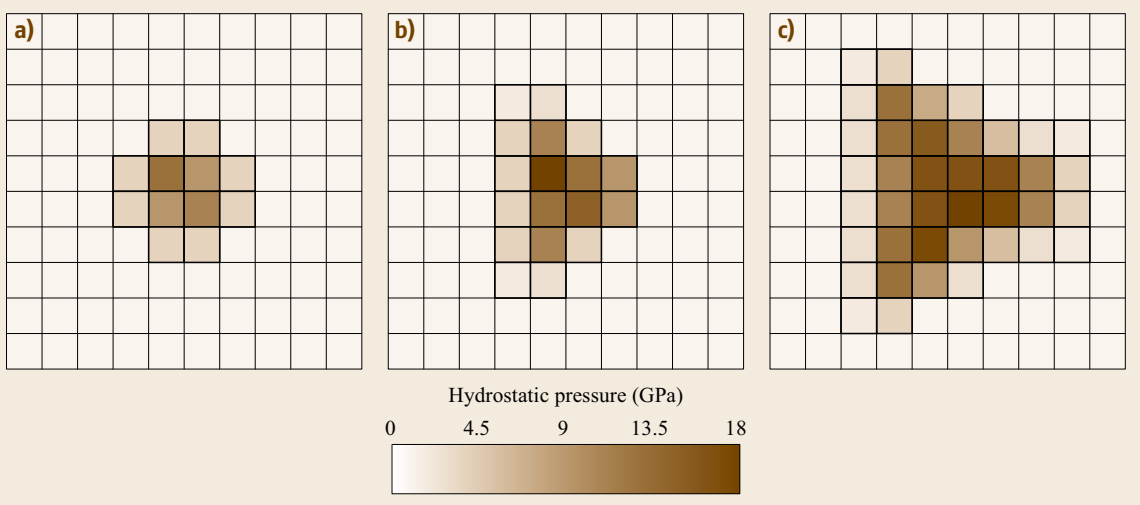

Fig. 30.14a–c Calculated hydrostatic pressure of surface cells at indentation depths of **(a)** 8.9 Å, **(b)** 15.7 Å, and **(c)** 25.3 Å (after [30.146], © IOP 2000)

nanometer scale depends on structure, rate of deformation, and surface temperature.

Interestingly, *Kallman* et al. [30.144] found that amorphous silicon does not crystallize upon indentation, but indentation of crystalline silicon at temperatures near the melting point transforms the surface structure near the indenter to the amorphous phase. The simulations do not predict transformation to the β-Sn structure under any of the conditions considered. These results agree with the outcomes of scratching experiments [30.151] that showed that amorphous silicon emerges from room-temperature scratching of crystalline silicon.

The *left-hand side* shows the surface when it is fully loaded, while the *right-hand side* shows the surface after the tip has been withdrawn (after [30.149], © AIOP 2003)

Kaxiras and coworkers revisited the silicon nanoindentation issue using a quasi-continuum model that couples interatomic forces from the Stillinger–Weber potential to a finite element grid [30.152]. They report good agreement between simulated loading curves and experiment provided that the curves are scaled by the indenter size. Rather than the β-Sn structure, however, atomic displacements suggest formation of a metallic structure with fivefold coordination below the indenter upon loading, and a residual simple cubic phase near the indentation site after the load is released rather than the mix of high-pressure phases characterized experimentally. Smith et al. attribute this discrepancy to shortcomings of the Stillinger–Weber potential inadequately describing the high-pressure phases of silicon. They also used a simple model for changes in electrical resistivity with loading involving contributions from both a Schottky barrier and spreading resistance. Simulated resistance-versus-loading curves agree well with experiment despite possible discrepancies between the high-pressure phases under the indenter, suggesting that the salient features of the experiment are not dependent on the details of the high-pressure phases produced.

Additional MD simulations of the indentation of silicon were carried out by *Cheong* and *Zhang* [30.145]. Their simulations provide further details about the phase transformations that occur in silicon as a result of nanoindentation. In particular, they find that the diamond cubic silicon is transformed into a body-centered tetragonal structure (β-Si) upon loading of the indenter, as illustrated in Fig. 30.12. Figure 30.13 shows that the coordination numbers of silicon atoms also coincide with that of the theoretical β-Si structure. The body-centered tetragonal structure is transformed into

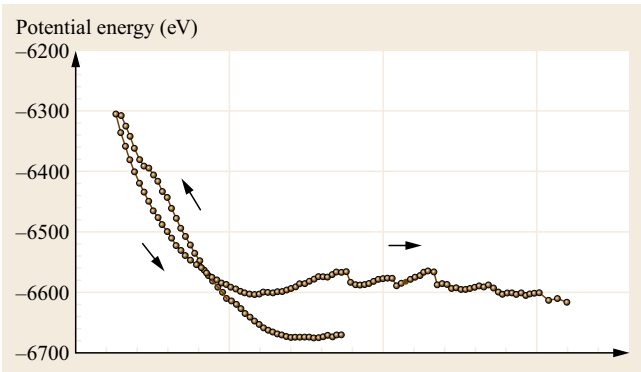

Fig. 30.16 Potential energy as a function of rigid-layer separation generated from an MD simulation of an elastic (nonadhesive) indentation of a hydrogen-terminated diamond (111) surface using a hydrogen-terminated, sp^3-hybridized tip (after [30.150], © Elsevier 1992)

amorphous silicon during the unloading stage. A second indentation simulation again predicted that that this is a reversible process. Atomistic simulations by *Sanz-Navarro* et al. [30.146] shows the relation between the indentation of silicon and the hydrostatic pressure on surface cells due to the nanoindentation, as illustrated in Fig. 30.14. These simulations further predict that the transformation of diamond silicon into the β-Si structure can occur if the hydrostatic pressure is somewhat over 12 GPa.

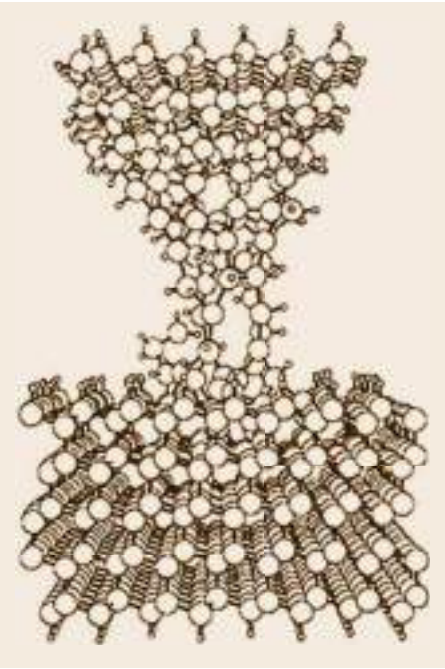

Fig. 30.17 Illustration of atoms in the MD simulation of the indentation of a hydrogen-terminated diamond (111) substrate with a hydrogen-terminated, sp^3-hybridized tip at selected time intervals. The figure illustrates the tip–substrate system as the tip was being withdrawn from the sample. *Large* and *small spheres* represent carbon and hydrogen atoms, respectively (after [30.150], © Elsevier 1992)

Multimillion atom simulations of the indentation of silicon nitride were recently carried out by *Walsh* et al. [30.149]. The elastic modulus and hardness of the surface was calculated using load–displacement relationships. Snapshots from the simulations, illustrated in Fig. 30.15, show that pile-up occurs on the surface along the edges of the tip. Plastic deformation of the surface is predicted to extend a significant distance beyond the actual contact area of the indenter, as illustrated in Fig. 30.15.

The indentation of bare and hydrogen-terminated diamond (111) surfaces beyond the elastic limit was investigated by *Harrison* et al. [30.150] using a hydrogen-terminated sp^3-bonded tip in MD simulations that utilized bond-order potentials. The simulations identified the depth and applied force at which the diamond (111) substrate incurred plastic deformation due to indentation. At low indentation forces, the tip–surface interaction is purely elastic, as illustrated in Fig. 30.16. This finding agrees with the findings of *Cho* and *Joannopoulos* [30.153], who examined the atomic-scale mechanical hysteresis experienced by an AFM tip indenting Si(100) with density functional theory. The calculations predicted that at low rates it is possible to cycle repeatedly between two buckled configurations of the surface without adhesion.

When the nanoindentation process of diamond (111) is plastic, connective strings of atoms are formed between the tip and the surface, as illustrated in Fig. 30.17. These strings break as the distance between the tip and crystal increases and each break is accompanied by a sudden drop in the potential energy at large positive values of tip–substrate separation. The simulations further predict that the tip end twists to minimize interatomic repulsive interactions between the hydrogen atoms on the surface and the tip. This behavior is

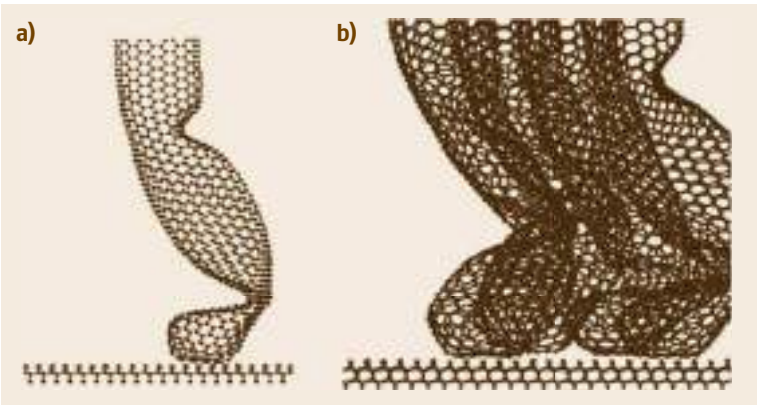

Fig. 30.18a,b Snapshots of the indentation of a single-wall nanotube **(a)** and a bundle of nanotubes **(b)** on hydrogen-terminated diamond (111)

predicted to lead to new covalent bond formation between the tip and the carbon atoms below the first layer of the surface and connective strings of atoms between the tip and the surface when the tip is retracted. Not surprisingly, when the surface is bare and not terminated with hydrogen atoms, the repulsive interactions between the tip and the surface are minimized and the tip indents the substrate without twisting [30.150]. Because carbon–carbon bonds are formed between the tip and the first layer of the substrate, the indentation is ordered (the surface is not disrupted as much by interacting with the tip) and the eventual fracture of the tip during retraction results in minimal damage to the substrate. The concerted fracture of all bonds in the tip gives rise to a single maximum in the potential versus distance curve at large distances.

Harrison et al. [30.154, 155] and *Garg* et al. [30.156, 157] considered the indentation of hydrogen-terminated diamond and graphene surfaces with AFM tips of carbon nanotubes and nanotube bundles using MD simulations and bond-order potentials. Tips consisting of both single-wall nanotubes and multiwall nanotubes were considered. The simulations predicted that nanotubes do not plastically deform during tip crashes on these surfaces. Rather, they elastically deform, buckle, and slip as shown in Fig. 30.18. However, as is the case for diamond tips indenting reactive diamond surfaces discussed above, strong adhesion can occur between the nanotube and the surface that destroys the nanotube in the case of highly reactive surfaces, as illustrated in Fig. 30.19.

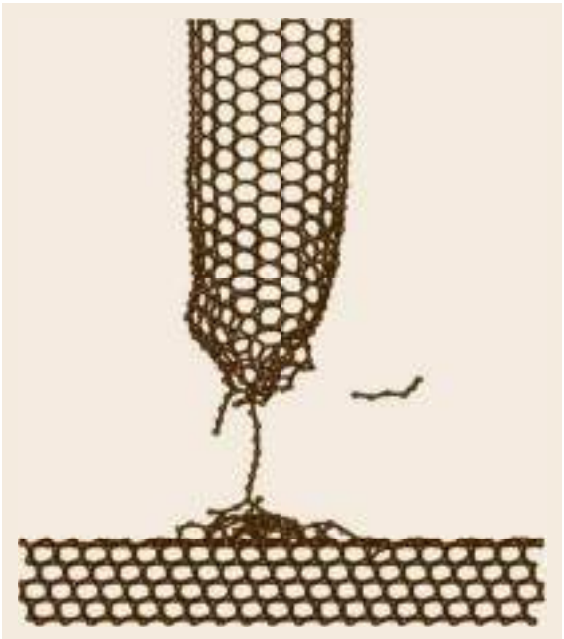

Fig. 30.19 Snapshot of a single-wall carbon nanotube as it is withdrawn following indentation on a bare diamond (111) surface (after [30.156], © APS 1999)

To summarize, MD simulations reveal the properties of ceramic tips and surfaces with covalent or ceramic bonding that are most important for nanometer-scale indentation. They predict that brittle fracture of the tip can occur that is sometimes accompanied by strong adhesion with the surface. They also reveal the conditions under which neither the tip nor the surface is affected by the nanoindentation process. The insight gained from these simulations helps in the interpretation of experimental data, and it also reveals the nanometer-scale mechanisms by which, for example, tip buckling and permanent modification of the surface occur.

30.2.2 Thin Films

In many instances, surfaces are covered with thin films that can range in thickness from a few atomic layers to several μm. These films are more likely to have properties that differ from the properties of bulk materials of similar composition, and the likelihood of this increases as the film thickness decreases. Nanoinden-

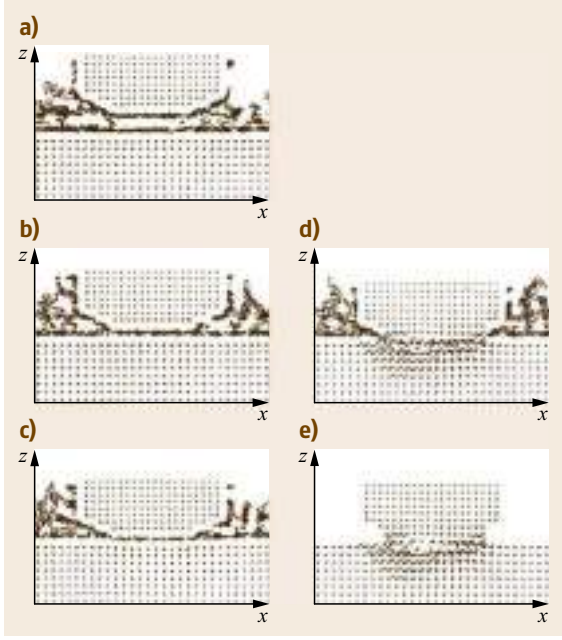

Fig. 30.20a–e Cutaways of the side view from molecular dynamics simulations of a Ni tip indenting a Au(001) surface covered with a hexadecane film. In (e) only the metal atoms are shown. Note how the hexadecane is forced out from between the metal surfaces (after [30.113], © Elsevier 1995)

tation is one of the best approaches to determining the properties of these films. Consequently, numerous computational simulations of this process have been carried out.

For example, MD simulations have been used to study the indentation of metal surfaces covered with liquid *n*-hexadecane films, as illustrated in Fig. 30.20. As the metal tip touches the film, some of the molecules from the surface transfer to the tip and this causes the film to *swell*. As the tip continues to push against the surface, the hydrocarbon film wets the side of the tip. The simulations show how the hydrocarbon film passivates the surface and prevents the strong attractive interactions discussed above for clean metal surfaces and tips from occurring.

In a series of MD simulations, *Tupper* and *Brenner* modeled the compression of a thiol self-assembled monolayer (SAM) on a rigid gold surface using both a smooth compressing surface [30.158] and a compressing surface with an asperity [30.159]. These simulations showed that compression with the smooth surface produced a compression-induced structural change that led to a change in slope of the simulated force versus compression curve. This transition is reversible and involves a change in the ordered arrangement of the sulfur head groups on the gold surface. A similar change in slope seemed to be present in the experimental indentation curves of *Houston* and coworkers [30.160], but was not discussed by the authors. The simulations with the asperity showed that the asperity is able to penetrate the tail groups of the SAM, as illustrated in Fig. 30.21, before an appreciable load is apparent on the compressing surface. This result indicates that it is possible to image the head groups of a thiol self-assembled monolayer that are adsorbed onto the surface of a gold substrate using STM, and consequently ordered images of these systems may not be indicative of the arrangement of the tail groups.

Zhang et al. [30.161] used a hybrid MD simulation approach, where a dynamic element model for the AFM cantilever was merged with a MD relaxation approach for the rest of the system, to study the frictional properties of alkanethiol SAMs on gold. They investigated the effect of several variables like chain length, terminal group, scan direction, and scan velocity. Their results show that friction forces decrease as the chain length of the SAMs increase. In the case of shorter chains such as C_7CH_3, the SAMs near the tip can be deformed by indentation, as illustrated in Fig. 30.22. This behavior is predicted to be the cause of higher friction that occurs for the short-length chains.

Harrison and coworkers have used classical MD simulations [30.155, 162] to examine the indentation of monolayers composed of linear hydrocarbon chains that are chemically bound (or anchored) to a diamond substrate. Both flexible and rigid single-wall, capped nanotubes were used as tips. The simulations showed that indentation causes the ordering of the monolayer to be disrupted regardless of the type of tip used. Indentation results in the formation of gauche defects within the monolayer and, for deep indents, results in the pinning of selected hydrocarbon chains beneath the tube. Flexible nanotubes tilt slightly as they begin to indent the softer monolayers. This small distortion is due to the fact that nanotubes are stiff along their axial direction and more flexible in the transverse direction. In contrast, when the nanotubes encounter the hard diamond substrate, after *pushing* through the monolayer, they buckle. This process is illustrated in Fig. 30.23 and the force curves are shown in Fig. 30.24. The buckling of the nanotube was previously observed when single-wall, capped nanotubes were brought into contact with hydrogen-terminated diamond (111) surfaces [30.154, 156]. In the absence of the monolayer, the nanotube tips encounter the hard substrate in an almost vertical position. This interaction with the diamond substrate causes the cap of the nanotubes to be *pushed* inside the nanotube (they invert). Increasing the load on the nanotubes causes the walls of the tube to buckle. Both the cap inversion and the buckling are reversible processes. That is, when the load on the tube is removed, it recovers its original shape.

Deep indents of the hydrocarbon monolayers using rigid nanotubes result in rupture of chemical bonds. The

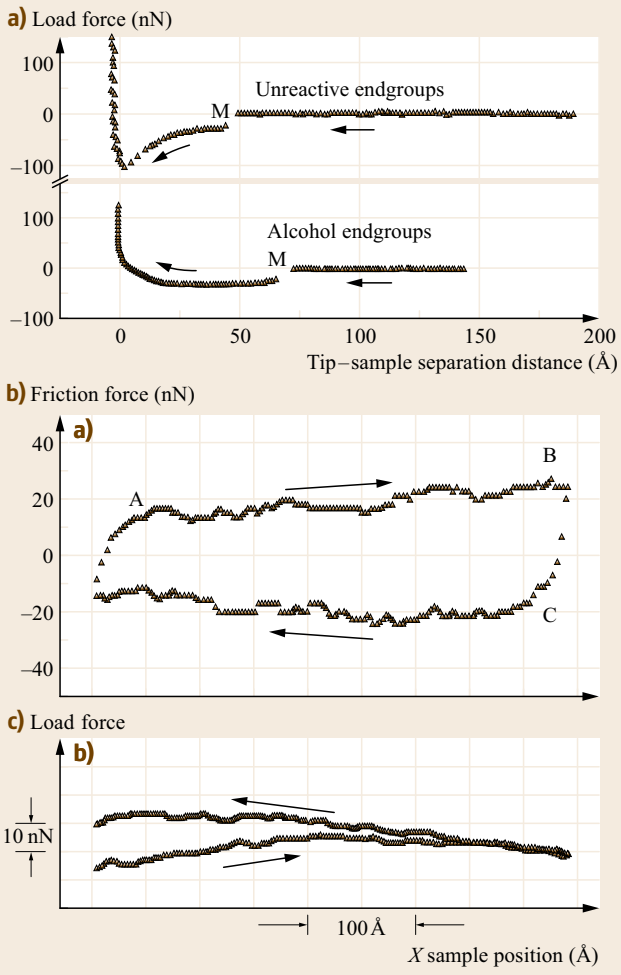
simulations also show that the number of gauche defects generated by the indentation is a linear function of penetration depth and equal for C_{13} and C_{22} monolayers. Thus, it is the tip that governs the number of gauche defects generated.

Leng and *Jiang* [30.163] investigated the effect of using tips coated with SAMs containing hydrophobic methyl (CH_3) or hydrophilic hydroxyl (OH) terminal groups to nanoindent gold surfaces that also are covered with SAMs with the identical terminal groups as the tip. Figure 30.25 contains snapshots for the indentation process predicted to occur for terminal OH/OH interactions during compression and the pull-off. The adhesion force of OH/OH pairs is calculated to be about four times larger than that of CH_3/CH_3 pairs, as shown in Fig. 30.26. This is due to the formation of hydrogen bonding between OH/OH pairs. This interaction is also expected to increase the frictional force between monolayers with OH terminations.

Related MD simulations by *Mate* predict that the end groups on polymer lubricants have a significant influence on the lubrication properties of polymers [30.164]. For instance, fluorinated end groups are predicted to be less reactive than regular alcohol end groups. When fluorinated films are indented, the normal force becomes more attractive as the distance between the tip and film decreases until the hard wall limit is reached and the interactions become repulsive. In contrast, when AFM tips indent hydrogenated films, the forces become increasingly repulsive as the distance between them decreases, as shown in Figs. 30.27 and 30.28. This predicted behavior is due to the compression of the end group beneath the tip. For the lubricant molecules to be squeezed out from between the tip and the surface, the hydrogen bonding between the two must first be broken and this increases the force needed to indent the system. As a result, a major effect of the presence of alcohol end groups is to dramatically increase the load that a liquid lubricant can support before failure (solid–solid contact) occurs.

When atomically sharp tips are used to indent solid-state thin films where there is a large mismatch in the mechanical properties of the film and the substrate, it is difficult to determine the true contact area between the tip and the surface during nanoindentation. In the case of soft films on hard substrates, pile-up can occur around the tip that effectively increases the contact area. In contrast, with hard films on soft substrates, *sink-in* is



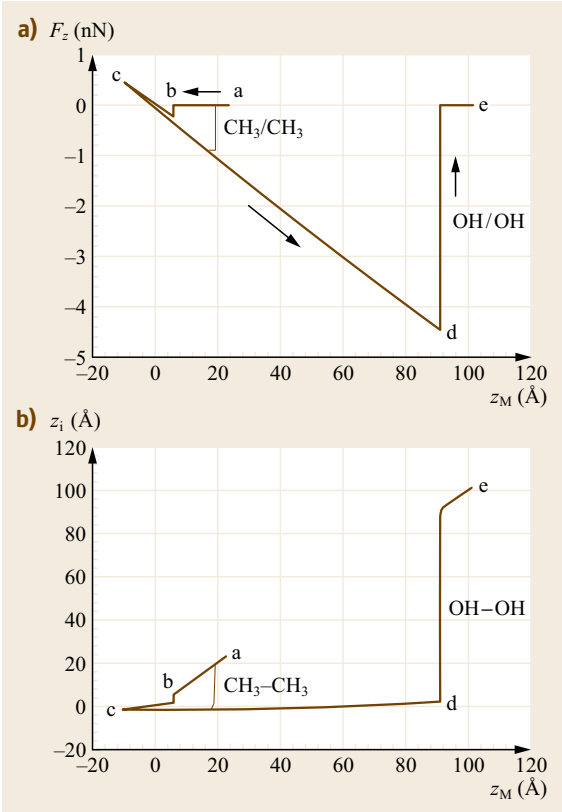


Fig. 30.26 **(a)** The force versus distance curve (indentation part only) for unbonded perfluoropolyether on Si(100). The unreactive end groups were from a 10 Å-thick film; the reactive alcohol end groups were from a 30 Å-thick film. experienced around the tip that decreases the true contact area.

A class of coatings that has received much attention is diamondlike amorphous carbon (DLC) coatings. DLC coatings are almost as hard as crystalline diamond and may have very low friction coefficients (< 0.01) depending upon the growth conditions [30.165–168]. They have therefore generated much interest in the tribological community and there have been several MD simulation studies to determine the mechanical and atomic-scale frictional properties of DLC coatings. MD simulations with bond-order potentials by *Sinnott* et al. [30.169] examined the differences in indentation behavior of a hydrogen-terminated diamond tip on hydrogen-terminated single-crystal diamond surfaces and diamond surfaces covered with DLC. In the former case, the tip goes through shear and twist deformations at low loads that change to plastic deformation and adhesion with the surface at high loads. When the surface is covered with the DLC film, the tip easily penetrates the film, as illustrated in Fig. 30.29, which *heals* easily when the tip is retracted so that no crater or other evidence of the indentation is left behind.

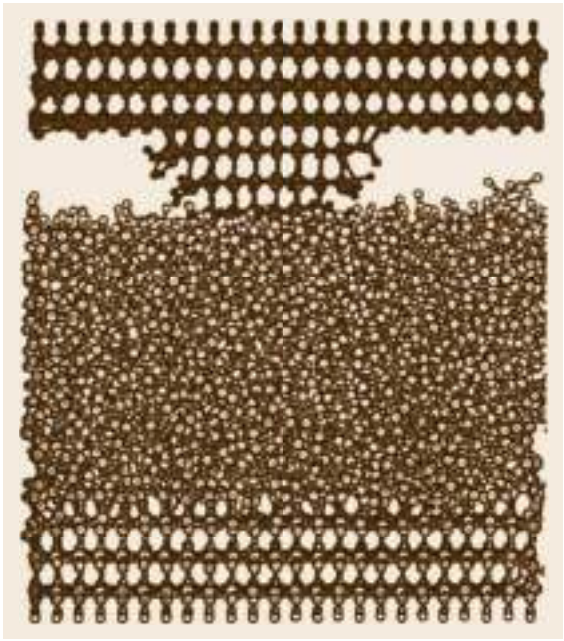

Fig. 30.29 Snapshot from a molecular dynamics simulation where a pyramidal diamond tip indented an amorphous carbon thin film that is 20 layers thick. The simulation took place at room temperature and the carbon atoms in the film were 21% sp^3-hybridized and 58% sp^2-hybridized (the remaining atoms were on the surface and were not counted) (after [30.169], © AIP 1997) ◄

MD simulations by *Glosli* et al. [30.170] of the indentation of DLC films that are about 20 nm-thick give similar results. In this case a larger, rigid diamond tip was used in the indentations and was also slid across the surface. During sliding, the tip plows the surface, which causes some changes to the film not seen during indentation. However, because the tip is perfectly rigid, adhesion between the film and surface is not allowed which influences the results.

This section shows that repulsive interactions between surfaces covered with molecular films and proximal probe tips are minimized relative to interactions between bare surfaces and indentation tips. The lubrication properties of polymers and SAMs can vary with chain length, the rigidity of the tip, and the chemical properties of the end groups. In some cases, indentations can disrupt the initial ordering of polymers and SAMs, which affects their responses to nanoindentation and friction.

30.3 Friction and Lubrication

Work is required to slide two surfaces against one another. When the work of sliding is converted to a less ordered form, as required by the first law of thermodynamics, friction will occur. For instance, if the two surfaces are strongly adhering to one another, the work of sliding can be converted to damage that extends beyond the surfaces and into the bulk. If the adhesive force between the two surfaces is weaker, the conversion of work results in damage that is limited to the area at or near the surface and produces transfer films or wear debris [30.171, 172]. While the thermodynamic principles of the conversion of work to heat are well known, the mechanisms by which this takes place at sliding surfaces are much less well established despite their obvious importance for a wide variety of technological applications.

Atomic-scale simulations of friction are therefore important tools for achieving this understanding. They have consequently been applied to numerous materials in a wide variety of structures and configurations, including atomically flat and atomically rough diamond surfaces [30.173–175], rigid substrates covered with monolayers of alkane chains [30.176], perfluorocarboxylic acid and hydrocarboxylic Langmuir–Blodgett (L–B) monolayers [30.177], between contacting copper surfaces [30.178, 179], between a silicon tip and a silicon substrate [30.119, 143], and between contacting diamond surfaces that have organic molecules absorbed on them [30.180]. These and several other studies are discussed below.

30.3.1 Bare Surfaces

Sliding friction that takes place between two surfaces in the absence of lubricant is termed *dry* friction even if the process occurs in an ambient environment. Simple models have been developed to model dry sliding friction that, for example, consider the motion of a single atom over a monoatomic chain [30.181]. Results from these models reveal how elastic deformation of the substrate from the sliding atom affects energy dissipation and how the average frictional force varies with changes in the force constant of the substrate in the direction normal to the scan direction. Much of the correct behavior involved in dry sliding friction is captured by these types of simple models. However, more detailed models and simulations, such as MD simulations, are required to provide information about more complex phenomena.

MD simulations have been used to study the sliding of metal tips across clean metal surfaces by numerous groups [30.179, 182–186]. An illustrative case is shown in Fig. 30.30 for a copper tip sliding across a copper surface [30.179]. Adhesion and wear occur when the attractive force between the atoms on the tip and the atoms at the surface becomes greater than the attractive forces within the tip itself. Atomic-scale stick and slip can occur through nucleation and subsequent motion of dislocations, and wear can occur if part of the tip gets left behind on the surface (Fig. 30.30). The simulations can further provide data on how the characteristic *stick–slip* friction motion can depend on the area of contact, the rate of sliding, and the sliding direction (Fig. 30.31).

An additional study of stick–slip in the sliding of much larger, square-shaped metal tips across metal surfaces was carried out by *Li* et al. [30.187] using EAM potentials. The initial structure of a NiAl tip and surface system is shown in Fig. 30.32. This study predicted that collective elastic deformation of the surface layers in response to sliding is the main cause of the stick–slip behavior shown in Fig. 30.33. The simulations also predicted that stick–slip produces phonons that propagate through the surface slab.

Large-scale simulations using pairwise Morse potentials that are similar in form to (30.6) were used to study the wear of metal surfaces caused by metal tips that plow the surface, as illustrated in Fig. 30.34. They provide insight into the wear track dependence of the sliding rate [30.188] and how variations in the scratching force, friction coefficient, and other quantities depend on the scratch depth [30.189], as illustrated in Fig. 30.35.

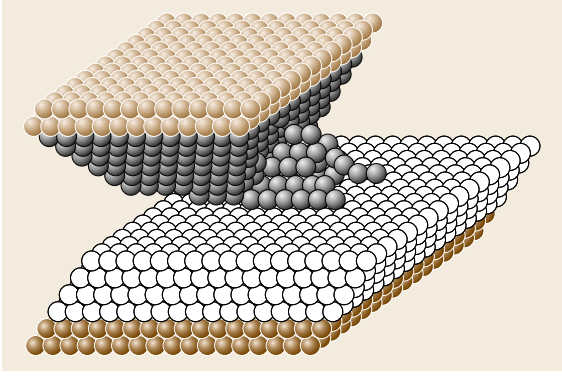

Fig. 30.30 Snapshot from a molecular dynamics simulation of a copper tip sliding across a Cu(100) surface. A connective neck between the two is sheared during the sliding, leading to wear of the tip. The simulation was performed at a temperature of 0 K (after [30.179], © APS 1996)

On the whole, the results of experimental studies show good agreement with the results of the computational studies described above. This is true despite the fact that all of these MD simulations use empirical potentials that do not include electronic effects and thus effectively assume that the electronic contributions to friction on metal surfaces are negligible. However, experiments have measured a nonnegligible contribution of conduction electrons to friction [30.190]. Thus, future simulations of metal-tip–metal-substrate interactions using more sophisticated tight-binding or first principles methods that include electronic effects are encouraged.

Layered ceramics, such as mica, graphite and MoS_2, that have structures that include strongly bound layers that interact with one another through weak van der Waals bonds, have long been known to have good lubricating properties because of the ease with which the layers slide over one another. They have, therefore, been the focus of some of the earliest experimental studies of nanometer-scale friction [30.19, 191]. The results of these early studies lead researchers to hypothesize that at high loads measured friction forces were related to *incipient sliding* [30.192, 193] caused by a small flake from the surface becoming attached to the end of the

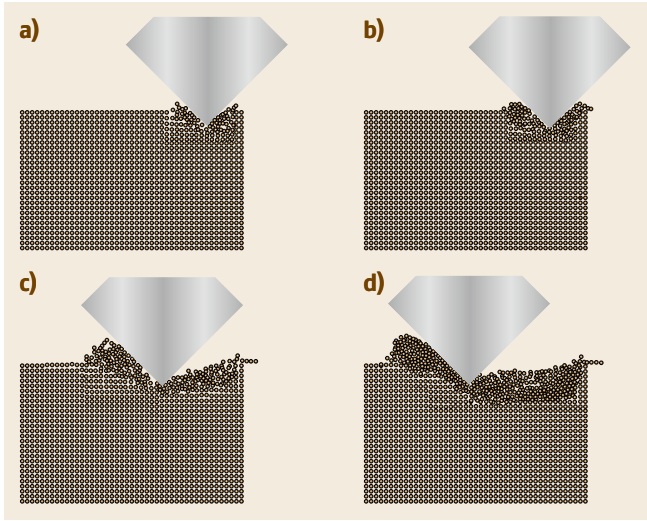

Fig. 30.34a–d Snapshots of the scratching of an aluminum surface with a rigid tip at a depth of 0.8 nm (after [30.189], © APS 2000)

tip. If true, this would mean that all measured interactions were between the surface and the flake, which has a larger contact area than the clean tip. However, subsequent simulations of constant force AFM images of graphite by *Tang* et al. [30.194] showed that there is no need for the assumption of a graphite flake under the tip to reproduce the experimental images of a graphite surface.

Surprisingly strong localized fluctuations in atomic-scale friction are displayed by layered ceramics [30.195–198]. For instance, square-well signals with sub-angstrom lateral width are obtained in FFM scans on $MoS_2(001)$ in the direction across the scan direction, while sawtooth signals are detected along the scan direction, as shown in Fig. 30.36. This finding can be explained by a stick–slip model by *Mate* et al. [30.19] and *Erlandsson* et al. [30.191] that assumes that the tip does a zigzag walk along the scan. Measured variations in the frictional force with the periodicity of cleavage planes [30.191] are consistent with the results of this simple model. However, additional experiments indicate a more complex tip–surface interaction, such as changes in the intrinsic lateral force between the substrate and the AFM tip [30.199] or sliding-induced chemistry between the tip and the surface [30.200, 201].

MoS_2 has proven to be a very successful solid lubricant for applications that operate in vacuum but its performance quickly deteriorates when exposed to ambient air. Recently, *Liang* et al. used ab initio DFT methods to examine the potential energy surfaces between sliding $MoS_2(001)|MoS_2(001)$, $MoS_2(001)|MoO_3(001)$, and $MoO_3(001)|MoO_3(001)$ interface systems in an effort to understand the deterioration in lubricity due to oxidation [30.202]. The potential energy surfaces give information on the minimum energy path along particular sliding directions from which lateral forces needed to slide the interface can be calculated. In this work a normal force of 500 MPa was applied to all three interfacial systems before the energy surface calculations were performed. It was found that the minimum energy path for self-mated $MoS_2(001)|MoS_2(001)$ was a zigzag path that avoided direct overlap of sulfur atoms in the topmost layers of the top and bottom surfaces. From this PE surface a lateral frictional force of 0.058 nN/atom was predicted for this interface. The

lowest frictional force of 0.011 nN/atom predicted in these calculations was for the $MoS_2(001)|MoO_3(001)$ interface along the channel direction formed by S atoms

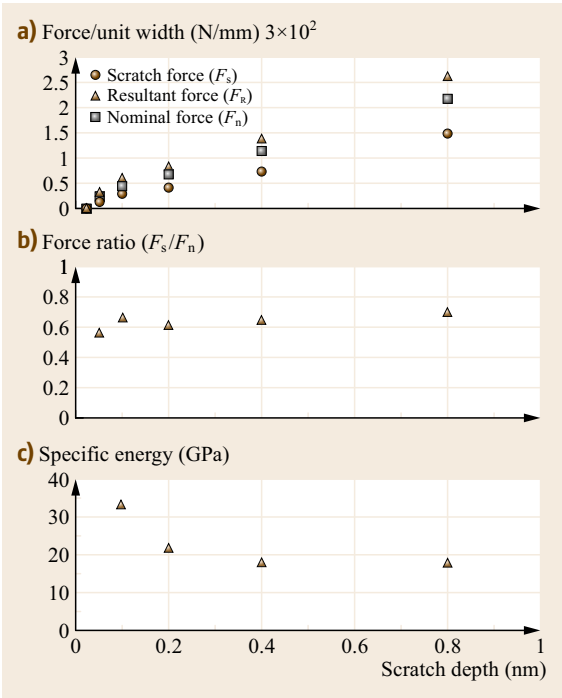

Fig. 30.35 Variation in **(a)** the scratching force, the normal force, and the resultant force, and **(b)** the friction coefficient, and **(c)** the specific energy during scratch processes similar to those shown in Fig. 30.34 at scratch depths ranging from 0.8 to almost 0 nm (after [30.189], © APS 2000)

at the sliding surface. Although this doesn't explain the mechanism by which degradation occurs experimentally, it is in general agreement with experimental results that show that this interface can produce lower frictional coefficients than pure MoS_2. As suggested by the authors, it may be a surface defect driven process that is currently inaccessible to first principles methods employed in these calculations. The last interface of $MoO_3(001)|MoO_3(001)$ was found to have the largest frictional force of 0.352 nN/atom.

Crystalline ceramics differ from layered ceramics in that they are held together by relatively strong covalent or ionic bonds. In the case of ionic systems, *Shluger* et al. [30.203] used a mixture of atomistic and macroscopic modeling methods to study the interaction of a MgO tip and a LiF surface. In particular, the tip–surface interaction was treated atomistically and the cantilever deflection was treated with a macroscopic approach. The results, shown in Fig. 30.37, show that if the tip is charged and in hard contact with the surface, tip and surface distortions are possible that can lead to motion of the surface ions within the surface plane and the transfer of some of the ions onto the tip.

In the case of covalently bound ceramics, there is extensive literature related to friction of diamond [30.204, 205] because, while it is the hardest material known, it also exhibits relatively low friction. The *ratchet mechanism* has been proposed for energy dissipation during friction on the macroscale in diamond, where energy is released by the transfer of normal force from one surface asperity to another. The elastic mechanism is another mechanism that has been proposed, where the released energy comes from

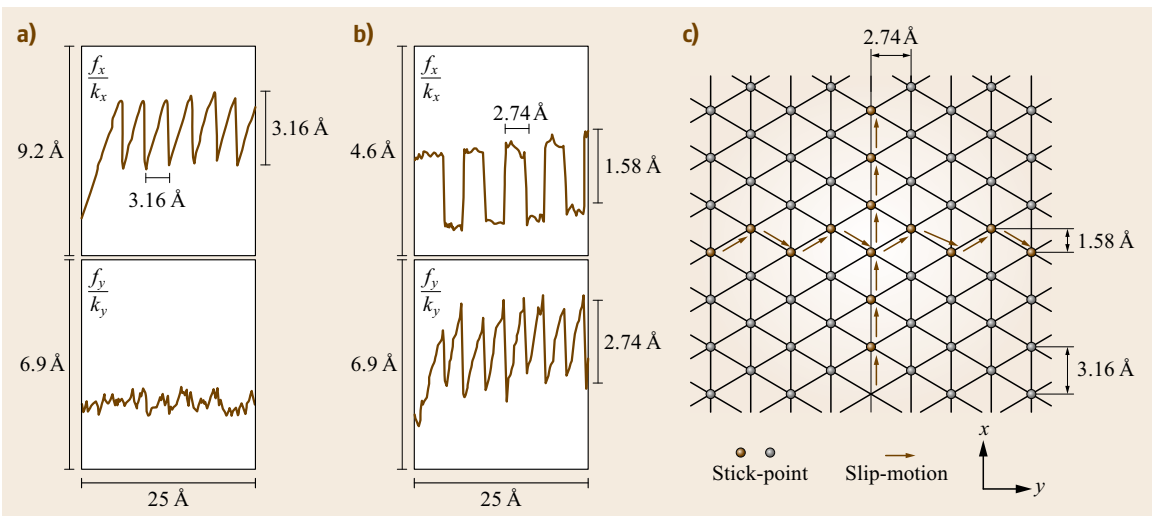

Fig. 30.36a–c Displacement data from a scan across a $MoS_2(001)$ surface. The data in **(a)** and **(b)** are form scans along the x -and y-directions, respectively, on the surface shown in **(c)** (after [30.198], © APS 1996)

elastic strain in an asperity. Atomic-scale friction has been measured experimentally [30.20] for diamond tips with near atomic-scale radii sliding over hydrogen-terminated diamond surfaces. These experiments are sensitive enough to detect the 2×1 reconstruction on the diamond (100) surface. Furthermore, the average friction coefficient determined with an AFM on H-terminated diamond (111) surfaces is about two orders of magnitude smaller than the value measured on bare, 2×1 diamond (111) surfaces, indicating greater adhesion in the latter case [30.206]. More recently, the friction between a tungsten carbide tip and hydrogen-terminated diamond (111) was examined with AFM in UHV by *Enachescu* et al. [30.207]. The friction between these two hard surfaces was shown to obey Derjaguin–Muller–Toporov or DMT [30.208] contact mechanics and the shear strength of the interface was determined to be 246 MPa.

Extensive MD simulations have been carried out by *Harrison* and coworkers that examine the friction between hydrogen-terminated diamond (111) surfaces [30.173, 209] and diamond (100) surfaces [30.210] in sliding contact and its temperature dependence [30.211]. The simulations of sliding between the diamond (111) surfaces reveal that the potential energy, load, and friction are all periodic functions of the sliding distance (Fig. 30.38). Maxima in these quantities occur when the hydrogen atoms on opposing surfaces interact strongly. Recent ab initio studies by *Neitola* and *Pakanen* of the friction between hydrogen-terminated diamond (111) surfaces also show that the potential energy is periodic with sliding distance (Fig. 30.39) [30.212]. Because the results of the ab initio studies and the MD simulations are in good agreement, Neitola and Park conclude that the potential model used in the MD studies is accurate.

As mentioned previously, the maxima in the load and the friction values during sliding are caused by the interactions of hydrogen atoms on opposing surfaces.

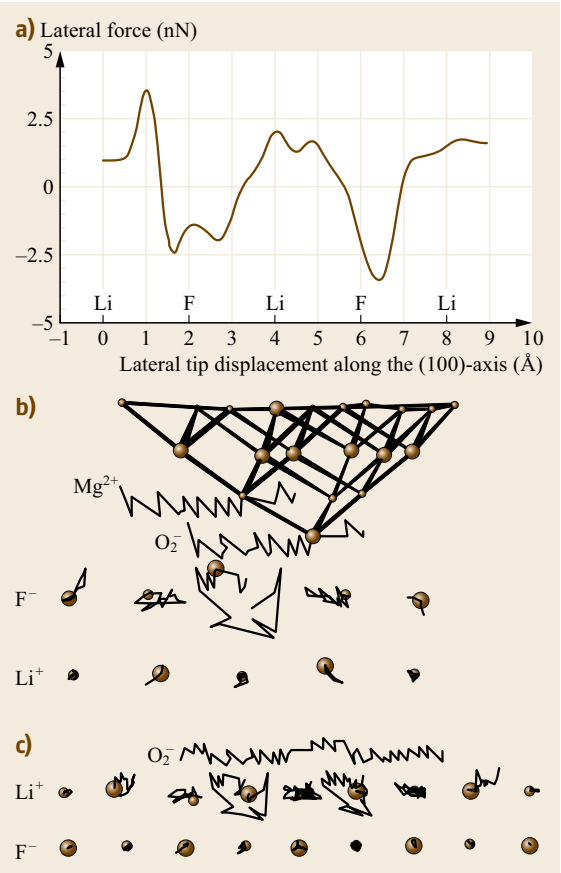

Fig. 30.37 **(a)** The lateral force calculated for a MgO tip scanning in the ⟨001⟩-direction on LiF(001). **(b,c)** A view of the side of the surface plane along the scan direction. The surface Li^+ and F^- atoms are seen to relax to relieve the frictional energy and this relaxation motion is indicated in the figure by the *lines*. **(b)** An ion on the surface can be moved into an interstitial site by the tip and then returns to its original position. **(c)** Reversible relaxation of the surface atoms (after [30.203], © Elsevier 1995)

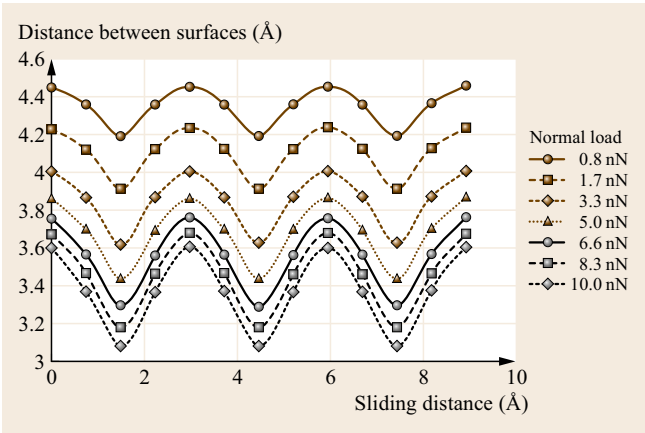

Fig. 30.39 Distance between hydrogen-terminated (111) crystals as a function of sliding distance (after [30.212], © ACS 2001)

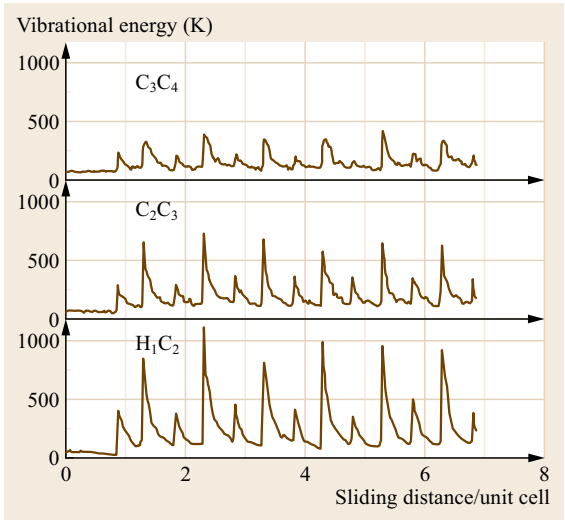

Fig. 30.40 Average vibrational energy of oscillators between diamond layers as a function of sliding distance. These energies are derived from a molecular dynamics simulation of the sliding of a hydrogen-terminated diamond (111) surface over another hydrogen-terminated diamond (111) surface. The vibrational energy between the first and second layers of the lower diamond surface is shown in the *lower panel*, between the second and third layers in the *middle panel*, and between the third and fourth layers in the *upper panel* (after [30.213], © Elsevier 1995)

When sliding in the $[11\bar{2}]$ direction, the H atoms *revolve* around one another, thus decreasing the repulsive interaction between the sliding surfaces because the hydrogen atoms are not forced to pass directly over one another [30.173]. Increasing the load causes increased stress at the interface. The opposing hydrogen atoms become *stuck*. Once the stress at the interface becomes large enough to overcome the hydrogen–hydrogen interaction between opposing surfaces, the hydrogen atoms *slip* past one another with the same *revolving* motion observed at low loads. This phenomenon is known as atomic-scale stick–slip and has the periodicity of the diamond lattice. It should be noted that due to the alignment of the opposing surfaces, the hydrogen atoms are directly in line with each other when sliding in the $[11\bar{2}]$ direction. However, the hydrogen atoms are not *aligned* with each other when sliding in the $[1\bar{1}0]$, so the friction in this direction is lower than in the $[11\bar{2}]$ direction. It should be noted, however, that experimentally all initial alignments are likely to be probed.

Harrison and coworkers have further shown that the peaks in the frictional force are correlated with peaks in the temperature of the atoms at the interface when two hydrogen-terminated diamond (111) surfaces are in sliding contact [30.209]. Figure 30.40 shows the vibrational energy (or temperature) between diamond layers as a function of sliding distance. These data clearly show that layers close to the sliding interface can be vibrationally excited during sliding. When the hydrogen atoms are *stuck* or interacting with each other strongly, the stress and friction force at the interface build up. When the hydrogen atoms *slip* past one another, the stress at the interface is relieved and the energy is transferred to the diamond in the form of vibration or heat. Thus, the peaks in the temperature occur slightly after the peaks in the frictional force.

It should be noted that atomic-scale stick slip is observed in other systems. *Perry* and *Harrison* used MD simulations to demonstrate that two hydrogen-terminated diamond (100) (2×1) surfaces in sliding contact also exhibit stick–slip [30.210]. In addition, it was shown that the shape of the friction versus sliding distance curves is influenced slightly by the speed of the sliding, with features in the curves becoming more pronounced at slower speeds. Stick–slip behavior was also observed in AFM studies of diamond (100) (2×1) surfaces [30.206]. However, in this case the stick–slip was over a much longer length scale and may be due to the fact that the surfaces were not hydrogen-terminated.

Mulliah et al. [30.214] used MD simulations with bond-order potentials [30.215] to model interactions between indenter atoms, EAM potentials [30.216] to model interactions between substrate atoms, and the Ziegler–Biersack–Littmack potential [30.217] to model interactions between indenter and substrate atoms to study the atomic-scale stick–slip phenomenon of a pyramidal diamond tip interacting with a silver surface at several sliding rates and vertical support displacements. These simulations showed that dislocations are related to the stick events emitting a dislocation in

the substrate near the tip. The scratch in the substrate is discrete due to the tip jumping over the surface in the case of small vertical displacements. In contrast, large displacements of 15 Å or more result in a continuous scratch. These simulations also showed how the dynamic friction coefficient and the static friction coefficient increase with increasing tip depth. The tip moves continuously through a stick and slip motion at large depths, whereas it comes to a halt in the case of shallow indents. Although the sliding rate can change the exact points of stick and slip, the range of sliding rates over the range of values considered in this study (1.0–5.0 m/s) has no influence on the damage to the substrate, the atomistic stick–slip mechanisms, or the calculated friction coefficients.

The effect of the way in which the tip is rastered across the surface in MD simulations was considered by *Cai* and *Wang* [30.218, 219] using bond-order potentials. In particular, they dragged silicon tips across several silicon surfaces, as illustrated in Fig. 30.41, in two different ways. In the first, they moved the tip every MD step while in the other they advanced the tip every 1000 steps. In both cases, the overall sliding rate is the same and equals 1.67 m/s. In both cases, wear of the tip such as is illustrated in Fig. 30.41 occurs. However, the mechanisms by which the wear occurs are found to depend on the approach used, and the latter approach is found to be in better agreement with experimental data.

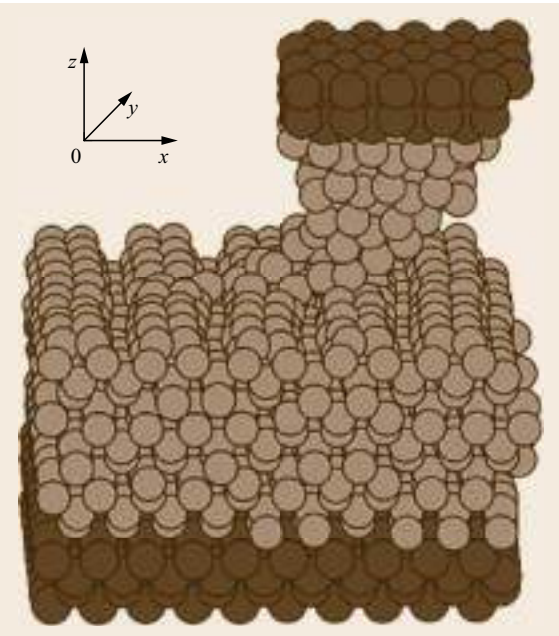

Fig. 30.41 Snapshots of a Si(111) tip interacting with a Si(001) 2 × 1 surface. The tip is rastering along the surface in the *x*-direction and starts off at a distance of 9 Å from the surface (after [30.218], © CCLRC 2002)

In many studies, diamond tips or diamond-decorated tips are used in friction measurements. Diamond is an attractive material for an FFM tip because of its high mechanical strength and the belief that such tips are wear-resistant. However, diamond tips that were used to scratch diamond and silicon surfaces and then imaged showed significant wear that increased with the increasing hardness of the tested material [30.220, 221]. This wear altered the shape of the tip and hence influenced the contact area that is used to determine friction coefficients.

In summary, MD simulations provide insight into dry sliding friction and the sliding of metal tips across clean metal, crystalline ceramics, and layered ceramics surfaces. Stick–slip friction or wear can occur depending on the sliding conditions. The good lubricating properties of layered ceramics are observed in the simulations along with localized fluctuations in atomic-scale friction. Crystalline ceramics, such as diamond, exhibit relatively low friction and the simulations show how stick–slip atomic-scale motion changes with the conditions of sliding and the way in which the simulation is performed.

30.3.2 Decorated Surfaces

While dry sliding friction in vacuum assumes that ambient gas particles have no direct effect on the results, MD simulations show that free particles between two surfaces in sliding contact influence friction to a surprisingly large degree. These so-called third-body molecules have been studied extensively by *Perry* and *Harrison* [30.180, 222, 223] using MD simulations with bond-order and LJ potentials. These simulations focus on the effect of trapped small hydrocarbon molecules on the atomic-scale friction of two (111) crystal faces of diamond with hydrogen termination. These molecules might represent hydrocarbon contamination trapped between contacting surfaces prior to a sliding experiment in dry friction, or hydrocarbon debris formed during sliding.

In particular, the effects on friction of methane (CH_4), ethane (C_2H_6), and isobutane ($(CH_3)_3CH$ trapped between diamond (111) surfaces in sliding contact were examined in separate studies (Fig. 30.42). The frictional force for all these systems generally increases as the load increases, as illustrated in Fig. 30.43. The simulations predict that the third-body molecules markedly reduce the average frictional force compared to the results for pristine hydrogen-terminated surfaces. This is particularly true at high loads, where the third-body molecules act as a boundary layer between the two

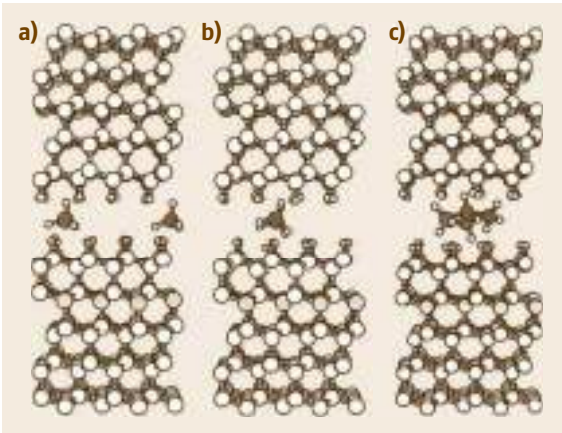

Fig. 30.42a–c Initial configuration at low load for the diamond plus third-body molecule systems. These systems are composed of two diamond surfaces, viewed along the [$\bar{1}$10] direction, and two methane molecules in **(a)**, one ethane molecule in **(b)**, and one isobutane molecule in **(c)**. Large *white* and *dark gray spheres* represent carbon atoms of the diamond surfaces and the third-body molecules, respectively. *Small gray spheres* represent hydrogen atoms of the lower diamond surface. Hydrogen atoms of the upper diamond surface and the third-body molecules are both represented by *small white spheres*. Sliding is achieved by moving the rigid layers of the upper surface from *left to right* in the figure (after [30.180], © ACS 1997)

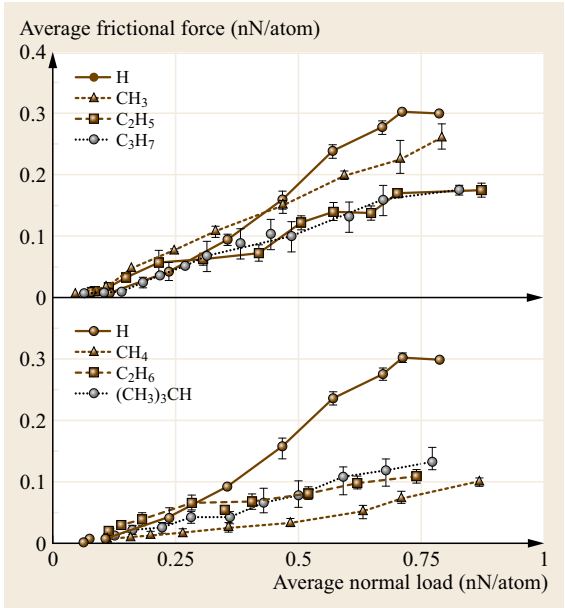

Fig. 30.43 Average frictional force per rigid-layer atom as a function of average normal load per rigid-layer atom for sliding the upper diamond surface in the [11$\bar{2}$] crystallographic direction. Data for the methane (CH_4) system (*brown triangles*), the ethane (C_2H_6) system (*brown squares*), the isobutane $(CH_3)_3CH$ system (*gray circles*), and diamond surfaces in the absence of third-body molecules (*brown circles*) are shown in the lower panel. Data for the methyl-terminated $-CH_3$ system (*brown triangles*), the ethyl-terminated ($-C_2H_5$) system (*brown squares*), the *n*-propyl-terminated ($-C_3H_7$) system (*gray circles*), and diamond surfaces in the absence of third-body molecules (*brown circles*) are shown in the *upper panel*. *Lines* have been drawn to aid the eye (after [30.180], © ACS 1997)

diamond surfaces. That is, the third-body molecules reduce the interaction of hydrogen atoms on opposing surfaces [30.223]. This is demonstrated by examining the vibrational energy excited in the diamond lattice during the sliding (Fig. 30.44). Significant vibrational excitation of the diamond outer layer (C−H) occurs in the absence of the methane molecules. Thus, the friction is ≈ 3.5 times larger when methane is not present. The application of load to the diamond surfaces causes the normal mode vibrations of the trapped methane molecules to change. Power spectra calculated from MD simulations [30.222, 223] show that even under low loads, the peaks in the power spectra are significantly broadened. Peaks in the low-energy region of the spectrum almost disappear with the additional application of load.

The size of the methane molecules allows them to be *pushed* in-between hydrogen atoms on the diamond surfaces while sliding [30.223]. However, steric considerations cause the larger ethane and isobutane molecules to change orientation during sliding. Conformations that lead to increased interactions with the diamond surfaces increase the average frictional force. Thus, despite the fact that the two diamond surfaces are farther apart when ethane and isobutane are present compared to when methane is present, the friction is larger because these molecules do not *fit* nicely into potential energy valleys between hydrogen atoms when sliding.

When similar hydrocarbon molecules (methyl, ethyl, and *n*-propyl groups) are chemisorbed to one of the sliding diamond surfaces, instead of trapped between the surfaces, different behavior is observed by *Harrison* et al. [30.174, 175, 209, 224]. Simulations show that methyl-termination does not decrease friction significantly but results in frictional forces that are nearly the same as they are for hydrogen-terminated diamond surfaces [30.213]. While the methane third-body molecules decrease the frictional force to a greater extent than the chemisorbed methyl groups, friction as a function of load is comparable for the ethyl-terminated and ethane systems, with the former giving

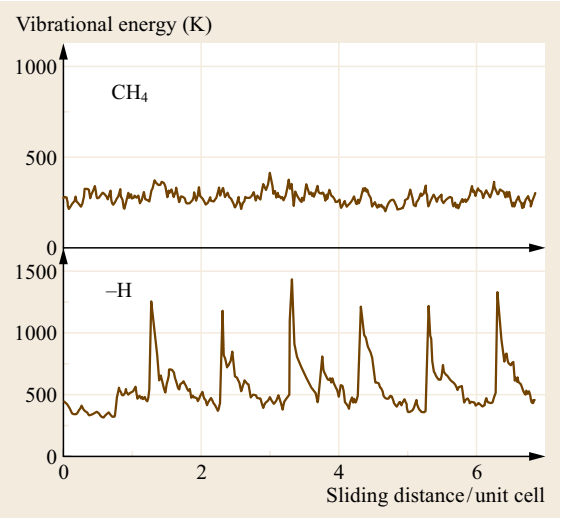

Fig. 30.44 Average vibrational energy between the (C−H) bonds of the upper diamond (111) surface versus sliding distance for hydrogen-terminated diamond (111) surfaces, with (CH_4) and without methane (H), trapped between them. The average normal load is approximately the same in both simulations and is in the range 0.8−0.85 nN/atom. The average frictional force on the upper surface is about 3.5 times smaller in the presence of the methane third-body molecules (after [30.223], © Elsevier 1996)

slightly higher frictional forces. Attaching the hydrocarbon groups to the diamond surfaces causes them to have less freedom to move between hydrogen atoms on opposing diamond surfaces during sliding. This generally increases their repulsive interaction with the diamond counterface.

MD simulations can also provide insight into the rich, nonequilibrium tribochemistry that occurs between surfaces in sliding contact. *Harrison* and *Brenner* examined the tribochemistry that occurs when ethane molecules are trapped between diamond surfaces in sliding contact, as illustrated in Fig. 30.45 [30.225]. This simulation was the first to show the atomic-scale mechanisms for the degradation of lubricant molecules due to friction. The type of debris formed during the sliding simulation is similar to the types of debris molecules that were observed in macroscopic experiments that examined the friction between diamond surfaces [30.226].

In the case of sliding metal surfaces, impurity molecules or atoms (both adsorbed and absorbed) on thin metal films can be expected to affect the film's properties. For example, calculations have shown that resistivity changes in the metal are strongly dependent on the nature of the adsorption bond [30.227]. When this result is used to interpret atomic-scale friction results obtained with the QCM, the sliding of adsorbate structures on metal surfaces are shown to be a combination of electron excitation and lattice vibrations. Additionally, other interesting quantum effects can come into play when the adsorbate is very different chemically from the surface on which it is sliding. For instance, the electronic frictional forces acting on small, inert atoms and molecules, such as C_2H_6 and Xe, sliding on metal surfaces have been calculated by *Persson* and *Volokitin* [30.228], where the metal surface was approximated by a electron gas (jellium) model. The calculations showed that the Pauli repulsive and attractive van der Waals forces are of similar magnitudes. In addition, the calculated electronic friction contributions agree well with the values derived from surface resistivity by *Grabhorn* et al. [30.229] and QCM measurements. These studies showed that parallel friction is mainly due to electronic effects while perpendicular friction is phononic in nature in this system.

In summary, MD simulations show that the average frictional force decreases significantly in systems with third-body molecules, especially at high loads. Simulations also provide information about the details of tribochemical interactions that can occur between lubricants and sliding surfaces. Additionally, the effect of the presence of small molecules on thin metal films can influence film properties, such as resistivity.

30.3.3 Thin Films

As discussed at the beginning of this section, the conversion of the work of sliding into some other less ordered form is responsible for friction at sliding solid interfaces. In the case of adhering systems, the work of sliding may be converted into damage within the bulk (plastic deformation), while in the case of weakly adhesive forces, friction can occur through the conversion of work to heat at the interface that causes no permanent damage to the surface (wearless friction). The latter case, when it is achieved through the presence of lubricating thin films, is the topic of this section.

There are several types of lubricating thin films, the simplest of which consist of small molecules that are analogous to wear debris that can *roll* between the sliding surfaces or that represent very short-chain bonded lubricants. These thin films were discussed in the previous subsection. The rest of this subsection will, therefore, focus on the effects of liquids, larger nanoparticles, self-assembled monolayers and solid thin films on lubrication and friction.

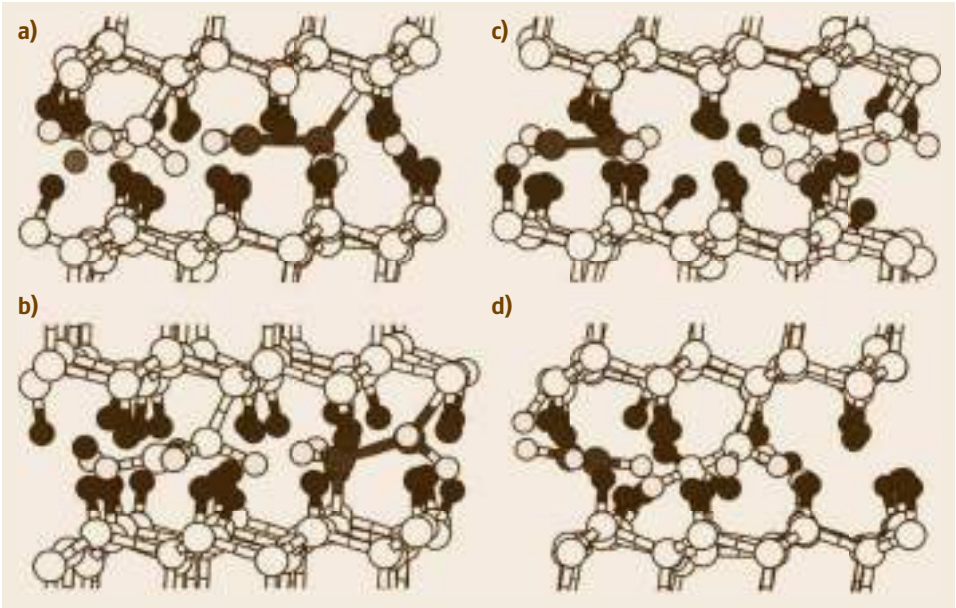

Fig. 30.45a–d Snapshots from a molecular dynamics simulation of the sliding of two hydrogen-terminated diamond (111) surfaces against one another in the [11$\bar{2}$] direction. The upper surface has two ethyl fragments chemisorbed to it. The simulation shows how sliding can induce chemistry at the interface. **(a)** Initial structure of the sliding surfaces with ethyl fragments chemisorbed to the top surface, **(b)** the ethyl fragments have started to react with atoms on the bottom surface, **(c)** continued sliding modifies the reactions, and **(d)** continued reactions are occurring between the ethyl fragments and the bottom surface (after [30.225], © ACS 1994)

Liquids

Liquids are common lubricants and so they have been studied in great depth at the macroscale. At the nanoscale, the tribological response of spherical liquid molecules has been well-characterized experimentally using the SFA and computationally with MD simulations by *Berman* et al. [30.230]. The SFA experiments considered one to three liquid layers and the stick–slip motion at the interface is found to increase in a quantized fashion as the number of lubricant layers decrease. When no external forces are applied to the system, the sliding stops and the solid–lubricant interactions are strong enough to force the liquid molecules to form a close-packed structure that is ordered. The transformation of the liquid into this solidlike structure causes the two surfaces to effectively bond to each other through the lubricant. When the surfaces start to slide again, lateral shear forces are introduced that steadily increase, which causes the molecules in the liquid to undergo small lateral displacements that change the film thickness. If these shear forces become greater than a critical value, the film disorders in a manner that is analogous to melting. This allows the surfaces to slide easily past each other in a manner that is still quantized. This sequence of events is nicely illustrated in Fig. 30.46 and can be reproduced multiple times for the same system.

Persson [30.231] used MD simulations with pairwise potentials similar to those in (30.6) to examine the mechanism by which this sharp transition occurs. They find that in the case of sliding on insulating crystal surfaces, the solid-state lubricant may be in a *superlubric* state where the friction is negligible. It is clear from the simulations, however, that any surface defects, even in low concentrations, will disrupt this state and transform the lubricant back into a fluid. In addition, when sliding occurs on metallic surfaces above cryogenic temperatures, the electronic contributions to friction are no longer zero and no superlubric state is possible.

High applied pressures can force the fluid molecules out from between the two confining surfaces [30.232]. The fact that liquid molecules close to a stiff surface are strongly layered in the direction perpendicular to the surface explains the experimental observation of a $(n \rightarrow n-1)$ layer transition, where n is number of monolayers, that is observed as the normal load increases [30.233]. Nucleation theory is used to calculate the critical pressure and determine the spreading dynamics of the $(n-1)$ island.

The reactivity of the liquid molecules are also critically important to boundary layer friction. MD studies by *Persson* [30.234] show that inert molecules interact

weakly with sliding surfaces. Consequently, as the rate of sliding increases, the molecular conversion from the solid state to the liquid state occurs in an abrupt manner. However, when the molecules interact strongly with the surfaces, they undergo a more gradual transition from the solid to the liquid state. *Persson* et al. [30.34] also considered systems where the molecules are attached to one of the surfaces, which causes the transitions to be abrupt. This is especially true if there are large separations between the chains.

While the studies discussed so far have focused on spherical liquids, most widely used liquid lubricants consist of long-chain hydrocarbons. Nonspherical liquid molecules have more difficulty aligning and solidifying. This is borne out in MD simulations by *Thompson* and *Robbins* [30.235] that show that spherical molecules have higher critical velocities than branched molecules. In particular, the simulations show that when the molecules are branched, the amount of time various parts of the system spend in the sticking and sliding modes changes with sliding rate. The critical velocity can also depend on the number of liquid layers in the film, the structure and relative orientation of the two sliding surfaces, the applied load and the stiffness of the surfaces.

Additional studies by *Landman* et al. [30.236] used MD simulations with bond-order and EAM potentials coupled with pair-wise potentials similar to (30.6) to study the sliding of two gold surfaces with pyramidal asperities that have straight chain $C_{16}H_{34}$ lubricant molecules trapped between them, as illustrated in Fig. 30.47. An important aspect of this study is that the sliding rate in the simulations is about 10 m/s, which is the same order of magnitude as the scanning speed in a computer disk. As the asperities approach each other, the hydrocarbon molecules begin to form layers. This is reflected in the oscillations in the frictional force shown in Fig. 30.48. When the asperities overlap in height and approach each other laterally, the pressure of the lubricant molecules increases to about 4 GPa which leads to the deformation of the gold asperities.

Glosli and *McClelland* [30.176] modeled the sliding of two ordered monolayers of alkane chains that are attached to two rigid substrates. This system is shown schematically in Fig. 30.49. The simulations predicted that energy dissipation occurs by a discontinuous plucking mechanism (sudden release of shear strain) or a viscous mechanism (continuous collisions of atoms of opposite films). The specific mechanism that occurs depends on the interfacial interaction strength. In particular, the *pluck* occurs when mechanical energy stored as strain is converted into thermal energy that leads to low friction forces at low temperatures. On the other hand, at higher temperatures some of the energy of sliding is dissipated through phonon excitations, which results in higher frictional forces. Interestingly, this trend reverses again at the highest temperatures considered when the molecules move so much that they slide easily over the surfaces, which decreases the frictional force. These results are summarized in Figs. 30.50 and 30.51.

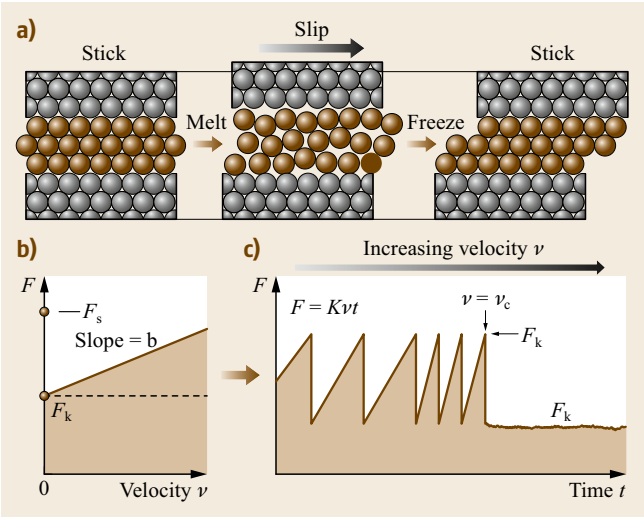

Fig. 30.46a–c The stick–slip transition that occurs for thin films of liquid between two sliding solid surfaces. F is the intrinsic friction and F_s is the friction where the liquid is in the rigid state; F_k is the friction where the liquid is in the liquidlike state. **(a)** Snapshots that indicate how the liquid melting and freezing is related to the stick–slip process. **(b)** Indicates the intrinsic friction relative to the friction values where the liquid is liquidlike and solidlike. **(c)** Illustrates how the intrinsic friction varies with time as the velocity increases (after [30.230], © ACS 1996)

Other studies of sliding surfaces with attached organic chains include MD simulations with LJ potentials by *Müser* and coworkers, [30.41, 237, 238] which considered friction between polymer *brushes* in sliding contact with one another. In particular, they considered the effect of sliding rate on the tilting of polymers and the effect of steady-state sliding versus nonsteady-state (*transient*) sliding. The simulations find that shear forces are lower for chains that tilt in a direction that is parallel to the shear direction. This tilting effect is significant for grafted polymers, as illustrated in Fig. 30.52, and less significant for absorbed polymers. This is due to the decrease in the differential frictional coefficient for the grafted polymers as well as the increase in the friction coefficient for absorbed polymers under shear. The tilting is also affected by the rate of sliding and is much larger at high sliding rates than small rates, as indicated in Fig. 30.52. The simulations further show that the inclination an-

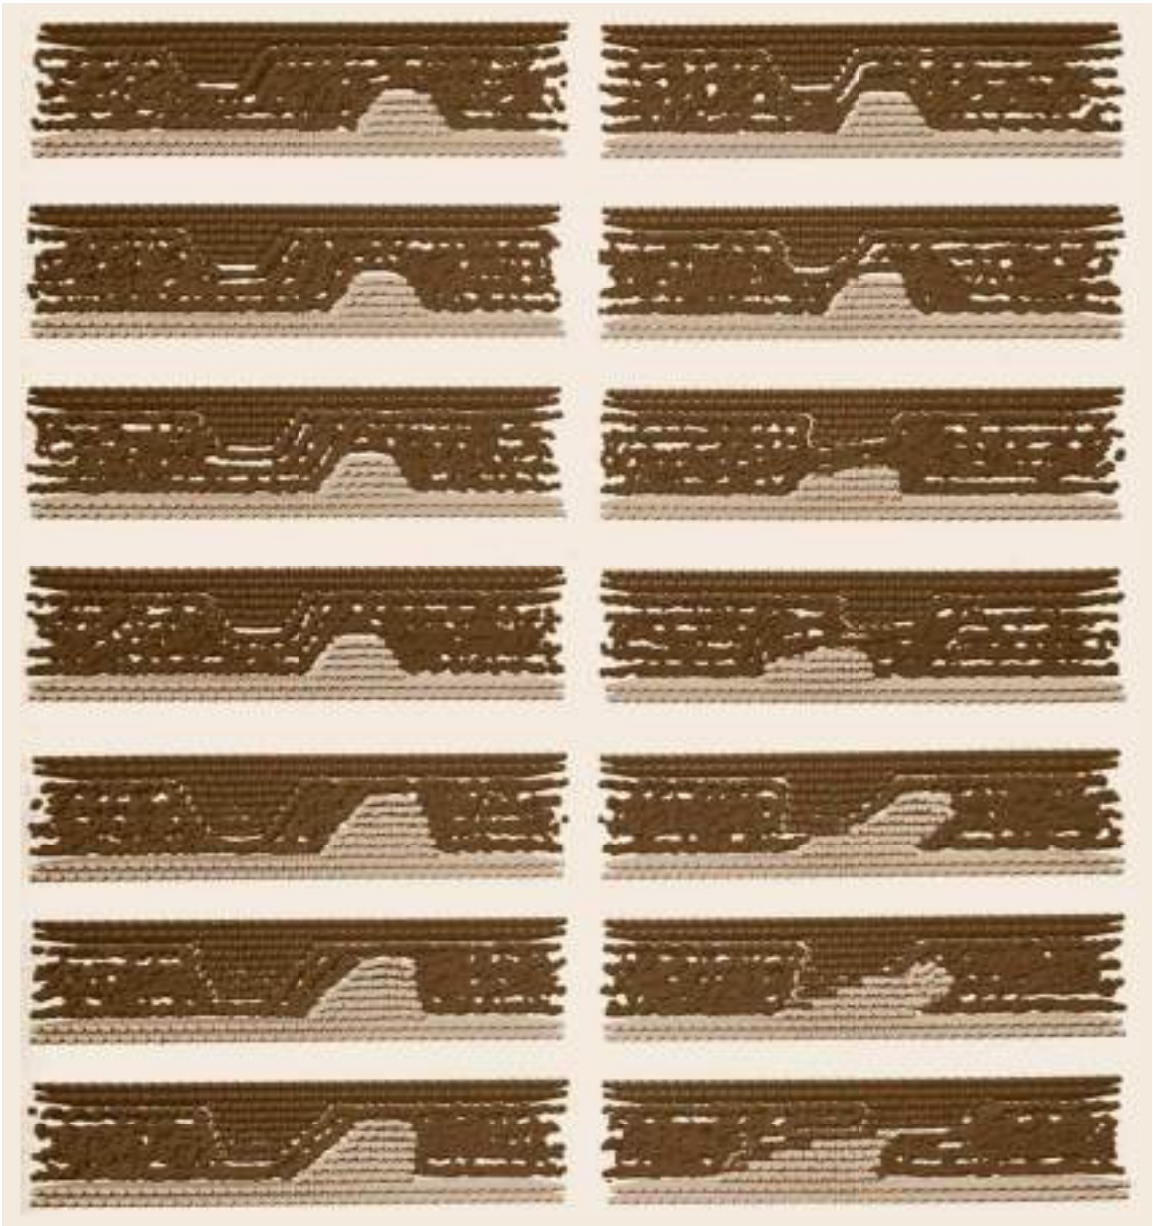

Fig. 30.47 Stills from a molecular dynamics simulation where Au(111) surfaces with surface roughness slide over one another while separated by hexadecane molecules. The scanning velocity is 10 m/s. Layering of the lubricant and asperity deformation occurs as the sliding continues. The *top three rows* show the results when the asperity heights are separated by 4.6 Å. The *bottom three rows* show the results when the asperity heights are separated by −6.7 Å (after [30.236], © ACS 1996)

gle of the chains decreases much more slowly than the shear stress, and the shear stress maximum is more pronounced if there is hysteresis in the chain orientations.

Typical friction loops for tips that are functionalized and sliding against surfaces that are functionalized in the same manner as illustrated in Fig. 30.25 are shown in Fig. 30.53. The friction force between the OH/OH pairs is significantly larger than the friction force between the CH_3/CH_3 pairs. This is due to the formation and breaking of hydrogen bonds during the shearing for the OH/OH pairs. The mean forces versus load forces

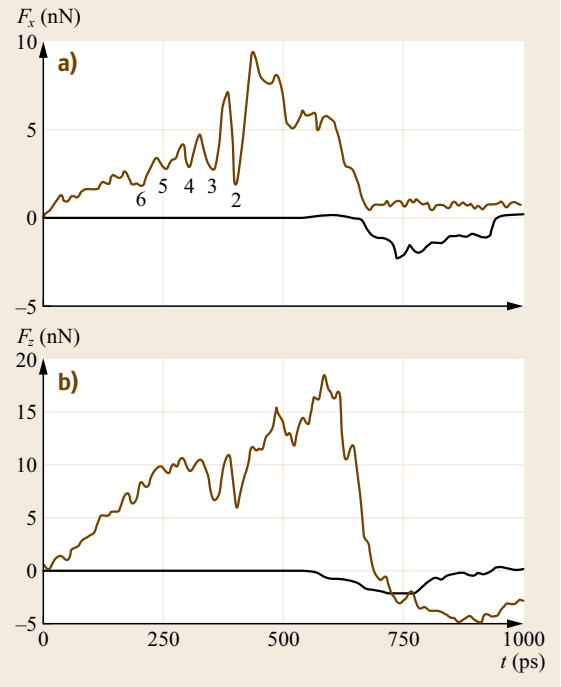

Fig. 30.48 **(a)** The lateral force (F_x) and **(b)** normal force (F_z) from the molecular dynamics simulations shown in Fig. 30.35 as a function of time. The forces between the two metal surfaces are shown by the *dashed line*. The force oscillations correspond to the structural changes of the lubricant in Fig. 30.35 (after [30.236], © ACS 1996)

for the OH/OH and CH_3/CH_3 pairs given in Fig. 30.54 are reduced by the tip radius.

MD simulations by *Manias* et al. considered the shearing of entangled oligomer chains that are attached to sliding surfaces, as illustrated in Fig. 30.55 [30.239]. They find that slip takes place within the film and that this occurs through changes in the chain conformations. Increased viscosity is predicted at the film–surface interface compared to the middle of the film, which results in a range of viscosities across the film as one moves away from the points of sliding contact.

To summarize this section, experiments and MD simulations show similar stick/slip transitions that occur for thin films of liquid between two sliding solid surfaces. Frictional properties are found to depend to a significant degree on molecular shape, whether the molecules are grafted on the surfaces or merely absorbed on them, and the degree of tilting in the case of molecular chains. In the case of long-chain molecules, temperature is found to affect the frictional force because the mechanical energy stored in long-chains can be converted into thermal energy by friction.

Self-Assembled and Polymer Thin-Film Structures

There have been numerous experimental studies of friction on SAMs on solid surfaces with AFM and FFM. The experimental results reveal relationships among elastic compliance, topography and friction on thin

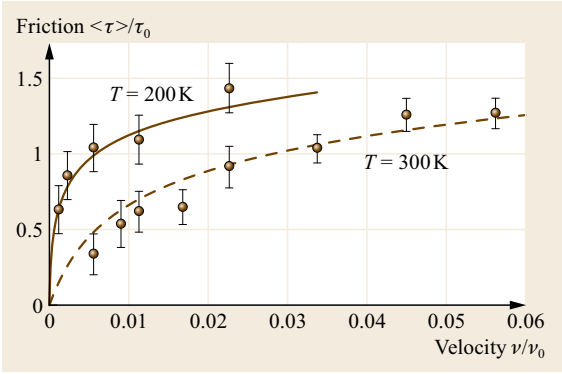

Fig. 30.51 A plot of calculated values of the average interfacial shear stress as a function of the velocity of sliding of the two surfaces shown in Fig. 30.33 (after [30.176], © APS 1993)

L–B films [30.240]. For example, they have detected differences in the adhesive interactions between the microscope tips and CH_3 and CF_3 end groups [30.109]. Fluorocarbon domains generally exhibit higher friction than the hydrocarbon films, which the authors attribute to the lower elasticity modulus of the fluorocarbon films that results in a larger contact area between the tip and the sample [30.240–242]. *Perry* and coworkers examined the friction of alkanethiols terminated with $-CF_3$ and $-CH_3$ [30.243]. The lattice constants for both films are similar and the films are well-ordered. The friction of the SAMs with chains that are terminated with fluorine end groups is larger than the friction of the SAMs with chains that are terminated with hydrogen end groups. However, the pull-off force is similar in both systems, which implies that these end groups have similar contact areas. The authors speculate that the larger $-CF_3$ groups interact more strongly with adjacent chains than the $-CH_3$-terminated chains. Therefore, the fluorinated chains have more modes of energy dissipation within the plane of the monolayer and, thus, have larger friction.

Molecular disorder of the alkyl chains at the surface can also affect the frictional properties of self-assembled films if the layers are not packed too closely together [30.244]. Indentation can induce disorder in the chains that then compress as the tip continues to press against them. If the tip presses hard enough, the film hardens as a result of the repulsive forces between the chains. However, if the chains are tilted, they bend or deform when the tip pushes on them in a mostly elastic fashion that produces long lubrication lifetimes. At low contact loads of about 10^{-8} N, wear usually occurs at defect sites, such as steps. Wear can also occur if there are strong adhesive forces between the film and the surface [30.245].

The friction of model SAMs composed of alkane chains was examined using MD simulations with bond-order and LJ potentials by *Mikulski* and *Harrison* [30.246, 247]. These simulations show that periodicities observed in a number of system quantities are the result of the synchronized motion of the chains when they are in sliding contact with the diamond counterface. The tight packing of the monolayer and commensurability of the counterface are both needed to achieve synchronized motion when sliding in the direction of chain tilt. The tightly packed monolayer is composed of alkane chains attached to diamond (111) in the (2×2) arrangement and the loosely packed system has $\approx 30\%$ fewer chains. The average friction at low loads is similar in both the tightly and loosely packed systems at low loads. Increasing the load, however, causes the tightly packed monolayer to have significantly lower friction than the loosely packed monolayer (Fig. 30.56). While the movement of chains is somewhat restricted in both systems, the tightly packed monolayer under high loads is more constrained with respect to the movement of individual chains than the loosely packed monolayer,

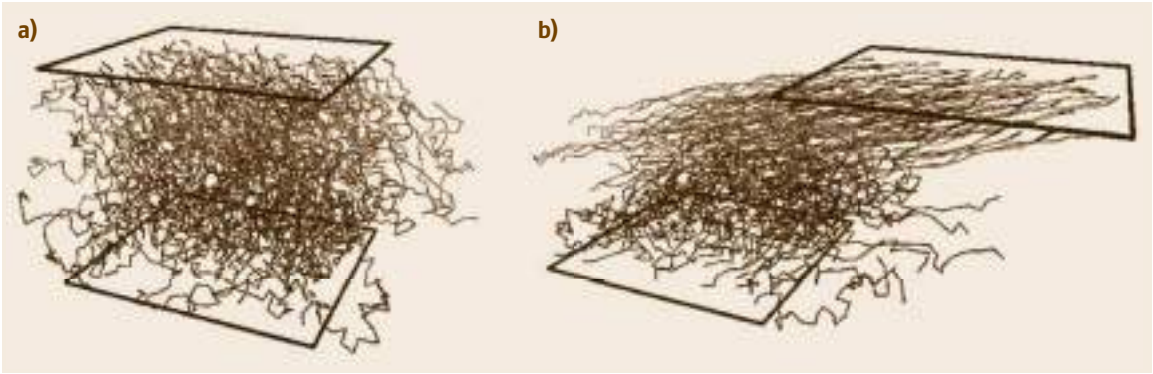

Fig. 30.52a,b Snapshots of sliding walls with attached polymers in a solvent. **(a)** illustrates the sliding process at low sliding rates while **(b)** illustrates the sliding process at high sliding rates (after [30.41], © CCLR 2002)

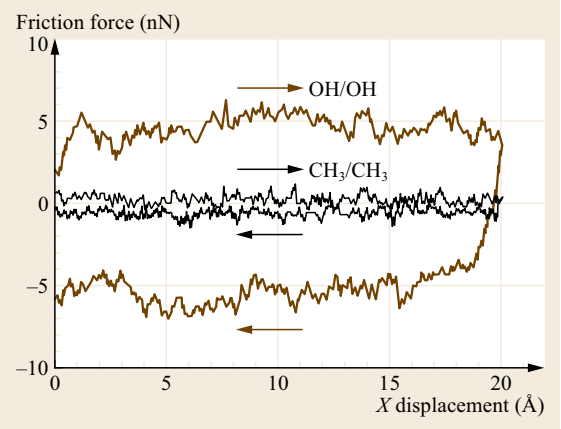

Fig. 30.53 Typical friction loops for the systems shown in Fig. 30.25 for CH_3/CH_3 and OH/OH pairs under a contact load of 0.2 nN (after [30.163], © ACS 2002)

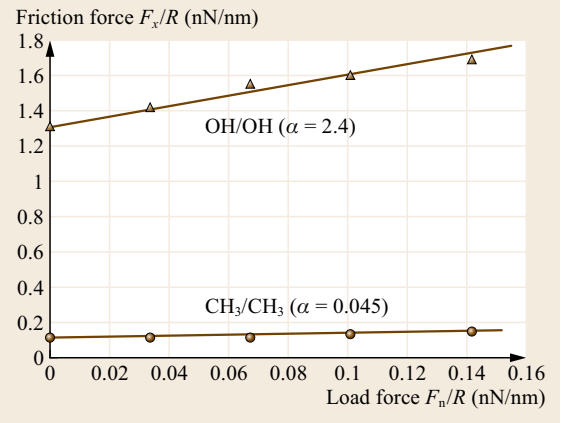

Fig. 30.54 Friction force versus contact load from the systems shown in Fig. 30.25 for CH_3/CH_3 and OH/OH (after [30.163], © ACS 2002)

as illustrated in Fig. 30.57. Therefore, sliding initiates larger bond-length fluctuations in the loosely packed system, which ultimately lead to more energy dissipation via vibration and, thus, higher friction. Thus, the efficient packing of the chains is responsible for the lower friction observed for tightly packed monolayers under high loads.

Several AFM experiments have examined the friction of SAMs composed of chains of mixed lengths [30.248]. For example, the friction of SAMs composed of spiroalkanedithiols was examined by *Perry* and coworkers [30.249]. The effects of crystalline order at the sliding interface were examined by systematically shortening some of the chains. The resulting increase in disorder at the sliding interface causes an increase in friction.

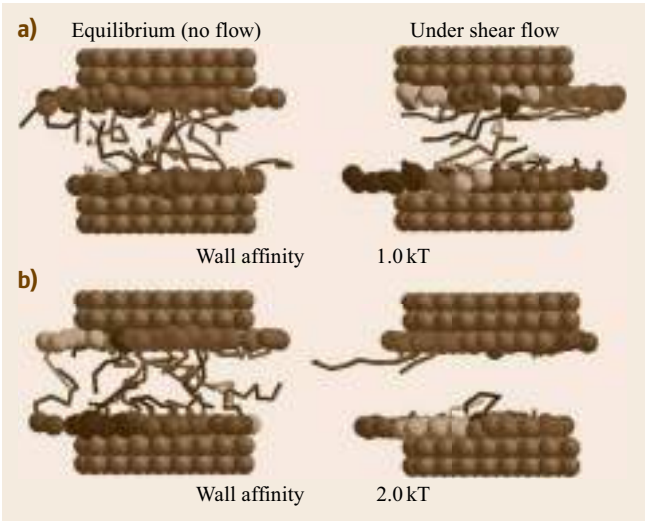

Fig. 30.55a,b Changes in the conformation of adsorbed hydrocarbon chains on weakly **(a)** and strongly **(b)** physisorbing surfaces at equilibrium and under shear (after [30.239], © ACS 1996)

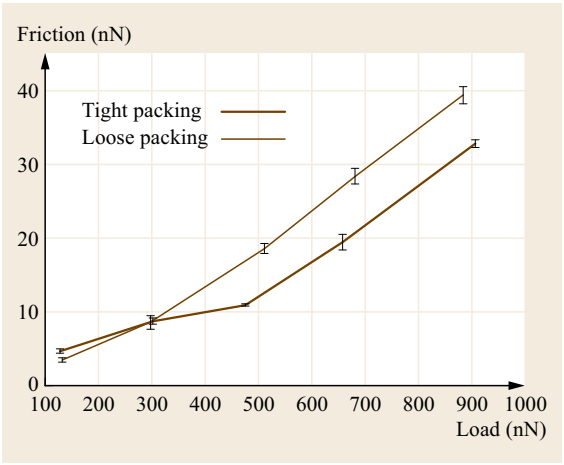

Fig. 30.56 Friction as a function of load when a hydrogen-terminated counterface is in sliding contact with C_{18} alkane monolayers (after [30.247], © ACS 2001)

The link between friction and disorder in monolayers composed of *n*-alkane chains was recently examined using MD simulations by *Harrison* and coworkers [30.250]. The tribological behavior of monolayers of 14 carbon atom-containing alkane chains, or pure monolayers, was compared to monolayers that randomly combine equal amounts of 12 and 16 carbon-atom chains, or mixed monolayers. Pure monolayers consistently show lower friction than mixed monolayers when sliding under repulsive (positive) loads in the direction of chain tilt. These MD simulations reproduce trends observed in AFM experiments of mixed-

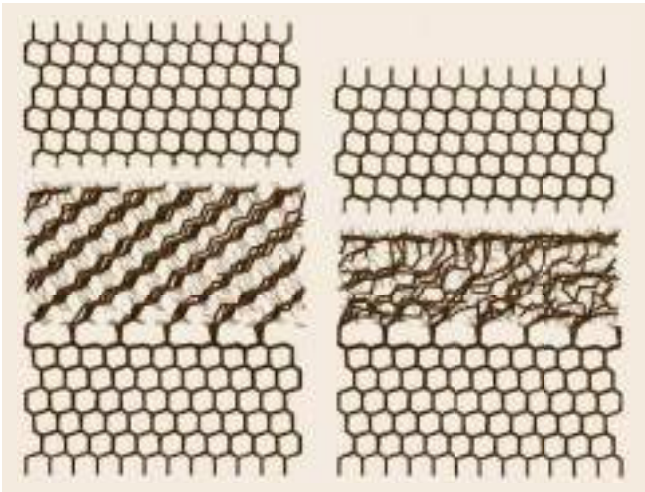

Fig. 30.57 Snapshots of tightly packed C_{18} alkane monolayers on the *left*, and loosely packed monolayers on the *right* under a load of about 500 nN. The chains in both systems are arranged in a (2×2) arrangement on diamond (111). The loosely packed system has 30% of the chains randomly removed. The sliding direction is from *left to right* (after [30.247], © ACS 2001)

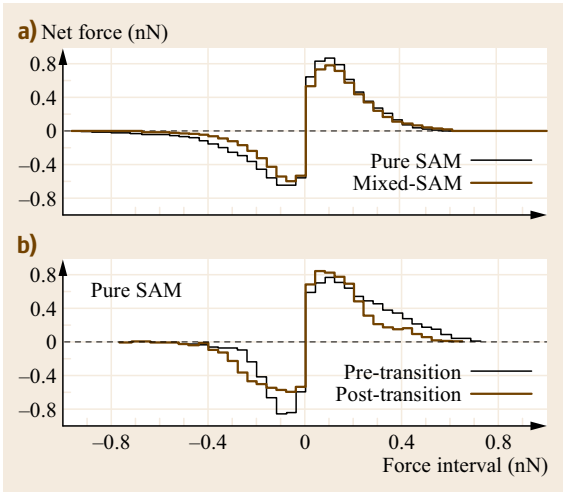

Fig. 30.58a,b The distribution of contact forces along the sliding direction (friction force). In **(a)**, the forces for the mixed and pure system sliding in the direction of chain tilt are shown. The forces for the pure system sliding in the transverse direction to the chain tilt are shown in **(b)**. Positive force intervals correspond to chain groups that resist tip motion while negative intervals correspond to chain groups that *push* the tip in the sliding direction. Forces from four runs with independent starting configurations are binned for all sets of data

length alkanethiols [30.248] and spiroalkanedithiols on Au [30.251]. *Harrison* and coworkers [30.252] have also examined the *odd-even* effect noted in experiment [30.253], where friction is found to be larger for SAMs differing by one methylene group. The MD simulations demonstrated that the effect was due to conformational differences in the chains of different length and became more pronounced at higher loads.

Because the force on individual atoms is known as a function of time in MD simulations, it is possible to calculate the contact forces between individual monolayer chain groups and the tip, where contact force is defined as the force between the tip and a $-CH_3$ or a $-CH_2$-group in the alkane chains. The distribution of contact forces between individual monolayer chain groups and the tip are shown in Fig. 30.58. It is clear from these contact force data that the magnitude, or scale of the forces, is similar in both the pure and the mixed monolayers. In addition, it is also apparent that the pure and mixed monolayers resist tip motion in the same way. That is, the shape of the histograms in the positive force intervals is similar. In contrast, the contact forces *pushing* the tip along differ in the two monolayers. The pure monolayers exhibit a high level of symmetry between resisting and pushing forces. Because the net friction is the sum of the resisting and pushing forces, the symmetry in these distributions of the pure monolayers results in a lower net friction than the mixed monolayers. Thus, the ordered, densely packed nature of the pure monolayers allows the energy stored when the monolayer is resisting tip motion (positive forces) to be regained efficiently when the monolayer *pushes* on the tip (negative forces). The distribution of negative contact forces in the mixed monolayers is different from the distribution of the positive forces. For this reason, mechanical energy is not efficiently channeled back into the mixed monolayer as the tip passes over the chains and, as a result, the friction is higher. The range of motion of the chains is monitored by computing the deviation in a chain group's position compared to its starting position, as illustrated in Fig. 30.59. It is clear from analyzing these data that the increased range of motion is linked to large contact forces. The increased range of motion of the protruding tails in the mixed system prevents the efficient recovery of energy during sliding (negative contact force distribution) and allows for the dissipation of energy.

The pure monolayers exhibit marked friction anisotropy. The contact force distribution changes dramatically as a result of the change in sliding direction, resulting in an increase in friction (Fig. 30.58). Sliding in the direction perpendicular to chain tilt can cause both types of monolayers to transition to a state where the chains are primarily tilted along the sliding direction. This transition is accompanied by a large change

in the distribution of contact forces and a reduction in friction.

Recently, the response of monolayers composed of alkyne chains, which contain diacetylene moieties, to compression and shear [30.254] was examined using MD simulations. These are the only simulations to date that show that compression and shear can result in cross-linking, or polymerization, between chains. The vertical positioning of the diacetylene moieties within the alkyne chains (spacer length) and the sliding direction both have an influence on the pattern of cross-linking and friction. Compression and shear cause irregular polymerization patterns to be formed among the carbon backbones, as illustrated in Fig. 30.60. When diacetylene moieties are located at the ends of the chains closest to the tip, chemical reactions between the chains of the monolayer and the amorphous carbon tip occur causing the friction to increase 100 times, as indicated in Fig. 30.61. The friction between the amorphous carbon tip and all of the diacetylene-containing chains is larger than the friction between a hydrogen-terminated diamond counterface and tightly packed monolayers composed of *n*-alkane chains [30.247]. This is attributed to the disorder at the interface caused by the irregular counterface.

Zhang and *Jiang* [30.255] used MD simulations to study the effect of confined water between alkyl monolayers terminated with $-CH_3$ (hydrophobic) and $-OH$ (hydrophilic) groups on Si(111), as illustrated in Fig. 30.62. For the hydrophobic molecules, the friction coefficient is almost constant independent of the number of water molecules. For the hydrophilic molecules, the friction coefficient decreases rapidly with an increase in the number of water molecules, as shown in Fig. 30.63. These results are in good agreement with surface force microscopy (SFM) experimental results. *Zhang* et al. [30.256] also studied the friction of alkanethiol SAMs on gold using hybrid molecular simulations at the same time scales as are used in AFM and FFM experiments. Various quantities were varied in the simulations, including chain length, terminal group, scan direction and scan velocity. The simulations showed that the frictional force decreases as the chain length increases and is smallest when scanned along the tilt direction. They also predicted a maximum friction coefficient for hydrophobic $-CH_3$-terminated SAMs and low friction coefficients for hydrophilic $-OH$-terminated SAMs as the scan velocity increases. The simulations further predicted a saturated constant value at high scan rates for both surfaces. These results are summarized in Figs. 30.64 and 30.65.

The work of *Chandross* et al. [30.257, 258] illustrates the effects of chain length on friction and stick–slip behavior between two ordered SAMs consisting of

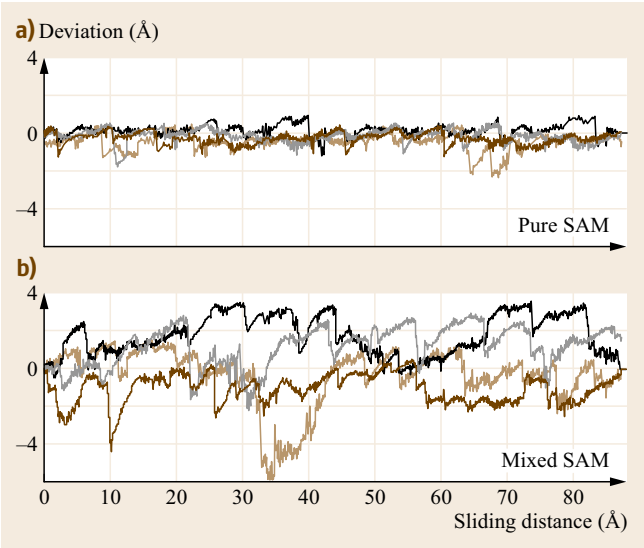

Fig. 30.59a,b Trajectories of individual chain groups that generate the largest contact forces when sliding in the direction of chain tilt for both the pure **(a)** and mixed monolayer systems **(b)**. The deviation is defined as the change in position along the sliding direction relative to the chain group's starting position. (The positions are averaged over 2000 simulation steps)

alkylsilane chains over a range of shear rates at various separation distances or pressure, as illustrated in Fig. 30.66. The adhesion forces between the two SAMs at the same separation distance decrease as the chain length increases from 6 to 18 carbon atoms. However, the friction forces are independent of the chain length and the shear velocity. The system size is shown to have an effect on the sharpness of the slip transitions but not on the dynamical events, as shown in Fig. 30.67. In a later paper, *Chandross* et al. used SiO_2 tips with radius of curvatures in the range of 3–30 nm to interact with fully physisorbed, fully chemisorbed, and a mixture of chemisorbed and physisorbed alkylsilane SAMs on amorphous Si [30.259]. This tip-based geometry allows for the exploration of actual contact area as a function of load, which was found to be proportional to the square root of the load.

SAMs have been very successful in the lubrication of surfaces that infrequently come into sliding or normal contact. Their inability to lubricate a reciprocating contact is due, in part, to the inability to replenish the coating in situ. One proposed solution is to use a chemically bound SAM in conjunction with a physisorbed mobile molecule in a *bound + mobile* lubricant scheme, which is similar to the lubricants used to mitigate head crashes in hard drives.

Irving and *Brenner* used molecular dynamics to study the interfacial structure, self-diffusion, and abil-

ity of the mobile phase to incorporate into defected sites [30.260]. A potential bound + mobile lubricant combination of a chemically bound octadecyltrichlorosilane (ODTS) SAM together with mobile tricresyl phosphate (TCP) molecules was studied. The simulations showed that the TCP did not incorporate into the interior of the close packed defect free ODTS SAM. The TCP molecules on the surface of the SAM were also not tightly bound to a particular surface site but instead were found to readily diffuse across the surface in a random walk fashion. An estimated diffusion barrier of 0.0937 eV with an Arrhenius prefactor of $26.47 \times 10^{-4}\,cm^2/s$ was calculated for single-molecule diffusion. It was also found that the TCP molecules would only localize in the vicinity of methylene groups ($-CH_2-$) along the backbone of the ODTS chain, which were exposed when a cylindrical defect was created in the SAM. To get to these local-

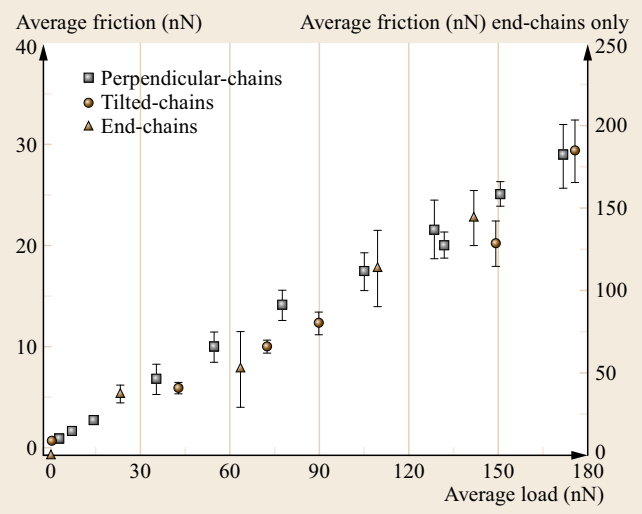

Fig. 30.61 Average friction on the tip as a function of load for the monolayer systems shown in Fig. 30.60. The *scale* for the average friction in the end-chain system is shown on the *right-hand side* of the figure (after [30.254], © ACS 2004)

izing sites, however, first required the TCP molecules to overcome an anisotropic energy barrier for inclusion into the cylindrical defect. This anisotropic barrier was found to depend on the direction of ODTS chain tilt and the direction the TCP molecules approached the cylindrical defect in the SAM. A later study used the diffusion information and multiscale methods to analyze the conditions under which this scheme would be successful [30.261].

Polymer thin films are also a widely studied for their lubricating properties. An example is polytetrafluoroethylene (PTFE), which has been used in a wide range of applications from satellites to frying pans. In a joint computational and experimental work *Jang* et al. examined the molecular origins of friction using classical molecular dynamics as well as an AFM and microtribometer [30.262]. The simulations predicted an anisotropic behavior of the friction coefficient depending on whether the sliding direction was parallel or perpendicular to the PTFE chains lying on the surface. Sliding directions parallel produced lower friction coefficients and wear while sliding perpendicular to alignment produced higher coefficients and wear. The microtribometer results were in agreement with these findings. Also of interest in the AFM work was that transfer films were always produced parallel to the sliding direction.

Similar experimental findings for anisotropic tribological behavior of polyethylene (PE) in the literature motivated *Heo* et al. to examine this system using classical molecular dynamics to study crystalline PE interfaces [30.263]. Like the findings for PTFE it was found that friction and wear had an anisotropic behavior that depended on molecular orientation and sliding direction. Unlike the findings for PTFE, the PE system exhibited a stick–slip motion as the interfaces passed by one another. The reason for the differences between the two systems was attributed to increased bond scission seen in PTFE as compared to PE under sliding conditions. This scission allows collections of molecules in PTFE to move at the interface, which does not occur as readily in the PE system.

In short, atomic-scale simulations show the relationship between elastic properties, degree of molecular disorder and friction of self-assembled thin films that illuminates the origin of the properties that are measured experimentally.

Nanoparticles

Nanoparticles are being considered for a wide variety of applications, including as fillers for nanocomposite materials, novel catalysts or catalytic supports, and components for nanometer-scale electronic devices [30.264]. They have also generated considerable interest as possible new lubricant materials that have the potential to function as *nanoballbearings* with exceptionally low friction coefficients. The nanoparticles of most interest for tribological applications include C_{60} [30.265–277], carbon nanotubes [30.278–285], and MoO_3 nanoparticles [30.286, 287], among others [30.288].

The experiments report wide variations in frictional coefficients (for instance, values of 0.06 to 0.9 have been measured for C_{60}) that may be caused by differences in the experimental methods used, the thickness of the nanoparticle layer or island, the atmosphere (argon versus air, levels of humidity) used, and the transfer of nanoparticles to the FFM tips. As a result, there is much that remains to be clarified about the tribological behavior of nanoparticle films.

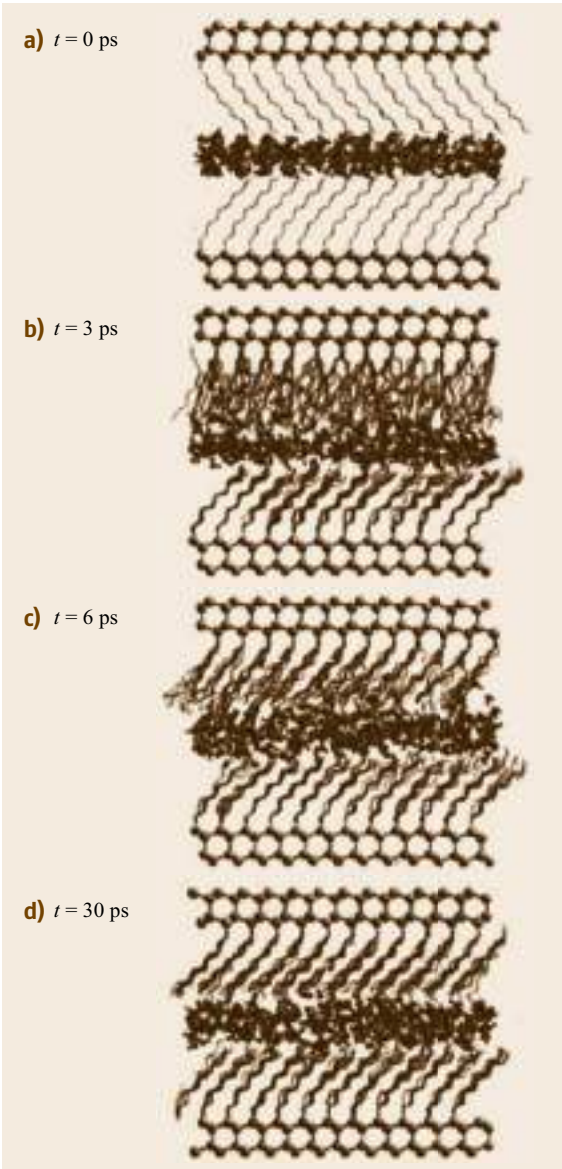

Fig. 30.62a–d Snapshots of hydrophilic monolayers and confined water molecules from MD simulations at 300 K. The tilt direction of monolayers on the top plate changed after $t = 10.0$ ps. **(a–d)** illustrates how the tilting of the monolayers change as a function of time, and the way in which the water becomes increasingly less confined (after [30.255], © AIP 2005)

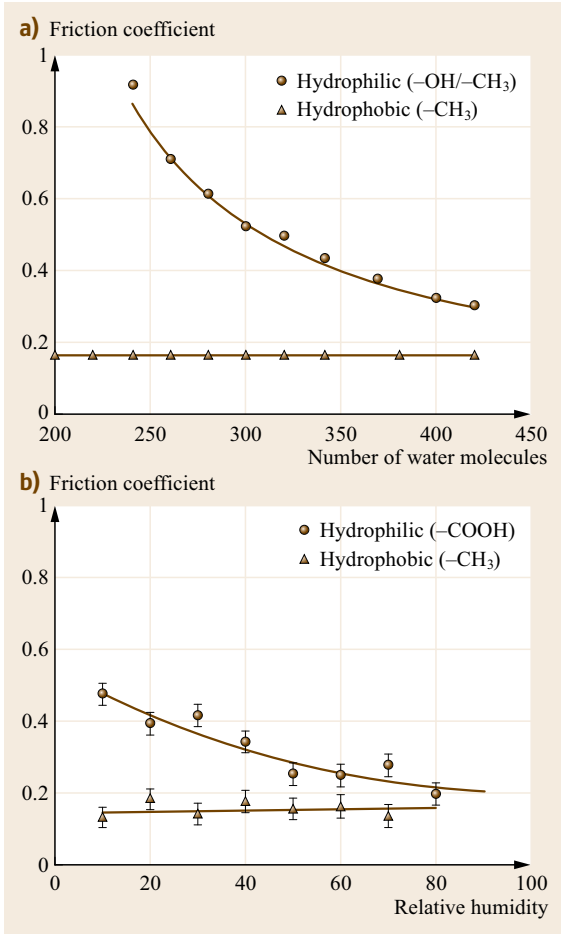

Fig. 30.63 (a) Friction coefficients for hydrophobic ($-CH_3$) and hydrophilic (50% mixed $-CH_3/-OH$) monolayers as a function of water molecules from MD simulations at 300 K ($H = 6.0$ Å), and **(b)** scanning force microscopy measurements of frictional forces of difference surfaces under various relative humidities (after [30.255], © AIP 2005)

In the case of C_{60}, the mechanistic response to applied shear forces has not been definitively determined. For example, some experimental studies show evidence of C_{60} molecules rolling against the substrate, each other, or the sliding surfaces [30.265, 270, 272, 275, 277] while others hypothesize that the low friction of C_{60} films is due in part to blunting of the tip by transfer of fullerene molecules to the tip apex. Fullerene films are found experimentally to have dissipation energies and shear strengths that are a full order of magnitude lower than the values that are typical for boundary lubricants [30.289]. Experimental testing of the frictional properties of fullerenes reveal low mechanical stability accompanied by progressive wear and transfer of fullerene materials when they are only physisorbed on a solid surface [30.290]. Furthermore, measurements with a FFM show that under certain conditions, adsorbed fullerene films deteriorate

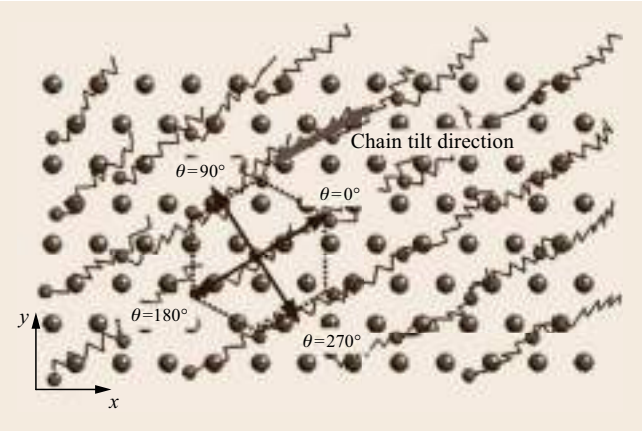

Fig. 30.64 Schematic illustration of the chain tilt and scan directions on alkanethiol SAMs/Au(111) in hybrid molecular simulations; θ is the angle between the tip moving direction and the chain tilt direction. The *larger spheres* represent substrate Au atoms, smaller spheres sulfur atoms in molecular chains, and *zigzag lines* molecular chains (after [30.256], © ACS 2003)

at pressures as low as about 0.1 GPa [30.291]. The challenge is therefore to obtain mechanically stable, ordered molecular films of fullerenes firmly attached to a solid substrate.

There have been several MD simulation studies to investigate the tribological properties of fullerenes. A representative study by *Legoas* et al. [30.292] investigated the experimentally observed low-friction system of C_{60} molecules positioned on highly oriented pyrolytic graphite. The results show that decreasing the van der Waals interaction between a C_{60} monolayer and graphite sheets, and the characteristic movements of graphite flakes over C_{60} monolayers, explains the measured ultralow friction of C_{60} molecules and graphite sheets.

Several MD simulation studies have also been carried out on the tribological properties of carbon nanotubes. For example, simulations by *Buldum* and *Lu* [30.278] and *Schall* and *Brenner* [30.281] indicate that single-wall carbon nanotubes roll when their honeycomb lattice is *in registry* with the honeycomb lattice of the graphite. If this registry is not present, the carbon nanotubes respond to applied forces from an AFM by sliding. This behavior is nicely summarized in Fig. 30.68. These MD simulation findings were simultaneously confirmed in experimental studies by *Falvo* et al. [30.280]. Experimental studies of multiwall carbon nanotubes on graphite [30.284] show similar evidence of nanotube rolling when the outer tube is pushed.

The tribological properties of nanotube bundles are important, as it is well-known that carbon nanotubes agglomerate together very readily to form bundles and are often grown in bundle form [30.264]. An experimental study by *Miura* et al. [30.285] of carbon nanotube bundles being pushed around on a KCl surface with an AFM tip indicates that bundles of single-wall carbon

nanotubes can be induced to roll in a manner that is similar to the rolling observed for multiwall nanotubes.

MD simulations by *Ni* and *Sinnott* [30.282, 283] considered the responses of horizontally and vertically aligned single-wall carbon nanotubes between two hydrogen-terminated diamond surfaces, where the top surface is slid relative to the bottom surface. The movement of the carbon nanotubes in response to the shear forces was predicted to be simple sliding for both orientations. Interestingly, the simulations do not predict rolling of the horizontally arranged carbon nanotubes even when they are aligned with each other in two-layer and three-layer structures. Instead, at low compressive forces, illustrated in Fig. 30.69, the nanotube bundles slide as a single unit, and at high compressive forces, also illustrated in Fig. 30.69, the deformed carbon nanotubes closest to the topmost moving diamond surface start to slide in a motion reminiscent of the movement of a tank or bulldozer wheel belt. However, when these moving carbon nanotube atoms would have turned the first corner at the top of the ellipse, they encounter the neighboring nanotube and cannot slide past it. This causes them to deform even further, form cross-links with one another, and, in some cases, move in the reverse direction to the sliding motion of the diamond surface. This causes the large oscillations in the normal and lateral forces plotted in Fig. 30.69.

A later study by *Heo* and *Sinnott* examined the frictional properties of single wall, double wall, and filled carbon nanotubes contained between two hydrogen terminated diamondlike carbon layers [30.293]. It was shown that over a wide range of loads the simulations predicted a friction coefficient of 0.13 for filled as well as unfilled nanotubes. This friction coefficient was found to be constant for pressures below 5 GPa, which should include most practical applications. At pressures above 5 GPa the friction coefficient was found to increase to 0.2. Unlike the work of Ni and Sinnott it was demonstrated that the nanotubes would roll in response to the applied shear. This difference was attributed to the finite size of the nanotubes used in this

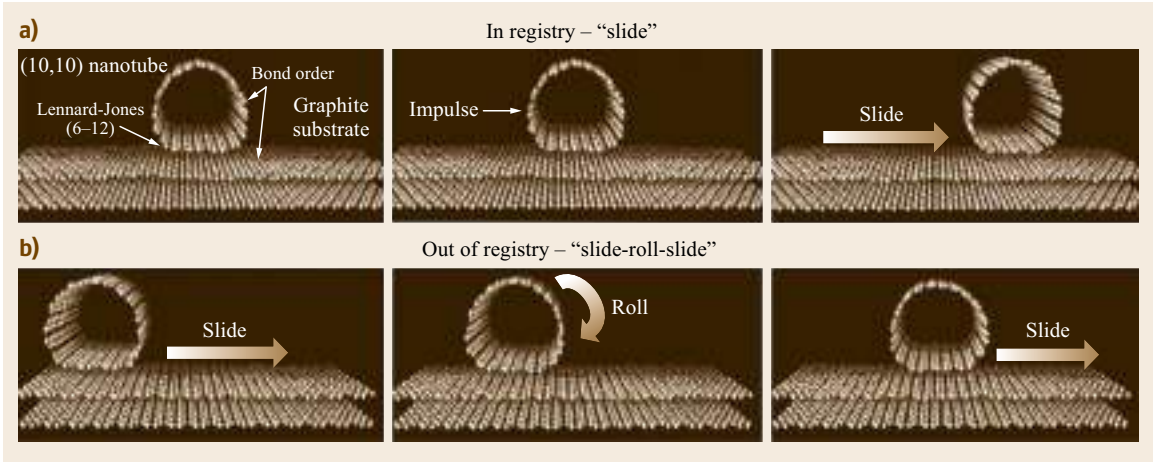

Fig. 30.68a,b Dynamics of a nanotube on a graphite surface. When the nanotube and graphite plane are out of registry **(a)**, the nanotube slides as it slows down from an initial impulse (*upper right panel*). When the nanotube is oriented such that it is in registry **(b)** with the graphite, it slows by a combination of rolling and sliding

simulation as compared to the infinite tubes used by Ni and Sinnott. Although the frictional properties were similar for all systems considered, it was found that filled nanotubes, whether they are double-walled nanotubes or nano-peapods, were more adept at sustaining higher load then the unfilled single-walled nanotubes. Surprisingly, it was also found that the addition of lubricating benzene molecules did little to alter the friction in the system. Rather, it was found that the addition of benzene altered the mechanism by which the system responded to the applied shear stress.

The responses of the horizontally arranged carbon nanotubes are substantially different from the responses of the vertically arranged nanotubes at high compression, as can be seen by comparing Figs. 30.69 and 30.70. The vertical, capped carbon nanotubes are quite flexible and bend and buckle in response to applied forces. As the buckle is forming, the normal force decreases then stabilizes in the buckled structure, as illustrated in Fig. 30.70. As the topmost diamond surface slides, the buckled nanotubes swing around the buckle *neck* which helps dissipate the applied stresses. For this reason, the magnitudes of the lateral forces are not significantly different for the vertical nanotubes at low and high compression, as indicated in Fig. 30.70.

When the ratio of the frictional (lateral) force to the normal force is taken to calculate friction coefficients for these systems, high, nonintuitive values were obtained. As outlined by *Ni* and *Sinnott* [30.282], this is because the actual contact area of the nanotubes is not proportional to the sliding force. In the case of the horizontal nanotube bundles, the tubes are able to deform and significantly change their contact area with the sliding surface with minimal change in the normal force, as shown in Fig. 30.69. In the case of the vertical nanotubes, the contact area remains approximately the

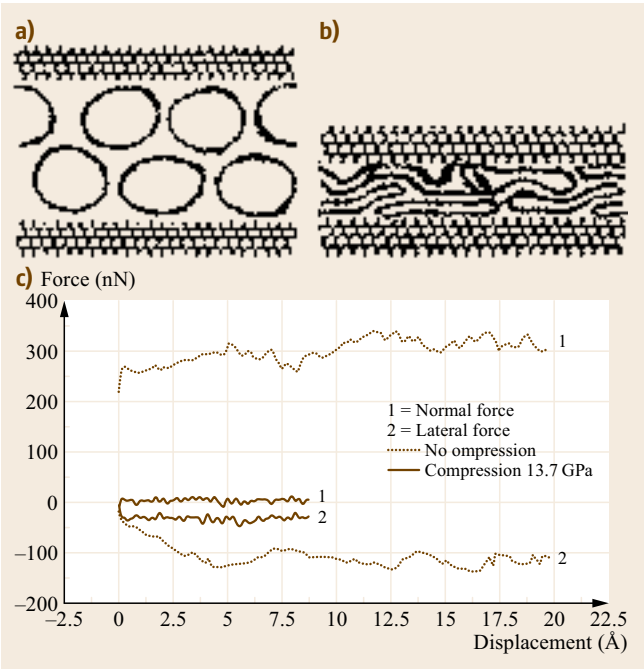

Fig. 30.69 (a,b) Snapshots from simulations that examine the sliding of the topmost diamond surface on horizontally arranged nanotubes at different compressions; **(a)** is at a pressure of ≈ 0 GPa; **(b)** is with a pressure of 13.7 GPa. **(c)** Plots of the normal and lateral components of force during sliding of the top diamond's surface on horizontally arranged nanotubes as a function of the displacement of the top diamond surface with respect to the diamond surface on the bottom

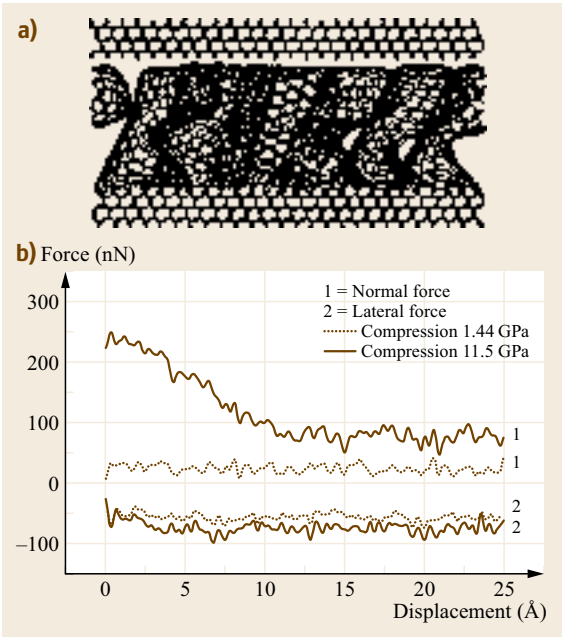

Fig. 30.70 **(a)** Snapshots from simulations that examine the sliding of the topmost diamond surface on vertically arranged nanotubes with one set of capped ends compressed at a pressure of 11.5 GPa. **(b)** Plots of the normal and lateral components of force during sliding of the top diamond's surface on vertically arranged nanotubes as a function of the displacement of the top diamond surface with respect to the diamond surface on the bottom

same regardless of the initial loading force because of the flexibility of the nanotubes. This causes the lateral forces to change only slightly with significant changes in the normal force, as shown in Fig. 30.70. This analysis indicates that care must be taken in calculating friction coefficients for nanotube systems. Recent experiments by *Dickrell* et al. [30.294] show good agreement with these predictions, as shown in Fig. 30.71.

To summarize, this section shows that nanoparticles show some promise as lubricating materials due to their exceptionally low friction coefficients in experiments and simulations. Some nanopaticles show lattice-directed sliding on substrates due to their unique atomic structures. However, there is much that remains to be done before the nanometer-scale friction of these materials is well understood.

Solid State

Surfaces are able to slide over each other at high loads with a minimum of resistance from friction in the presence of liquid lubricants. Some solid thin films can also fulfill these functions and, when they do, are termed solid lubricants. Solid lubricants are generally defined

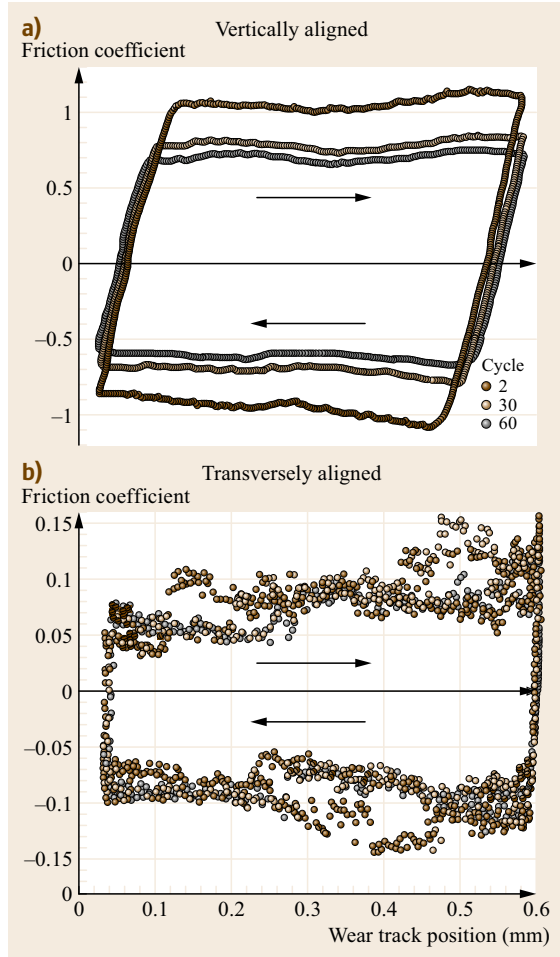

Fig. 30.71a,b Coefficient of friction data versus track position collected for one full cycle of reciprocating sliding for nanotubes that are vertically **(a)** and transversely aligned **(b)** (after [30.294])

as having friction coefficients of 0.3 or less and low wear.

Bowden and *Tabor* showed how thin solid films can reduce friction as follows [30.296]. The total friction force F_f is given as

$$F_f = AF_S + F_p \,, \tag{30.11}$$

where F_p is the plowing term, A is the area of contact and F_S is the shear strength of the interface. If the surfaces are soft, F_S will be reduced while the other parameters will increase. However, if the surfaces under the solid film are very stiff, A and F_p will decrease thereby decreasing friction. The properties specific to the film will also have an effect on friction. For instance, if the films are less than 1 μm thick, the surface asperities will be able to break through the film to eventually

cause wear between the surfaces under normal circumstances. On the other hand, if the lubricant film is too thick, there will be increased plowing and wear that causes the frictional forces to increase. It is important that the lubricant not delaminate in response to the frictional forces, so strong bonds between the lubricant and the surface are required for a solid state lubricant to be effective.

The most common materials used as solid lubricants have layered structures like graphite or MoS_2, that, as discussed above, experience low friction. It is not necessary for the lubricant film to have a layered structure to give low friction. For example, diamondlike carbon has some of the lowest coefficients of friction measured and yet does not have a layered structure. Similarly, not all layered structures are lubricants. For instance, mica gives a relatively high coefficient of friction (> 1).

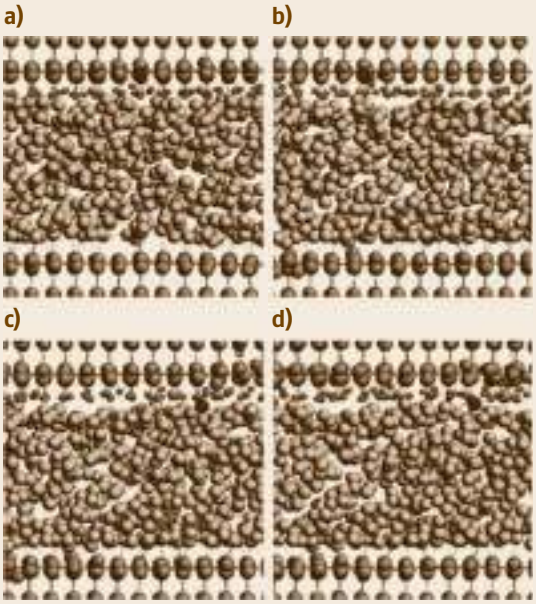

Fig. 30.72a–d A series of chemical reactions induced by sliding of the counterface over the thin film under an average load of 300 nN. **(a)** The sliding causes the rupture of a carbon–hydrogen bond in the counterface. **(b)** The hydrogen atom is incorporated into the film and forms a bond to a carbon atom in the film. **(c)** A bond is formed between the unsaturated carbon atoms in the film and the carbon that suffered the bond rupture in the counterface, and continued sliding causes this carbon to be transferred into the film. **(d)** The transferred carbon forms a bond with another carbon in the counterface. The counterface has slid 0.0 Å **(a)**, 15.9 Å **(b)**, 26.1 Å **(c)**, and 30.5 Å **(d)** (after [30.295], © ACS 2002)

The atomic-scale tribological behavior that occurs when a hydrogen-terminated diamond (111) counterface is in sliding contact with amorphous, hydrogen-free, DLC films was examined using MD simulations by *Gao* et al. [30.295]. Two films, with approximately the same ratio of sp^3–sp^2 carbon but different thicknesses, were examined. Similar average friction was obtained from both films in the load range examined. A series of tribochemical reactions occur above a critical load that result in a significant restructuring of the film, which is analogous to the *run-in* observed in macroscopic friction experiments, and reduces the friction. The contribution of adhesion between the counter-

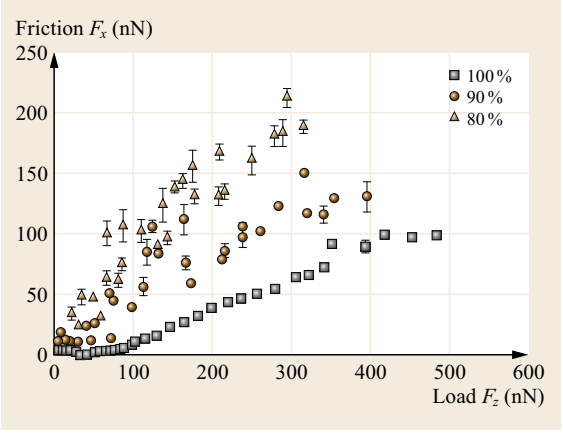

Fig. 30.73 Friction curves for the thin film system with a counterface that is 100% hydrogen-terminated (*gray squares*), 90% hydrogen-terminated (*brown squares*), and 80% hydrogen-terminated (*brown triangles*) (after [30.295], © ACS 2002)

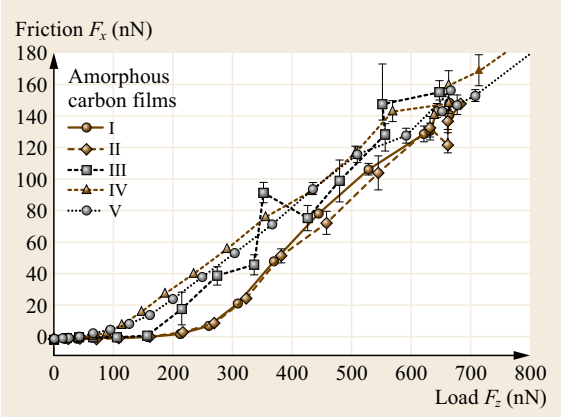

Fig. 30.74 Average friction versus load for five amorphous carbon films. Films I–III are hydrogen-free and contain various ratios of sp^2-to-sp^3 carbon. Films IV and V are both over 90% sp^3 carbon and have surface hydrogenation

face and the sample to friction is examined by varying the saturation of the counterface. The friction increases when the degree of saturation of the diamond counterface is reduced by randomly removing hydrogen atoms. Lastly, two potential energy functions that differ only in their long-range forces are used to examine the contribution of long-range interactions to friction in the same system (as illustrated in Figs. 30.72 and 30.73).

MD simulations were also recently used by *Gao* et al. [30.297] to examine the effects of the sp^2–sp^3 carbon ratio and surface hydrogen on the mechanical and tribological properties of amorphous carbon films. This work showed that, in addition to the sp^2–sp^3 ratio of carbon, the three-dimensional structures of the films are important when determining the mechanical properties of the films. For example, it is possible to have high sp^2-carbon content, which is normally associated with softer films, and large elastic constants. This occurs when sp^2-ringlike structures are oriented perpendicular to the compression direction. The layered nature of the amorphous films examined leads to novel mechanical behavior that influences the shape of the friction versus load data, as illustrated in Fig. 30.74. When load is applied to the films, the film layer closest to the interface is compressed. This results in the very low friction of films I and II up to ≈ 300 nN and the response of films IV and V up to 100 nN. Once the outer film layers have been compressed, additional application of load causes an almost linear increase in friction for films I and II as well as IV and V. Film III has an erratic friction versus load response due to the early onset of tribochemical reactions between the tip and the film.

30.4 Conclusions

This chapter provides a wide-ranging discussion of the background of MD and related simulation methods, their role in the study of nanometer-scale indentation and friction, and their contributions to these fields. Specific, illustrative examples are presented that show how these approaches are providing new and exciting insights into mechanisms responsible for nanoindentation, atomic-scale friction, wear, and related atomic-scale and molecular scale processes. The examples also illustrate how the results from MD and related simulations are complementary to experimental studies, serve to guide experimental work, and assist in the interpretation of experimental data. The ability of these simulations and experimental techniques such as the surface force apparatus and proximal probe microscopes to study nanometer-scale indentation and friction at approximately the same scale is revolutionizing our understanding of the origin of friction at its most fundamental atomic level.

31. Cellular Nanomechanics

Roger D. Kamm, Jan Lammerding, Mohammad R. K. Mofrad

Numerousapplications of nanotechnology have been developed to understand mechanobiology of living cells and probe their unique mechanical properties in health and disease. In addition, since biological materials exhibit such a wide spectrum of properties, they offer new concepts for nonbiological biomimetic applications. In this chapter, the biomechanical properties of a cell and its subcellular compartments are described. First, a qualitative picture is presented of the relevant building blocks: the cytoskeleton, cell membrane, nucleus, adhesive complexes, and motor proteins. Next, the various methods used to probe cellular and subcellular mechanics are described, and some of the quantitative results presented. These measurements are then discussed in the context of several theories and computational methods that have been proposed to help interpret the measurements and provide nanomechanical insight into their origin. Finally, current understanding is summarized in the context of directions for future research.

31.1 Overview

31.1.1 The Importance of Cell Mechanics in Biology and Medicine

All living things, despite their profound diversity, share a common architectural building block: the cell. Cells are the basic functional units of life, yet they are themselves composed of numerous components with distinct mechanical characteristics. To perform their various functions, cells undergo or control a large range of intra- and extracellular events, many of which involve mechanical phenomena or may be guided by the forces experienced by the cell. These micro- and nanomechanical phenomena range from macroscopic events such as the maintenance of cell shape, motility, adhesion, and deformation, to microscopic events such as how cells sense mechanical signals and transduce them into a cascade of biochemical signals, ultimately leading to a host of essential biological responses.

Cell mechanics plays a major role in biology and physiology. The ability of a cell to perform its function often depends on its shape, and shape is maintained through structural stiffness. In the blood circulation system, red blood cells, or erythrocytes, exist in the form of biconcave disks that are easily deformed to help

facilitate their flow through the microcirculation and have a relatively large surface-to-area ratio to enhance gas exchange. White cells, or leukocytes, are spherical, enabling them to roll along the vascular endothelium before adhering and migrating into the tissue. Because their diameter is larger than some of the capillaries they pass through, leukocytes maintain excess membrane in the form of ruffles or microvilli so that they can elongate at nearly constant volume and not obstruct the microcirculation. In other organs, cells also serve specialized functions; For example, in the lung, airway epithelial cells are covered with a bed of cilia, finger-like cell extensions that propel mucus along the pulmonary airways. Lastly, the cytoskeletal structure in skeletal or cardiac muscle cells is specifically organized to actively generate forces and to sustain large strains. In each of these examples, the internal structure of the cell along with the cell membrane provide the structural integrity to maintain the particular shape needed by the cell to accomplish its function, although the specific components of the structure are highly variable and diverse.

Cell mechanics also plays an important role in cell migration. Migration is critical during early development, but also in the fully differentiated organism, e.g., in wound repair when cells from the surrounding, undamaged tissue migrate into the wound, in angiogenesis (i. e., the generation of new blood vessels), or in combating infection when cells of the immune system transmigrate from the vascular system across the vessel wall and into the infected tissues. In cancer, cell migration and invasion is a crucial step of metastasis, i. e., the spreading of cells from the primary tumor to distant tissues and organs. Regardless of the specific context, cell migration occurs in several stages and cellular mechanics and dynamics are critical modulators at each of these steps.

The importance of cell mechanics in biology is most apparent in mechanotransduction, i. e., the ability of the cell to sense and respond to externally applied forces, and these phenomena form the basis for the field that is now recognized as *mechanobiology*. Most cells are able to sense when a physical force is applied to the cell, and respond through a variety of biological pathways leading to such diverse effects as changes in membrane channel activity, up- or down-regulation of gene expression, alterations in protein synthesis, and altered cell morphology. The signaling cascades that become activated as a consequence of mechanical stress have generally been well characterized. However, the initiating processes by which cells convert the applied force into a biochemical signal are less well understood, and researchers have just begun to unravel some of these fundamental mechanisms. Stretch-activated ion channels or strain-induced activation of G proteins are two recognized means of mechanotransduction. Similarly, disruption of microtubules or conformational changes of cytoskeletal proteins that alter their binding affinities have been demonstrated as cellular mechanosensors. Others have focused on the role of the glycocalyx, a layer of carbohydrate-rich proteins on the cell surface, in the response of endothelial cells to fluid shear stress. Another potential mechanism is that forced deformations within the nucleus could directly alter transcription or transcription factor accessibility. Constrained autocrine signaling is yet another mechanism whereby the strength of autocrine signaling is regulated by changes in the volume of extracellular compartments into which the receptor ligands are shed. Changing this volume by mechanical deformation of the tissues can increase the level of autocrine signaling. Finally, others have demonstrated that conformational changes in intracellular proteins in the force transmission pathway connecting the extracellular matrix with the cytoskeleton through focal adhesions (FAs) are a key mechanotransduction mechanism. Understanding of these fundamental cellular functions has led to a general appreciation of how signals can be transmitted via parallel chemical and mechanical pathways, and that communication between these two is bidirectional. For reviews of this topic, see [31.1–6].

31.1.2 Examples Drawn from Biology and Pathophysiology

Many studies during the past two decades have shed light on a wide range of cellular responses to mechanical stimulation. It is now widely accepted that stresses experienced in vivo are instrumental in a wide spectrum of pathologies (reviewed in [31.5]). One of the first diseases found to be linked to cellular stress was atherosclerosis, where it was demonstrated that hemodynamic shear influences endothelial function, and that conditions of low or oscillatory shear stress are conducive to the formation and growth of atherosclerotic lesions. Even before then, the role of mechanical stress in bone growth and healing was widely recognized, and since then, many other stress-influenced cell functions have been identified. Hair cells in the inner ear translate acoustic vibrations into biochemical signals and thereby enable hearing; conversely, leftward fluid flow generated by oscillating cilia (hair-like extensions) of epithelial cells during gestation is responsible for the normal left–right patterning in early mammalian embryos, and mutations in molecular motors that abolish cilia motion and directed fluid flow result in Kartagener's syndrome, in which left–right patterning becomes random. Mechanotransduction of muscle cells

is pivotal to exercise-induced muscle growth (hypertrophy), and defects – caused for example by mutations in mechanosensitive proteins – can result in muscular dystrophies. Asthma is another particularly salient example where the epithelial cells lining the airways are subjected to stresses as the pulmonary airways constrict during breathing, and airway wall remodeling. Further knowledge of the mechanisms by which cells respond to such forces could enhance our understanding of these diseases.

31.2 Structural Components of a Cell

Aside from providing the outer boundary of a cell and nucleus, membranes enclose numerous intracellular structures as well, and the discussion in this section pertains to all of these.

31.2.1 Membranes

The term *membrane* generally refers to the phospholipid bilayer and the proteins associated with it. The phospholipids contained in the membrane are arranged in two layers, or *leaflets*, with their hydrophobic tails pointing inward and their hydrophilic heads outward. Together, they constitute a bilayer $\approx$6 nm in thickness (Fig. 31.1). In addition to the phospholipids, the membrane contains glycolipids and cholesterol. While the amount of glycolipids is small, constituting only $\approx$2% of the total lipid content, cholesterol is a major plasma membrane constituent, $\approx$20% by weight, a value that remains quite constant among different cell types. The specific membrane composition is critical for determining membrane structural integrity; for example, both the bending stiffness and the viscosity of the lipid bilayer are strongly dependent on the cholesterol content. Membrane composition, and thus mechanical and chemical properties, differ between the plasma membrane surrounding the cell and the membranes encapsulating intracellular organelles, such as the nucleus. Thus, it is possible to select experimental conditions (e.g., mild detergents such as digitonin) that disrupt the plasma membrane while leaving intracellular membranes intact. Cellular membranes also contain many membrane-associated proteins, which account for $\approx$50% of the membrane by weight, but because of their relatively large molecular weight, only $\approx$1–2% of the number of membrane molecules. Membrane proteins serve a variety of functions, ranging from signaling to transport of ions and other molecules across the membrane to cell–cell and cell–matrix adhesion.

The plasma membrane has associated macromolecular structures on both intra- and extracellular sides, giving rise to a three-layer composite construction. On the intracellular side, the membrane is physically attached to a cortex or the cytoskeleton. The cortex is a dense, filamentous structure that lends stiffness to the membrane, and can also interact with various transmembrane proteins, often impeding their free diffusion either by steric interactions or direct chemical bonding. In some cells, the cortex is simply a region of dense cytoskeletal matrix in the vicinity of the bilayer. In others, it exhibits a distinctly different structure or composition; for example, erythrocytes possess a cortex composed of a network of spectrin tetramers linked by actin filaments. This network is attached to the membrane by ankyrin and the integral membrane protein band 3. This spectrin network accounts for much of the bending stiffness exhibited by the red cell membrane.

Most cells are coated by a *glycocalyx*, which has been shown to extend as far as 0.5 μm from the surface of endothelial cells, where it forms a compressible barrier separating circulating erythrocytes and leukocytes from the endothelial membrane. The glycocalyx is composed of short oligosaccharide chains, glycoproteins, glycolipids, and high-molecular-weight proteoglycans, all organized into an interconnected network with an overall negative charge. Although its function is not

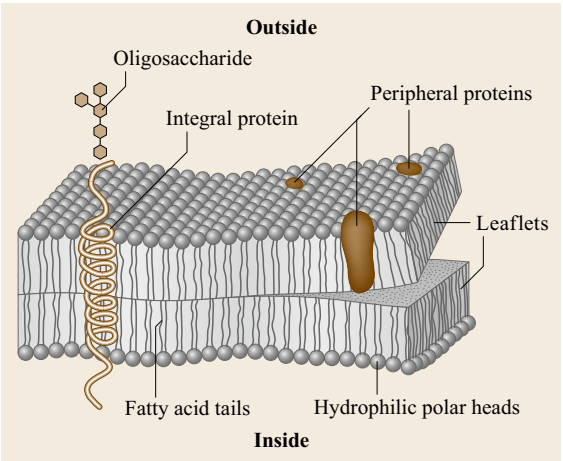

Fig. 31.1 A model of the lipid bilayer, showing the hydrophilic heads (polar head groups) on the exterior surfaces and the hydrophobic tails (fatty acid tails) pointing in. Also shown are examples of transmembrane or integral membrane proteins. The total thickness of the bilayer is $\approx$ 6 nm (after [31.7])

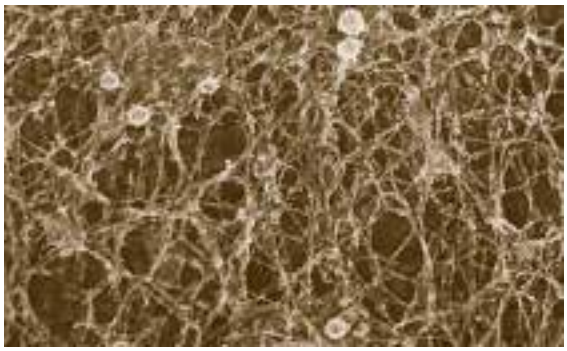

Fig. 31.2 The cytoskeleton of a macrophage lamellipodium as seen by electron microscopy. The fibrous structure is mainly composed of actin filaments (© John Hartwick, Harvard Medical School)

completely understood, it apparently plays a role in macromolecular transport across the endothelium and is an important factor in the interaction between bloodborne cells and the endothelium. Studies have demonstrated that the glycocalyx in a capillary is readily compressed by a passing leukocyte, yet is sufficiently rigid to prevent flowing erythrocytes from approaching the endothelial surface. Recent studies demonstrate that steric interference of the glycocalyx, which is substantially taller than transmembrane cell surface receptors, can also modulate cell adhesion and cell surface receptor clustering [31.3, 8]. These findings are particularly relevant in cancer invasion and metastasis, since malignant cancer cells often have altered expression of glycans and glycoproteins that results in a bulkier glycocalyx, which promotes integrin clustering and focal adhesion assembly [31.3].

31.2.2 Cytoskeleton

The cytoskeleton is the network of biopolymers that permeates the cell and largely accounts for its structural integrity. At high magnification, this network appears to be composed of several distinct types of intertwined filaments with a variety of interconnections, as can be seen in the micrograph in Fig. 31.2. The apparent stiffness of the network, as that of other fibrous materials, depends fundamentally upon the elastic properties of the constituent fibers, but also on the level of prestress generated by actomyosin contractility.

The cytoskeletal matrix is primarily composed of three constituents: actin microfilaments ($\approx 5-9$ nm in diameter), microtubules (≈ 24 nm), and intermediate filaments (≈ 10 nm) (Table 31.1). These form a complex interconnected network that exists in a state of constant flux, especially when the cell is dividing, migrating or undergoing other dynamic processes. All are polymers built from protein subunits, held together by noncovalent bonds. They also share the common feature that they cross-link, often with the aid of other proteins, to form bundles and lattice networks. The higher-order structures formed by these polymers, as we will see, are critical determinants of cytoskeletal elasticity and can vary substantially between different cells.

Actin Microfilaments

Actin filaments play an essential role in virtually all types of motility. Actin–myosin interactions are of obvious importance in muscle, but are also instrumental in the migration and movement of nonmuscle cells. Actin polymerization in combination with cytosolic pressure is one of the critical factors initiating cell migration through the formation of filopodia or lamellipodia [31.5, 10].

Actin is one of the most prevalent proteins found in the cell, ranging in concentration from 1–10% by weight of total cell protein in nonmuscle cells, to 10–20% in muscle. Molecular actin is composed of 375 amino acids (molecular weight 43 kDa) and is found in at least six isoforms that differ from each other only slightly. Of these, four are found in muscle and the other two in nonmuscle cells. Actin exists in either globular form (G-actin monomers) or filamentous form (F-actin polymers), with the balance between the two being a highly dynamic process that is finely regulated by a variety of different factors. F-actin is a long, flexible filament, $\approx 5-9$ nm in diameter. Subunits (monomers) are organized into a double-stranded helix having structural and functional polarity (pointed or negative, and

Table 31.1 The main constituents of the cytoskeleton and their mechanical properties. Note that the effective Young's modulus, estimated using the diameter and bending stiffness values for actin filaments and microtubules, is approximately the value that would be predicted on the basis of van der Waals attraction between two surfaces [31.9]. Recall that the persistence length and bending stiffness are related through the expression $l_p = K_b/k_B T$, and that $K_b = EI = \pi/4a^4E$ for a rod of circular cross-section with radius a

	Diameter $2a$ (nm)	Persistence length l_p (μm)	Bending stiffness K_b (N m^2)	Young's modulus E (Pa)
Actin filaments	5–9	17	7×10^{-26}	$1.3–2.5\times10^9$
Microtubules	25	1000–5000	2.6×10^{-23}	1.9×10^9
Intermediate filaments	10	1–3	$4–12\times10^{-27}$	$1–3\times10^9$

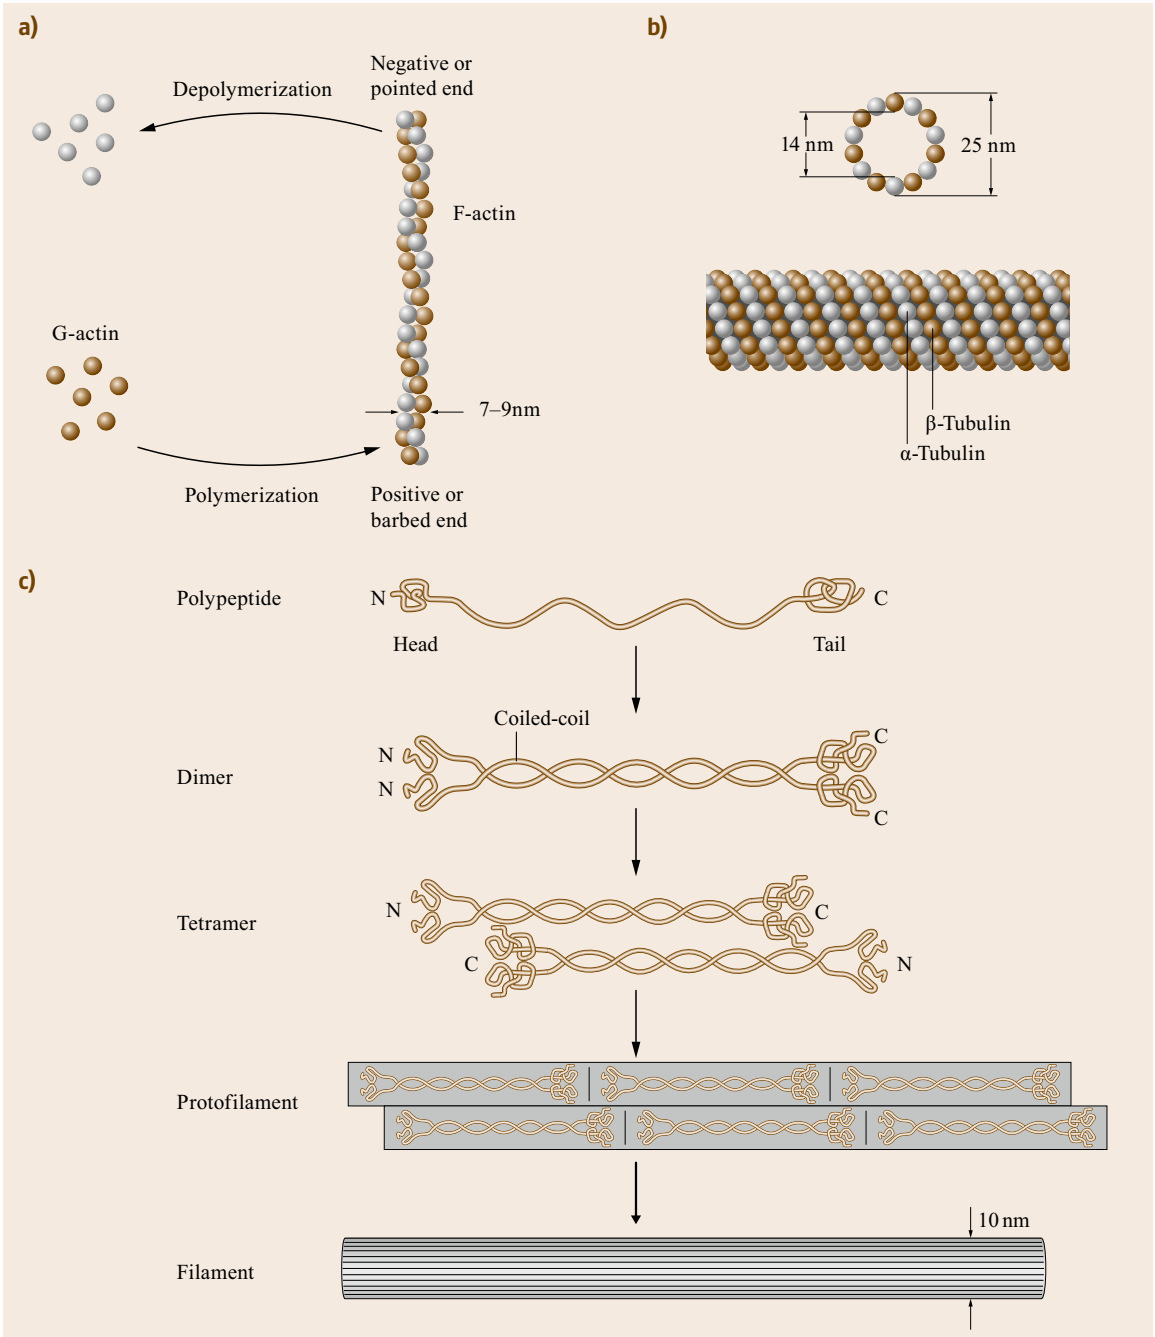

Fig. 31.3 **(a)** Schematic showing the polymerization of G-actin monomers to form F-actin. **(b)** α- and β-tubulin organized into microtubules. **(c)** Organizational structure of a cytoplasmic intermediate filament

barbed or positive ends) and a half-pitch of $\approx 37\,\text{nm}$ (Fig. 31.3a). At the barbed end, an adenosine triphosphate (ATP) binding cleft is exposed, allowing for binding of monomer and linear growth of the filament. ATP binding and hydrolysis play a critical role in regulating actin dynamics and controlling the length of the actin filament. In addition, variations in the local levels of specific actin binding proteins such as Arp2/3, formin, or gelsolin can selectively promote actin polymerization, induce actin filament branching, sever actin

filaments, or cap actin filaments at the pointed or barbed end.

The F-actin filaments can further organize into quaternary structures such as bundles or a lattice network with the aid of *actin binding proteins* (ABPs). The bundles, also referred to as *stress fibers*, are closely packed parallel arrays of filaments, connected to each other by several members of the ABP family (e.g., α-actinin, fascin, and scruin) and molecular motors of the nonmuscle myosin II family, which give the stress fibers their contractile properties. Stress fibers can vary in size, but are typically several hundred nanometers in diameter. Actin stress fibers tend to form when the cell requires additional strength, such as in endothelial cells, in response to an elevated shear stress, or in migrating fibroblasts. These fibers often concentrate around and attach to focal adhesion sites, and are therefore critical to cell adhesion. Actin networks consist of an interconnected matrix of F-actin filaments, the junctions of which are often seen to be nearly orthogonal. At least two distinct types of network are observed – cortical (membrane-associated and more planar in nature) and non-membrane-associated, which possess a more isotropic three-dimensional structure. The formation of bundles and networks is facilitated by a variety of cross-linking proteins such as filamin, which forms a V-shaped polymer that connects two actin filaments nearly at right angles.

The elastic properties of actin filaments have been measured in a variety of ways: by axial stretch [31.11], twisting [31.12, 13], and bending [31.14]. By all methods, single actin filaments were found to exhibit a Young's modulus in the range of $(1.3–2.5) \times 10^9\,\mathrm{N/m^2}$. This range compares favorably with that measured for silk and collagen [31.15] and is also roughly consistent with predictions based on van der Waals bonding between surfaces [31.9].

Intermediate Filaments

Intermediate filaments, which form ≈ 10 nm-diameter fibers in vitro and in vivo, are much less studied than actin and not as well characterized. Perhaps this is due to the fact that there is no single molecular constituent that composes the intermediate filaments (IFs); instead, there are more than 50 different IF genes that have been identified. Expression of specific IFs is very cell type and tissue specific, such as expression of vimentin in fibroblasts and many mesenchymal cells, or desmin in striated muscle cells.

Intermediate filaments constitute ≈ 1% of total protein in most cells, but can account for up to 85% in cells such as epidermal keratinocytes and neurons [31.16]. While they come in many varieties, they share a common structural organization. All have a large central α-helical rod domain flanked by amino- and carboxy-terminal domains. Assembly occurs by the formation of dimers into a coiled coil structure. For cytoplasmic IFs, the dimers assemble in a staggered antiparallel array to form tetramers that connect end to end to form apolar protofilaments. These protofilaments assemble into a rope-like structure containing ≈ 8 subunits each (Fig. 31.3c) [31.16, 17]. Although intermediate filaments are more stable than microfilaments, they can be modified by phosphorylation. Intermediate filaments exhibit a lower bending stiffness than either microfilaments or microtubules, as evidenced by their persistence length of only 1–3 μm. Linker proteins such as bullous pemphigoid antigen 1 (BPAG1) and plectin contain both actin and IF binding domains, providing a means by which these networks can be linked. Evidence also exists for plectin binding to microtubules.

Intermediate filaments are often found surrounding the nucleus and extending outward to the plasma membrane. In epithelial cells, keratin filaments connect to the plasma membrane at desmosomes and hemidesmosomes and help them to withstand mechanical stress. In addition to these cytoplasmic IFs, multicellular organisms also express nuclear IFs, lamins, which form a dense protein network underneath the inner nuclear membrane and are described in more detail in Sect. 31.2.3.

Microtubules

Microtubules are important in determining cell shape, and they play a critical role in separating chromosomes during mitosis. Microtubules are central to the motion of cilia and flagella. Compared with either microfilaments or intermediate filaments, microtubules are rigid structures, but exist in a dynamic equilibrium, much as do microfilaments. Microtubules take the form of hollow cylinders with ≈ 25 nm outer diameter and 14 nm inner diameter. The tubular structures are composed of tubulin, a globular dimer consisting of two 55 kDa polypeptides, α- and β-tubulin. The dimers polymerize to form microtubules that consist of 13 linear protofilaments forming a hollow-cored cylinder (Fig. 31.3b). The filaments are polar, having a rapidly growing end and a slowly growing end, mediated by hydrolysis of guanosine triphosphate (GTP) after polymerization. If hydrolysis occurs too quickly, before new GTP-bound tubulin can bind to the end, the microtubule might disassemble. Depending on the rate of hydrolysis and rate of GTP-bound tubulin addition to the end, the microtubule can either grow or shrink [31.18]. In fact, free ends tend to alternate between periods of steady growth and disassembly in a stochastic manner.

During interphase, microtubules tend to be anchored at their negative ends to the centrosome, located

near the nucleus. From there they extend to all parts of the cell, suggesting a strong role in maintaining the structural integrity of the cell and providing a cellular *highway* system for cargo transported by motor proteins such as the kinesins and dyneins. In many of these situations, the microtubule is thought to play a structural role that relies on its having a high bending stiffness, which was found to be of the order of $2.6\times10^{-23}\,\mathrm{N\,m^2}$ [31.15].

31.2.3 Nucleus

The nucleus is the distinguishing feature of eukaryotic cells and directs and controls deoxyribonucleic acid (DNA) replication, ribonucleic acid (RNA) transcription and processing, and ribosome assembly [31.19]. Most eukaryotic cells contain a single nucleus. However, some specialized cells (e.g., red blood cells) become anucleate during their maturation, while other cells such as skeletal and cardiac muscle cells can become multinucleated due to cell fusion. With a diameter in the range of $\approx 5-20\,\mu\mathrm{m}$, the nucleus is the largest cellular organelle. The nucleus is separated from the cytoplasm by the nuclear envelope, which consists of two lipid bilayers, the inner and outer nuclear membrane, nuclear pores, and the underlying nuclear lamina, a dense protein network consisting mostly of lamin proteins that control the nuclear shape, size, and stability (Fig. 31.4). The outer nuclear membrane is continuous with the endoplasmic reticulum and connects to the inner nuclear membrane at the nuclear pores, thus enclosing the perinuclear space. Nuclei typically contain a few thousand nuclear pores, composed of hundreds of proteins that form the nuclear pore complex that controls transport between the nucleus and the cytoplasm [31.20, 21].

The nuclear interior contains the packaged DNA in the form of chromatin as well as diverse intranuclear compartments referred to as subnuclear bodies that include nucleoli, Cajal bodies, and promyelocytic leukemia (PML) bodies. These subnuclear bodies are not surrounded by membranes but self-organize through processes only incompletely understood. Chromatin can be organized into two distinct forms, the dense and transcriptionally silent heterochromatin often located at the nuclear periphery, and the typically gene-rich and transcriptionally active euchromatin. Chromatin is composed of $\approx 30\,\mathrm{nm}$ fibers that arise from regular wrapping of DNA around histone octamers to form nucleosomes resembling beads on a string and subsequent further compaction facilitated through the linker histone H1. This process allows the $\approx 2\,\mathrm{m}$ of human DNA to be packaged into a nucleus a few micrometers in diameter. The chromatin fibers in turn form higher-order structures such as euchromatin and heterochromatin, which can be dynamically regulated by biochemical modification (e.g., by methylation, acetylation or phosphorylation) of histone proteins and DNA. Furthermore, chromatin fibers from single chromosomes often form distinct and nonoverlapping chromosome territories. In addition to chromatin and nuclear bodies, the nuclear interior also contains several structural proteins, including nuclear actins, myosin, spectrin, and nucleoplasmic lamins A and C [31.22–26]. However, it remains unclear what intranuclear structures (often referred to as nuclear matrix) these proteins form within the nuclear interior and how such structures could contribute to nuclear processes such as transcription, and DNA damage repair.

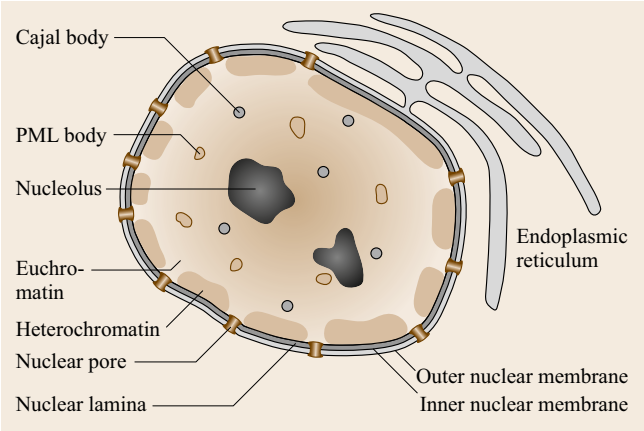

Fig. 31.4 Schematic drawing of a mammalian cell nucleus. The nucleus is surrounded by the inner and outer nuclear membranes and the underlying nuclear lamina. Nuclear pores allow transport between the nuclear interior and the cytoplasm. The nuclear interior consists of densely packed heterochromatin, mostly located at the nuclear periphery, the transcriptionally active euchromatin, and several intranuclear structures such as Cajal and promyelocytic leukemia (PML) bodies and the nucleoli. Not shown are intranuclear structures formed by lamins and other proteins that constitute the nuclear matrix

Importantly, the nucleus cannot be viewed in isolation from the surrounding cytoskeleton. The molecular mechanism by which the nucleus is connected to the cytoskeleton has puzzled researchers for many years, as it was unclear how forces required for nuclear positioning and anchoring could be transmitted across the 50 nm-wide perinuclear space. Recent work in *Caenorhabditis elegans*, *Drosophila melanogaster*, yeast, and mammalian cells led to the discovery of two new families of nuclear envelope proteins that form the linker of nucleoskeleton and cytoskeleton (LINC) complex that transmits forces from the cytoskeleton across the nuclear envelope to the nuclear interior [31.27, 28]. The LINC complex (Fig. 31.5) consists of large nesprin isoforms located on the outer nuclear membrane that can bind to cytoskeletal F-actin, microtubules (via kinesin and dynein), and intermediate filaments (via plectin). At

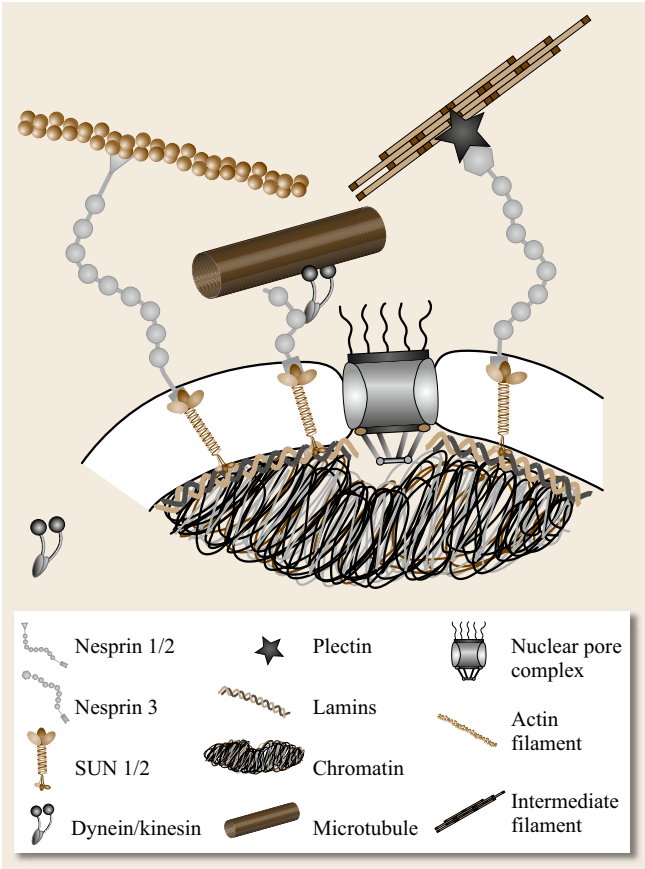

Fig. 31.5 Nucleocytoskeletal coupling across the nuclear envelope. Schematic drawing of the current model of force transmission between the cytoskeleton and nucleus across the LINC complex in mammalian somatic cells. The largest nesprin-1 and nesprin-2 isoforms contain an N-terminal actin-binding domain that can interact with cytoskeletal actin filaments. Shorter isoforms of nesprin 1 and 2 do not contain an actin-binding domain, but may still interact with other cytoskeletal elements through their large spectrin repeat regions (*brown and grey spheres*). Nesprins-1, -2, and -4 can also interact with microtubules via dynein and/or kinesin molecular motors. Nesprin-3 can directly bind to plectin, which can associate with intermediate filaments. Nesprins interact with trimers of the inner nuclear membrane proteins SUN1 and SUN2 across the perinuclear space through their C-terminal KASH (Klarsicht, ANC-1, Syne Homology) domain. SUN proteins can in turn bind to the nuclear lamina, nuclear pore complexes, and other inner nuclear membrane proteins. These proteins interact with chromatin and intranuclear proteins, thus completing the physical link between the cytoskeleton and the nuclear interior. However, how the interaction between SUN proteins and nesprins, or their binding to other nuclear and cytoplasmic proteins, is regulated remains a matter of active research

the same time, nesprins physically interact across the perinuclear space through their conserved C-terminal KASH (Klarsicht, ANC-1, Syne Homology) domain with Sad1p/UNC-84 (SUN) proteins, which are located at the inner nuclear membrane. There, SUN proteins can bind to lamins, chromatin, nuclear pores, and other nuclear envelope proteins, thus creating a physical link between the cytoskeleton and the nucleus [31.29, 30]. Due to this intricate coupling between the nucleus and the cytoskeleton, defects in nuclear envelope proteins can have direct effects on cytoskeletal structure and mechanics; For example, fibroblasts lacking the nuclear envelope proteins lamin A and C have reduced cytoskeletal stiffness and disturbed actin, vimentin, and microtubule organization [31.31–33]. Mutations in lamins, nesprins, and SUN proteins can result in muscular dystrophies and cardiomyopathies [31.34], in part by disturbing nucleocytoskeletal coupling and impairing nuclear stability [31.35–37].

31.2.4 Cell Contractility and Motor Proteins

All muscle cells use the molecular motor composed of actin and myosin to produce active contraction. These are arranged in a well-defined structure, the sarcomere, and the regularity of the sarcomeres gives rise to the characteristic striated pattern seen in skeletal muscle cells and cardiac myocytes. Importantly, even nonmuscle cells contain contractile machinery, which they use for a variety of functions such as maintaining cell tension, changing cell shape, and cell migration. Prominent bundles of actin filaments, called stress fibers, are contractile and house myosin filaments. The macromolecular organization of stress fibers bears similarities to sarcomeres – actin filaments are in parallel arrangement with the filament polarity alternating alongside; laterally, a space of $\approx 10\,\mathrm{nm}$ is maintained that situates parallel bipolar myosin II filaments in between. The myosin head moves toward the positive pole of the actin filaments during a power stroke, producing a net contractility for an alternating-polarity arrangement. Stress fibers (like sarcomeres) have a troupe of proteins, e.g., α-actinin, filamin, troponin, caldesmon, and tropomyosin, which control the arrangement of actin and myosin, and regulate their interaction. The formation and strengthening of stress fibers is intricately linked to the mechanism by which cells respond to their physical environment. First, stress fibers are known to form between points in the cell where actin–myosin contractility is resisted. Typically these are hot spots of protein activity known as focal adhesions, where the actin cytoskeleton is anchored to transmembrane inte-

grins, which are anchored to the matrix proteins. The focal adhesion also includes a cascade of proteins that relay biochemical signals, regulate its strengthening, and organize the cytoskeleton for the growth of stress fibers (e.g., cross-linking actin and recruiting myosin).

31.2.5 Adhesion Complexes

Adhesion complexes are collections of proteins forming a physical linkage between cytoskeleton and extracellular matrix (ECM) and between cells. A cell can use focal adhesions to gain traction on the ECM during the process of spreading and migration. The assembly of focal adhesions is a dynamical process that is closely regulated by the mechanical and chemical cues that the cell experiences. Both intracellular and extracellular mechanical stresses transmitted through focal adhesions are important in the formation of a focal adhesion complex, whereas the release of stress results in the turnover of a focal adhesion. The myosin-mediated contractile force transmitted to the ECM and the tension applied to the adhesion complex are necessary for promoting focal adhesion development. In contrast, disruption of myosin activity effectively inhibits the formation of focal adhesions. In the absence of myosin contractile force, externally applied mechanical forces can also promote the formation of focal adhesions. This force-regulated focal adhesion assembly allows a cell to probe the mechanical stiffness of its surroundings and respond accordingly, for example, by migrating in the direction of increasing substrate stiffness. Adhesion complexes also play an important role in helping tissues form by holding the cells together. The cells of most tissues are bound directly via cell–cell junctions. Cell–cell adhesion complexes are found in many different types, depending on tissue and cell type, and serve in both mechanical coupling of cells as well as intercellular transport.

31.3 Experimental Methods

31.3.1 Methods of Force Application

Measuring cellular or subcellular biomechanics often requires the application of precisely controlled forces to single or multiple cells and quantification of the induced deformation, although some techniques rely on detecting forces generated by the cells or on observing particles within the cytoplasm subjected to thermal motion. Consequently, experimental methods can be divided into active (Table 31.2; Fig. 31.6) and passive techniques. In the active techniques, applied forces are generally in the same range as physiological forces acting at the cellular and molecular level (Table 31.3), and induced displacements are on the nanometer or micrometer scale. For most methods – whether they are active or passive – the cellular deformations are detected based on computer-based image analysis of bright-field or fluorescence microscopy images, but some techniques also apply quadrant photodiode detectors for faster and higher-resolution tracking of microspheres embedded in the cytoplasm.

Active Measurements

Atomic Force Microscopy. Atomic force microscopy (AFM) – only developed in 1986 – is now routinely used in cell biology to *image* cells, measure cytoskeletal stiffness, and quantify single-molecule interactions. In an atomic force microscope, a small tip attached to a flexible cantilever is controlled with (sub)nanometer precision to carefully probe (i. e., indent) the cell surface. The deflection of the cantilever can then be used to infer the indentation depth and calculate the applied force. The tip of the cantilever typically has the shape of a pyramid (with a tip radius of $\approx 20\,\text{nm}$), but some applications use small polystyrene beads ($0.1-5\,\mu\text{m}$ diameter) attached to the cantilever or tipless probes to provide a larger contact area with the cell. The mechanical properties of the probed cell (e.g., Young's modulus or shear modulus) are inferred from the force–indentation curves, often assuming a Hertz model for a linear elastic, isotropic material [31.38], although several modifications have been proposed to account, for example, for the finite thickness of thin cell extensions such as lamellipodia [31.39] or the pericellular brush present on many cells [31.40]. These theoretical models often provide a surprisingly good fit to

Table 31.2 Methods of force application

Method	Typical force range
Atomic force microscopy	10 pN–100 nN
Microindenter	1–100 nN
Microplate stretcher	1–100 nN
Magnetic bead microrheology (twisting)	10 pN–1 nN
Magnetic bead microrheology (pulling)	100 pN–10 nN
Optical traps	1–500 pN
Micropipette aspiration	1–100 nN
Substrate strain	1–30% strain
Shear flow	1–100 Pa
MEMS devices	0.5–1500 nN

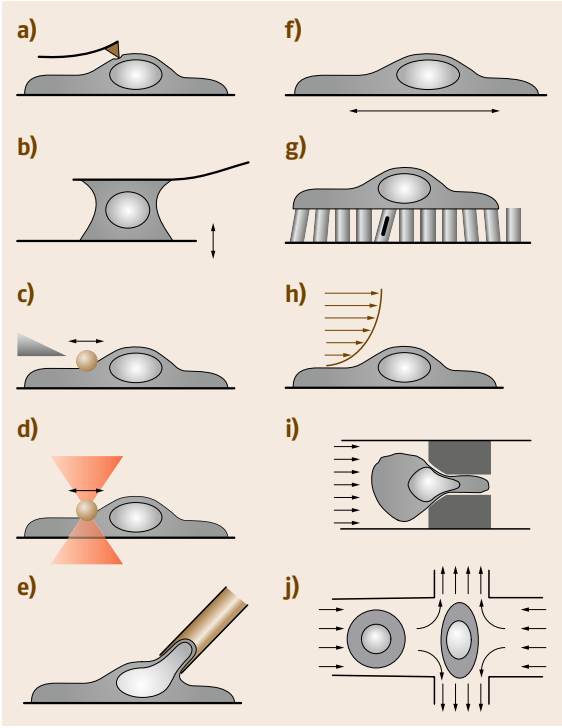

Fig. 31.6 Experimental methods for cellular force application. Overview of techniques to apply precisely controlled forces or deformations to cells for active cellular biomechanics measurements: **(a)** atomic force microscopy, **(b)** parallel microplate stretcher, **(c)** magnetic bead microrheology, **(d)** optical trap, **(e)** micropipette aspiration of adherent cell, **(f)** substrate strain experiments, **(g)** micropillars that deform (i. e., deflect) under cellular traction forces (this passive technique can be modified by embedding small magnetic particles in some of the pillars, which can then be actively manipulated to apply a highly localized force on the basal cell surface), **(h)** flow chamber for fluid shear-stress application, **(i)** perfusion of cells through microfluidic pores or constrictions (cell deformability and friction can be inferred from the transit times), and **(j)** hydrodynamic cell stretching using two opposing fluid streams

the experimental data, despite the fact that cells are nonisotropic, nonhomogeneous, and nonlinear elastic materials. One benefit of the atomic force microscope is that the usable force range spans several orders of magnitude (Table 31.2), depending on the spring constant of the selected cantilever. Therefore, AFM can also be used for single-molecule measurements, for example, to measure bond strength. In this case, the AFM probe is functionalized with low concentrations of the protein of interest and then brought into contact with the appropriate binding partner immobilized on a rigid surface.

Table 31.3 Typical force ranges in cell biology

Biological force	Force range
Force generated by motor proteins (e.g., kinesin, myosin)	$\approx 1-10$ pN
Force transmitted by protein–protein interactions (rate dependent)	$\approx 1-200$ pN
Force required for (partial) protein unfolding	≈ 100 pN
Force generated by migrating or contracting cells	≈ 1 nN–10 μN

After binding occurs, the AFM tip is then carefully retracted until the molecules dissociate, which results in a sudden drop of force. Rupture forces at different velocities can be directly inferred from AFM data.

Magnetic Twisting Cytometry. In this technique, mechanical measurements are based on the displacements of small ($\approx 0.2-5\,\mu$m diameter), ferromagnetic or paramagnetic beads attached to the cell surface and subjected to a magnetic force. Early versions of this technique [31.41, 42] used two orthogonal magnetic fields, one to magnetize the ferromagnetic particles with a brief, intense pulse, and the second one to induce a twisting, magnetic torque to the beads. The induced bead rotation is then measured by a change in the orientation of the induced magnetic field or through microscopic observations. The latter approach offers the advantage that it can detect rotation and displacement of individual beads, so that loosely attached beads that might rotate freely can be excluded from the overall measurements. In a related variant of this technique, often referred to as magnetic trap or tweezers, paramagnetic beads on the cell surface or inside the cytoplasm are manipulated by a single- or multipole electromagnet controlled through a computer. The force acting on a paramagnetic bead inside a magnetic field is given by the equation $F = \mu_0 \chi V \nabla(\boldsymbol{H} \cdot \boldsymbol{H})$, where F is the magnetic force, μ_0 is the permeability constant, χ is the volume susceptibility, V is the bead volume, and $\boldsymbol{H}$ is the external magnetic field strength. Thus, the applied force increases with increasing field strength and increasing field gradient. For a single-pole magnetic trap, the magnetic field decays rapidly with increasing distance from the tip of the pole. This results in a steep gradient and large forces near the tip that exponentially decay away from the tip, requiring careful calibration of the magnetic trap. One of the limitations of single-pole magnetic traps is the unidirectional force direction, i. e., forces can only be exerted in the direction towards the magnetic trap (pulling), but this can be overcome by using multipole magnetic traps. Another limitation is that the bead localization on the cell is random, so care must be taken to only compare results from cells with similar bead positions (e.g., on the nucleus, the nuclear

periphery, or the lamellipodia). Lastly, the induced bead rotation and displacement are strongly dependent on the bead attachment angle, i. e., how deep the magnetic bead is embedded in the cell surface, requiring careful controls or confirmation by confocal three-dimensional (3-D) reconstruction.

Optical Traps/Tweezers. This technique is similar to the magnetic trap experiments, as the induced displacement of microscopic beads (50 nm–1 μm) attached to the cell surface or inside the cytoplasm subjected to a precisely controlled force is used to determine the mechanical properties of the cytoskeleton. The major difference is that, in an optical trap, a focused laser beam is used to position and displace a bead with high refractive index on the cell, allowing precise bead manipulation in all directions. The optical trap acts as an elastic spring with a tunable spring constant, so the force applied to the bead can also be controlled with high precision (Chap. 20). Another advantage of the optical trap system is that multiple beads can be independently controlled by splitting the laser beam, so that cells can, for example, be stretched between two beads that are slowly moved apart. The biggest limitation of using optical traps in cell mechanics experiments is that the maximal force level is limited to < 1 nN, as larger forces would require higher laser power that could excessively heat the cell. While the small forces generated by an optical trap are ideally suited for single-molecule studies and are sufficient for experiments that measure, for example, membrane tethers, they are often too small to induce large-scale cellular deformations, especially when probing stiffer cells such as myocytes.

Micropipette Aspiration. In these experiments, single adherent or suspended cells are partially aspirated into a micropipette with a $\approx 2-10$ μm-diameter opening by applying precisely controlled suction pressure (typically 100−10 000 Pa). The aspirated cell is imaged on a microscope and cellular deformations such as the aspirated tongue lengths are computed from the cell geometry. In a technique called fluorescent/confocal-imaged microdeformation, fluorescent labeling of specific intracellular components such as the nucleus, the nuclear lamina, or nucleoli is used to provide additional information on the subcellular deformations during micropipette aspiration [31.43–46]. One potential limitation of the micropipette aspiration technique is that the interpretation of the experiments is not always straightforward. Analytical or computational models are often necessary to derive material properties from the geometric measurements of the aspirated cells and the applied pressure, and the underlying assumptions may at times be difficult to validate. However, this technique has been proved to be very useful when studying cells with relatively homogeneous structural organization such as red blood cells or neutrophils [31.44, 47–49]. In recent years, microfluidic devices have been developed to enable higher-throughput measurements applying the same principles as micropipette aspiration, but using arrays of microfabricated channels to aspirate or perfuse many cells in parallel [31.50–55].

Substrate Strain. Unlike the other techniques, these experiments do not apply controlled forces to single cells, but instead use carefully controlled strain application to induce deformation in cells plated on a flexible substrate. Generally, cells are plated on transparent, elastic silicone membranes coated with extracellular matrix proteins and subjected to uniaxial or biaxial strain. Depending on the particular experiment, the strain can be held constant or varied over time (e.g., cyclic strain application). Strain levels normally do not exceed 30% in order to avoid damaging the cells, but the exact levels are cell-type dependent. Cells are imaged under a microscope before, during, and after strain application, and small markers or fluorescently labeled components of the cells are used to calculate intracellular deformations and applied membrane strain. Since the cell is firmly attached to the extracellular matrix on the silicone membrane through cell surface receptors which are connected to the cytoskeleton, the cytoskeleton will experience strain levels comparable to the applied substrate strain, whereas the stiffer nucleus typically deforms significantly less [31.32, 56]. The advantages of this technique are that force can be applied to several cells at once and that the strain application closely resembles physiological mechanical stress, e.g., in muscle cells or endothelial cells subjected to blood vessel expansion. Recently, this technique has even been adapted to study nuclear deformation in muscle tissue of living worms [31.36]. The major limitations are that this technique is only suitable for adherent cells and that the applied forces cannot be determined directly.

Shear Flow. The most commonly used devices for shear stress application are the cone and plate rheometer and flow (or perfusion) chambers. Cone and plate rheometers allow precise control over the applied shear stress, but are generally not equipped to image cells during shear stress application, making it difficult to visualize induced cellular deformations. On the other hand, flow chambers are routinely used to study cellular deformations under shear stress [31.57] or to investigate cellular responses to shear stimulation such as calcium influx or cytoskeletal remodeling. Parallel-plate flow chambers with channel heights ≈ 100 μm

are now widely available using standard soft lithography and microfluidics, allowing for precise control of the fluid shear stress acting on a cell monolayer and simultaneous imaging of the cells using a microscope. The shear stress at the cell surface can be calculated for a Newtonian fluid in the parallel-plate geometry as $\tau = 6Q\mu/wh^2$, valid when $h \ll w$, where τ is the fluid shear stress at the wall (and cell surface), Q is the flow rate, μ is the viscosity, w is the channel width, and h is the channel height. The shear stress can thus be adjusted to physiological shear stress levels ($\approx 0.1-10$ Pa) by altering the height of the flow chamber or modulating the flow rate, and experiments can be carried out with either constant or pulsatile flow. However, the actual shear stress at the cell surface might deviate from the predicted wall shear stress, as small variations in the cell height and topology can cause local variations, which might in fact contribute to the alignment of endothelial cells to the flow direction. Recent work has extended these methods to characterize the mechanical phenotype of populations of cells in suspension [31.58, 59]. This approach also has potentially important clinical implications, such as in the use of mechanical markers of diseases such as cancer [31.55].

Passive Measurements

In contrast to the active measurements, these experiments measure forces generated by the cells themselves or quantify the random motion of particles embedded in the cytoplasm subjected to thermal fluctuations. Typical examples of passive measurement techniques include particle tracking of beads in the cytoplasm and traction force microscopy. In passive bead microrheology, small ($0.1-2\,\mu$m diameter) beads are injected into the cytoplasm or taken up by endocytosis and are then tracked with high spatial and temporal resolution with a laser beam and quadrant photodetector. The complex cytoplasmic shear modulus $G(s)$ can then be computed from the unilateral Laplace transform of the measured mean-squared displacement $\langle \Delta r^2(s) \rangle$ using a generalized Stokes–Einstein equation as $G(s) = k_B T/(\pi a s \langle \Delta r^2(s) \rangle)$, where s is the Laplace frequency, k_B is the Boltzmann constant, T is the temperature, and a is the bead radius [31.60], although care must be taken with this approach to avoid artifacts associated with active, motor-driven motions [31.61]. Traction force microscopy (TFM) was originally based on wrinkles generated in thin silicone sheets by the contraction of cells plated on top of these sheets, but has subsequently been refined for more quantitative force determination by plating cells on polyacrylamide gels with fluorescent beads embedded in the gel. The mechanical stiffness of the polyacrylamide gel can be tuned based on the cross-linker concentration, and microscopic measurements of the induced displacement of beads near the surface can be converted into cellular forces exerted on the gel by elastic theory [31.62, 63]. In another alternative to TFM, cells are coated on a fine grid of microfabricated micropillars made of polydimethylsiloxane (PDMS) [31.64]. In this case, the stiffness of the micropillars can be controlled by adjusting their cross-sectional area or length, and the cellular force exerted on each micropillar can be measured based on the deflection of the pillar using beam bending theory. This technique offers the advantage that force application is localized to individual micropillars, and that the geometry and stiffness can be independently adjusted.

An important recent advance has enabled TFM to be performed on cells embedded in a 3-D tissue. If the mechanical properties of the surrounding matrix are known, then the tissue displacements can be used to calculate stresses within the material or at the cell surface [31.65]. The methods of analysis are similar to those used in 2-D, but are much more complex in three dimensions. Moreover, interpretation of the data is complicated by the use of realistic matrix materials that are subject to both remodeling and degradation by the cells, leading to uncertainties regarding the matrix properties that become both heterogeneous and nonisotropic.

Another method used to infer single-molecule strains is to tether a pair of fluorophores to the molecule with the emission wavelength of one (the *donor*) corresponding to the absorption wavelength of the other (the *acceptor*), termed fluorescence (or Förster) resonant energy transfer (FRET) microscopy. In the most common versions, the intramolecular strain or tension sensors, a pair of FRET fluorophores is separated by an elastic linker domain. As the linker domain becomes stretched under applied force, the ratio of the emitted light from the acceptor to that from the donor changes, and this ratio can be used as a measure of the distance between them [31.66]. Such molecular strain sensors have been successfully applied to focal adhesions (vinculin), nesprins, and various other molecules. In addition to intramolecular FRET, the FRET fluorophores can also be incorporated into two interacting molecules, such as cell surface receptors [31.67]. In both cases, the FRET system can be calibrated using AFM or optical traps so that the change in the ratio of energy from the acceptor to that from the donor (the FRET ratio) can be converted into a force, although this conversion is fraught with numerous potential errors. As a result, the probes are most often used to indicate semiquantitative changes in the relative stretch/tension between two conditions of the cell.

Passive methods can also be applied for measurement of cell or matrix stiffness in the absence of any

added label or particles. A recent development in this connection utilizes the frequency change of scattered light by the internal filaments of the cytoskeleton to measure the uniaxial longitudinal compression modulus in confined compression [31.68]. Measured values of frequency shift have shown strong correlations with the moduli measured at more typical physiologically important frequencies.

31.3.2 Rheological Properties

The rheological properties of the cell, such as its viscoelastic properties and its diffusion parameters, are key to the cell's ability to accomplish its diverse functions in health and disease. A wide range of computational and phenomenological models as well as experimental techniques have been proposed over the past two decades to describe the cell, giving rise to several, often contradictory, theories for describing the rheology of the cytoskeleton. The highly heterogeneous structure of the cytoskeleton, coupled with a small linear response regime [31.69] and active dynamics and continuous remodeling, present a major challenge for quantitative measurements and descriptions of its rheology [31.70].

Nonetheless, a wide range of computational models exist for cytoskeletal rheology and mechanics, ranging from continuum to discrete descriptions of the cytoskeleton (reviewed in [31.71]). A major challenge in cytoskeletal rheology and mechanics is how to relate experimental observations to theoretical and phenomenological models. Much effort has recently focused on the interesting rheological behavior of cells, measured by one of the methods described above. Most often, cellular viscoelastic properties are expressed in terms of the complex shear modulus (see *Viscoelastic Solid/Poroelastic Solid*), the real part G' indicating the elastic component, and the imaginary part G'' the viscous component. While each measurement method has its drawbacks, perhaps the most comprehensive data have been obtained through magnetic twisting cytometry (Fig. 31.6). These measurements have shown that a cell exhibits a relatively simple power-law behavior over much of the frequency domain, with [31.72]

$$G' + \mathrm{i}G'' = G_0 \left(\frac{\omega}{\omega_0}\right)^{x-1} (1+\mathrm{i}\eta)\Gamma(2-x) \times \cos\left[\frac{\pi}{2}(x-1)\right] + \mathrm{i}\omega\mu \,, \qquad (31.1)$$

where Γ is the Gamma function, μ is the viscosity, and $\eta = \tan((x-1)\pi/2)G_0$, ω_0, and x are parameters of the model. All but x, however, have been found to be nearly constant in all experiments. This turns out to be similar to the behavior of soft glassy materials, although the fundamental basis for this behavior remains a topic of some debate.

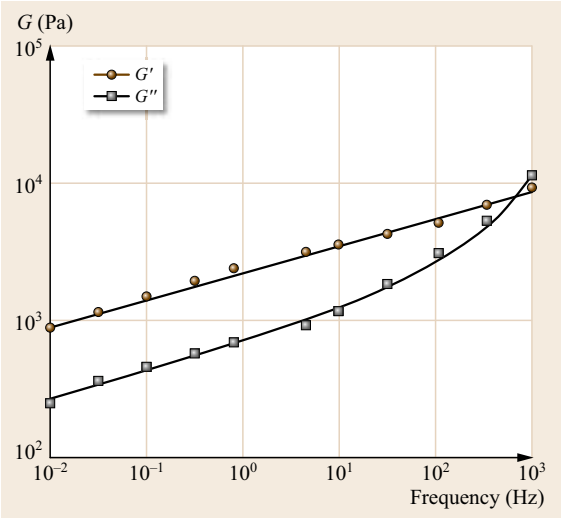

Fig. 31.7 Typical experimental results for the frequency-dependent shear moduli of a wide range of cell types and conditions obtained by magnetic twisting cytometry (after [31.72])

The data in Fig. 31.7 [31.72] apply to small deformations in the linear regime. However, linearity persists up to surprisingly large deformations. Much of what we know about nonlinear effects has been obtained from experiments on reconstituted gels, typically of actin with one or more actin cross-linking protein. From these experiments, the following observations have been made:

1. Linearity persists up to $\approx 30\%$ strain.
2. Values of G' and G'' in this linear regime are often orders of magnitude lower than are measured in cells.
3. Strain stiffening is observed at strains $> 30\%$, followed by a precipitous drop in G' at strains of $\approx 70\%$.

All of these issues continue to be actively studied in the hope of generating a comprehensive understanding of cytoskeletal rheology.

31.3.3 Active Force Generation

The cytoskeleton is an active structure that maintains cell shape and facilitates its motion. The cytoskeletal network is in a nonequilibrium state that drives motor proteins as force-generating features in cells. The cytoskeleton is activated by these molecular motors, which are nanometer-sized force-generating proteins, e.g., myosin. To better understand the nature of

such active force-generation systems, researchers have developed simplified models of the active cytoskeleton by mixing actin with actin binding proteins (e.g., filamin and α-actinin) and molecular motor proteins (myosins) [31.73]. Such a reconstituted synthetic cytoskeleton exhibits local contractions reminiscent of living cells. Tension generated by contraction can lead to drastic increase of the cytoskeletal stiffness. Such models demonstrated that a remarkably simple system, with just three components (myosin, actin, and ATP), can reproduce key phenomena also observed in far more complex living cells [31.67].

31.3.4 Biological Responses

The cellular responses to mechanical stimuli take place over several time scales and range from intracellular signaling to changes in cellular morphology and function. The fastest responses occur within seconds to minutes of stimulation and include changes in intracellular ion concentrations (especially Ca^{2+}) through opening of mechanosensitive ion channels and activation of cellular signaling pathways such as nuclear factor-κB (NF-κB), phosphatidylinositol-3-kinase (PI3K)/protein kinase B (Akt), protein kinase C (PKC), Rho family GTPases, and mitogen-activated protein kinases (MAPKs) [31.74, 75]. These first steps do not require synthesis of new proteins, but involve modification (e.g., phosphorylation) and intracellular translocation of existing proteins. These initial events often trigger activation of mechanosensitive immediate early genes such as *egr-1*, *c-fos*, *c-jun*, or *c-myc* encoding transcription factors that turn on additional downstream genes. These later response genes often include proteins involved in cellular structure (e.g., actin, myosin) or extracellular matrix remodeling. However, cytoskeletal remodeling in response to mechanical stress or strain can start even before synthesis of new proteins as early signaling pathways can also mediate polymerization and depolymerization of cytoskeletal structures; For example, endothelial cells exposed to fluid shear stress begin to align with the flow direction within 20 min, and the process is completed within 24 h. The multifaceted response to mechanical stimulation can effectively mediate several cellular functions, including DNA and RNA synthesis, hypertrophy (increase in cell size), proliferation, apoptosis, migration, and extracellular matrix remodeling.

31.3.5 Nonlinear Effects

As described above, cells are composed of intricate networks of filamentous structures, called the cytoskeleton. These networks exhibit unique properties including relatively large shear moduli with strong signatures of nonlinear response in which, for example, the shear modulus can increase drastically under modest strains [31.76, 77]. Models of semiflexible polymer networks have emerged to describe these unique properties and the dynamics of the cytoskeletal networks. These models involve a semiflexible description of the constituent actin filaments [31.78]. Quantitative models of the nonlinear behavior of the cytoskeletal network are essential for understanding the complex, dynamic, and nonlinear behavior of cells, and ultimately tissues and organs.

31.3.6 Homogeneity and Anisotropy

Cells are inhomogeneous structures composed of various intracellular components, including the lipid bilayer membrane that encases the cell, the actin cortex, which is a dense actin network providing stability for the cell membrane, cytoskeletal networks, and the nucleus, which itself comprises various important substructures. The cytoskeleton is primarily responsible for the structural integrity and stiffness exhibited by a cell. It is composed of a system of highly entangled protein filaments that permeate the microfluidic space of the cytosol. The major components of the cytoskeletal network, i. e., the actin filaments, intermediate filaments, microtubules, and their cross-linking proteins, offer an exquisite microenvironment which is highly inhomogeneous and anisotropic in its structure and geometry.

31.4 Theoretical and Computational Descriptions

As is evident from the discussion above, the cytoskeleton is a complex biopolymer network with varying degrees of connectivity, existing in a state of dynamic equilibrium. The dynamic state arises from the ongoing polymerization and depolymerization of the constituent filaments and the changing density of cross-links between filaments of the same or different families. This picture is complicated further by the milieu of other intracellular constituents that may or may not affect structural properties exhibited by the cell.

Our objective in this section is to come to a better appreciation of how the elastic properties and geometric arrangement of the constituent filaments give rise to the material properties observed by the various ex-

perimental methods just described. These experiments have shown that the elastic modulus of cells can vary considerably from one cell type to another. Cells of the epidermis, for example, require greater structural integrity than red blood cells that are subjected to relatively low shear stresses in the blood. Even within a given cell type, the elastic properties can change. Skeletal muscle, for example, changes its modulus by over an order of magnitude within a small fraction of a second. Other cells change too, but more often over a longer time period, in response, for example, to changes in their mechanical environment.

According to the various measurements that have been made, cell shear moduli fall in the range $\approx$ 10–10 000 Pa, and therefore exhibit a stiffness somewhat lower than collagen gels (or common gelatins) at low concentration or relaxed skeletal muscle. This wide range of moduli can be attributed to differences in the models used as a basis to infer the shear modulus from the data as well as to real cell-to-cell variability. At best, these numbers inferred from experiment should be viewed as measures of an *effective stiffness*, and comparisons between different measurement methods and interpretation should be made with caution. Other biological materials (e.g., bone, wood) exhibit a much higher modulus, but not because of their cellular content. Rather, their high stiffness is due to the calcification in bone and the matrix molecules found in wood and most plants. In tissues, too, the stiffness we measure is more often associated with the extracellular matrix with its elastin and collagen, than the resident cells. Even within the cytoskeleton, individual filaments (i. e., F-actin, intermediate filaments, and microtubules) exhibit moduli much greater than the measured bulk modulus of the cytoskeleton. In the next section we explore different approaches that have been developed to relate the properties of the individual fibers to those of the assembled network.

31.4.1 Continuum Models

Elastic Solid

In several of the experiments described earlier, the assumption of a homogeneous and isotropic elastic solid is used to infer a value for an effective Young's modulus for the cell. It is not our intention here to provide a comprehensive description of elasticity theory, but rather to outline some of the basics. For a full derivation of the governing equations, the reader is referred to any of a number of excellent textbooks [31.79]. Assuming equilibrium conditions (i. e., that all forces balance each other) and a material that can be modeled as a Hookean (i. e., linear) elastic solid, the constitutive equations relating the mechanical stress and strain can be written in tensor notation as $\tau_{ij} = C_{ijkl}\varepsilon_{kl}$, where the summation convention is used. Here τ_{ij} are the elements of the stress tensor, ε_{kl} are the elements of the strain tensor, and C_{ijkl} is the 81-element coefficient matrix. In the case of an isotropic material, the coefficient matrix reduces to just two independent elastic constants, with the constitutive equation now reduced to the following simplified form

$$\tau_{ij} = 2Ge_{ij} + \lambda\varepsilon_{kk}\delta_{ij}\,, \tag{31.2}$$

where λ and G are the Lamé constants with G being termed the shear modulus. This expression can also be written in the inverted form

$$\varepsilon_{ij} = \left[\frac{(1+\nu)}{E}\right]\tau_{ij} - \left(\frac{\nu}{E}\right)\tau_{kk}\delta_{ij}\,. \tag{31.3}$$

Here the two material constants are now given as ν, the Poisson's ratio, and E, the Young's modulus. When using these to solve a particular problem, a set of appropriate boundary conditions also needs to be posed; For example, in the case of measurements by an indentation probe, the displacement of the surface in contact with the probe might be given. In addition, it would be necessary to specify that the opposite side of the cell is held fixed, and that the unsupported sides and the region on the upper surface not in contact with the probe have zero applied stress. Given these, the equations above provide a complete solution.

The use of the above equations presumes that the response of the cytoskeleton can be represented by an *elastic continuum* lacking any discernible microstructure. The validity of this clearly depends upon the length scale of interest in the problem, and is a serious concern in the context of cytoskeletal mechanics where the typical length scale (spacing distance between filaments) may be on the order of 10–100 nm. This becomes comparable to the linear dimension of the region of interest in some of the experimental procedures (e.g., cell poking, AFM measurements) and needs to be kept in mind. Furthermore, while this is a convenient approach for analyzing how cells deform under loading, it provides no insight into the relationship between the macroscopic properties that are measured and the elastic properties of the constituent matrix elements.

Viscoelastic Solid/Poroelastic Solid

A viscoelastic material is to an elastic material as a spring and dashpot network is to a system containing only springs. In both the discrete and continuous systems, the instantaneous displacement or strain is a function of the stress history. Similarly, the instantaneous stress depends on the strain history. This simple

realization, in combination with the assumption that all functions describing the material properties are continuous, leads to a set of generalized constitutive equations for a viscoelastic solid.

Many of the experiments performed on cells have been interpreted in the context of either an elastic or viscoelastic model. However, it might be argued that, like bone, cartilage, and many other biological tissues, it may be more appropriate to view the cytoskeleton as a poroelastic material. While attempts to apply a poroelastic model to studies of cell mechanics are just beginning, it remains to be seen whether a viscoelastic or poroelastic description is more appropriate. For a description of poroelastic theory, the reader is referred to [31.80].

Oscillatory Simple Shear. A useful example of viscoelastic behavior derives from the case in which the upper surface of a sample is being oscillated sinusoidally in the plane of the surface so that the shear strain satisfies $\varepsilon_{21} = \varepsilon_{21}^* \sin \omega t$ and the material experiences an oscillatory shear stress. In this case, the stress in the viscoelastic material will also vary sinusoidally, but out of phase with the strain. The relationship between stress and strain is often described by introducing the complex shear modulus (as introduced above), $G^* = G' + \mathrm{i}G''$, satisfying the following expressions

$$\tau_{21}(t) = \varepsilon_{21}^*(G' \sin \omega t + G'' \cos \omega t) \,, \tag{31.4}$$

$$\begin{aligned} \tau_{21}(t) &= \tau_{21}^* \sin(\omega t + \phi) \\ &= \tau_{21}^* \cos\phi \sin \omega t + \tau_{21}^* \sin\phi \cos \omega t \,, \end{aligned} \tag{31.5}$$

so that G', G'', and ϕ, the phase lag, are related to the amplitudes of strain and stress through the expressions

$$G' = \omega \int_0^\infty G(t') \sin \omega t' \, \mathrm{d}t' = \left(\frac{\tau_{21}^*}{\varepsilon_{21}^*}\right) \cos\phi \,, \tag{31.6}$$

$$G'' = \omega \int_0^\infty G(t') \cos \omega t' \mathrm{d}t' = \left(\frac{\tau_{21}^*}{\varepsilon_{21}^*}\right) \sin\phi \,. \tag{31.7}$$

Note that G' represents the component of stress in phase with the imposed strain and G'' the out-of-phase component. For a purely elastic material (in which strain and stress are in phase), G' is simply the shear modulus G and G'' is zero. On the other hand, it can be shown that, for a viscous Newtonian fluid, G' is zero and $G'' = \mu\omega$, where μ is the Newtonian viscosity.

It should be noted that these results could also have been obtained by expressing the time-varying strain as a complex quantity. In so doing, the shear modulus is complex, and G' and G'' are, respectively, the real and imaginary parts of the stress–strain ratio.

31.4.2 Biopolymer Models

Cytoskeletal networks can be viewed as a polymer gel in which the matrix is considered to consist of relatively straight segments connecting junctions where the filaments are either chemically cross-linked, or effectively so due to entanglements (Fig. 31.8a). Using concepts from polymer physics [31.81], the force required to change the length of one segment of a polymer filament (F-actin, for example) of length L_e by an amount δ can be expressed as

$$F_\mathrm{T} \approx \frac{k_\mathrm{B} T l_\mathrm{p}^2}{L_\mathrm{e}^4}\delta \approx \frac{K_\mathrm{b}^2}{k_\mathrm{B} T L_\mathrm{e}^4}\delta \,, \tag{31.8}$$

where k_B is Boltzmann's constant, T is temperature, K_b is the bending stiffness of the filament, l_p is the persistence length, and L_e is the distance between the points where the tension is applied (or the distance between points of entanglement or cross-linking between network filaments). This expression arises from a consideration of the curvature of the polymer resulting from Brownian or thermal fluctuations, and is based on the assumption that thermal energy is equally partitioned among the different modes of oscillation. The polymer filaments are therefore assumed to be bent prior to the application of stress. Externally imposed forces either increase or decrease the end-to-end length of these filaments, and the deformation produced depends both on the intrinsic bending stiffness of the filaments and on their initial degree of curvature due to thermal fluctuations.

For a network composed of such filaments in which the distance separating points at which physical bonds exist between the filaments or regions of entanglement is L_e, the change in filament length between bonds due to a shear strain θ is $\delta \propto \theta L_\mathrm{e}$. Making use of the fact that the number of filaments per unit area parallel to the surface on which the stress is applied scales inversely with the square of the characteristic mesh spacing ξ, the shear stress required to produce a strain θ is given by

$$\tau \propto F_\mathrm{T} \frac{(\text{number of filaments})}{(\text{unit area})} \propto \frac{k_\mathrm{B} T l_\mathrm{p}^2 \theta}{\left(L_\mathrm{e}^3 \xi^2\right)} \,, \tag{31.9}$$

from which a shear modulus of the (elastic) network G_n can be determined as the ratio of stress to strain

$$G_\mathrm{n} \propto \frac{\tau}{\theta} \propto \frac{k_\mathrm{B} T l_\mathrm{p}^2}{\left(L_\mathrm{e}^3 \xi^2\right)} \,. \tag{31.10}$$

The scaling of G_n clearly depends on both the distance between cross-links or entanglements and the mesh

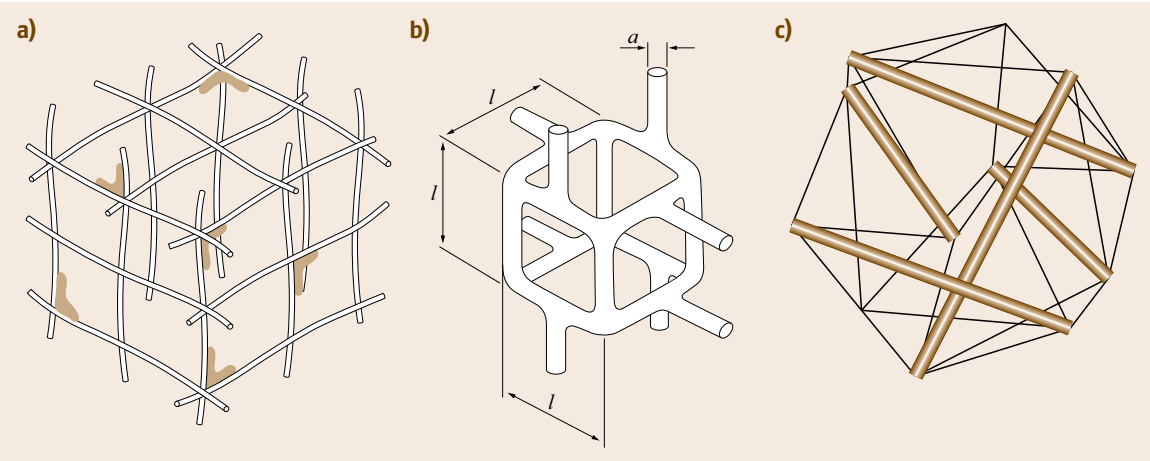

Fig. 31.8a–c Cell mechanics models. **(a)** Schematic of a network of biopolymers consisting of a fiber matrix with cross-links. **(b)** Unit cell used in the cellular solids model (after [31.82]). **(c)** Tensegrity structure showing the balance between elements in compression (*cylinders*) and others in tension (*lines*) (after [31.83])

size. As the concentration of polymer increases, ξ decreases and so likely does L_e, at least in terms of the degree of entanglement. As the concentration of actin binding protein (ABP) increases, L_e will decrease. The mesh spacing ξ also depends on the monomer concentration or solid fraction Φ (monomer volume/total volume). Assuming that the filaments are stiff and homogeneously dispersed through the medium, this relationship can be expressed as $\xi \propto a/\Phi^{1/2}$, where a is the monomer or filament radius. Substituting yields

$$G_n \propto \frac{k_B T l_p^2 \Phi}{\left(L_e^3 a^2\right)} . \tag{31.11}$$

In the limit of a highly cross-linked network, in which case $L_e \approx \xi$, this leads to

$$G_n \propto k_B T l_p^2 \left(\frac{\Phi}{a^2}\right)^{5/2} . \tag{31.12}$$

Alternatively, we can express this in terms of the density of cross-links ρ_c. Note that, if ρ_c is the number of cross-links per unit volume, it should vary inversely with the volume associated with each bond or entanglement, i. e., as L_e^{-3}. Combining this with the expressions (31.10–31.12) gives

$$G_n \propto k_B T l_p^2 \frac{\Phi \rho_c}{a^2} . \tag{31.13}$$

The Young's modulus of the network E_n can be obtained by a similar procedure, and can be shown to scale in the same manner as G_n.

31.4.3 Cellular Solids

The theory of cellular solids was developed for the purpose of relating the macromechanical properties of low-density cellular materials to their microstructural characteristics. The approach used is based on the concept that the material can be modeled as being composed of many *unit cells*, one representation of which is shown in Fig. 31.8b. When a cellular solid is stressed under tension or compression, the fibers act like struts and beams that deform under stress. The unit cell model in Fig. 31.8b has struts or fiber elements of length L and cross-section of radius a. The relative density of the material is defined by the volume fraction of solid material Φ. This is calculated as the solid volume contained within a unit cell ($\propto a^2 L$) divided by the total unit cell volume ($\propto L^3$) or $\Phi \propto (a/L)^2$. Beam theory gives the deflection δ of a beam of length L subject to a force F acting at its midpoint as

$$\delta \propto \frac{F L^3}{E_f I} , \tag{31.14}$$

where E_f is the stiffness of the beam constitutive material and I is the beam's second moment of area. The moment of area for a beam of thickness a is given by $I \propto a^4$. The stress τ is the force per unit area, or $\tau \propto F/L^2$. The strain is related to the beam deflection δ by $\varepsilon \propto \delta/L$. Using these, combined with the expressions above, the network Young's modulus or elastic modulus can be expressed as

$$E_n = \frac{\tau}{\varepsilon} = \frac{c_1 E_f I}{L^4} , \tag{31.15}$$

where c_1 is a constant of proportionality, or

$$\frac{E_n}{E_f} = c_1 \Phi^2 \,. \tag{31.16}$$

Data from a wide range of materials and cell geometries give a value for c_1 of ≈ 1 [31.82]. A similar analysis for cellular materials subjected to shear stresses results in an expression for the network shear modulus G_n [31.82]

$$\frac{G_n}{E_f} \propto c_2 \Phi^2 \,, \tag{31.17}$$

where $c_2 \approx 3/8$. If the material is linearly elastic and isotropic, these values lead to a value of $1/3$ for the Poisson ratio ν.

31.4.4 Tensegrity

Networks can also derive their structural integrity from an interaction between members that are in compression and members in tension. Some familiar large-scale examples include circus tents and geodesic domes. In the case of the circus tent, the rigidity of the structure is due to the balance between the tent poles in compression and the ropes anchored to the ground in tension. The rigidity of the structure, in this case, is related to the elastic characteristics of the tension elements.

Ingber [31.84] first proposed that the cytoskeleton behaves like a tensegrity structure with the microtubules acting in compression and the F-actin microfilaments acting in tension. In support of this concept, microtubules have been shown to be capable of supporting compressive loads and the F-actin network exhibits behavior at junctions consistent with their being in tension. Intermediate filaments may also be involved, although their contributions at this stage are unclear.

Analysis of a fully three-dimensional tensegrity network begins, as in the case of the cellular solids model, with a unit cell consisting of an interconnected system of elements in tension in balance with other elements in compression. When the three-dimensional tensegrity network of Fig. 31.8c is used, analysis shows that prestress plays an important role. Intuitively, it is not surprising that networks with greater pretension in the elastic members should exhibit greater resistance to deformation. The effect of prestress increases the network Young's modulus for small strains, and only in the limit of infinite prestress does E_n become independent of prestress. *Wang* and coworkers [31.85] showed that the cytoskeleton exhibits this same tendency, becoming increasingly stiff when, for example, the cell passes from a spherical (low prestress) to flattened (high prestress) state.

Nonetheless, evidence suggests that the simplicity of this model may undermine the accuracy of its predictions. Continuum mechanics predicts that a free, simply supported beam tends to buckle in the first mode of buckling and that is the case for in vitro loading of a single microtubule. However, in vivo imaging of microtubules indicates that the buckling mostly occurs in higher modes. This buckling mode switch takes place mostly because of lateral support of microtubules via their connections to actin and intermediate filaments, which themselves are tensile members of the tensegrity cytoskeleton model. Since these loads are exerted throughout the microtubule length, they introduce a considerable amount of microtubule bending behavior [31.86]. The sensitivity of the tensegrity model of the cytoskeleton to flexural deflections of microtubules has been explored recently. Microtubules, as crucial components of the cytoskeleton, cooperate with actin filaments to confer the cell with dynamic stability. Using an anisotropic continuum model for microtubules, it has been suggested that the bending energy could exceed the axial energy of microtubules by 40-fold, necessitating a modification to the tensegrity model in order to account for the flexural response of microtubules.

31.5 Mechanics of Subcellular Structures

31.5.1 Cell–Cell and Cell–Matrix Adhesions

Cells can adhere to their surroundings by either nonspecific or receptor–ligand (specific) bonding. Though both mechanisms are likely active in most situations, receptor–ligand bonding is the stronger of the two, by a considerable margin, and is therefore the most relevant mechanically. In situations for which either the receptors or their ligands are not present, however, such as might be the case in certain in vitro experiments, nonspecific binding can be important as well, and can produce a net attractive force per unit area of ≈ 100 Pa at a separation distance of ≈ 25 nm.

Models for Receptor-Mediated Adhesion

Cell–cell adhesion has obvious similarities to adhesion of cells to substrates, and the extracellular matrix, so similar approaches can be used for all of these situations. This requires, in addition, consideration of such factors as the distribution, type, and density of receptor–

ligand bonds or potential bonds, and the elastic properties of the structures to which they are anchored. On the intracellular side, this involves the series of couplings that link the receptor to the cell. In the simplest case, this might simply be a link to the lipid bilayer if the receptor has no intracellular connections. More typically, especially for couplings with a structural role, it involves a series of proteins ultimately linking the receptor to the cytoskeleton.

The typical setting in vivo is one in which cells adhere to other cells or to the extracellular matrix. Adhesions are more easily probed, however, through in vitro experiments, where cell adhesion more often occurs to an artificial substrate mediated through one of several extracellular proteins that are used to coat the surface. Typically, either collagen or fibronectin is used. Cells are often adhered to these substrates, but to produce a more controlled environment, rigid beads are sometimes coated with the appropriate receptors so that one specific receptor–ligand interaction can be probed. While these systems are useful as models of certain adhesion phenomena, it is important to recognize in the interpretation of these experiments that, when bound to a rigid substrate or bead, the binding proteins cannot freely diffuse, as they would in a more natural environment. In particular, the formation of focal adhesions would not occur in bead–substrate experiments because the receptors would be constrained from aggregating.

It is useful to consider a single adhesion bond, for example, one linking the actin matrix of the cytoskeleton to a β_1 integrin, and the integrin receptor binding to the extracellular matrix beyond the cell membrane. If the bond is stressed, as for example if the cell experiences a force relative to the ECM, it will at first stretch an amount dictated by the level of force in the bond and the stiffness of the complex. Each bond, as well as each protein in the bond complex, can be thought of as having a certain stiffness, giving rise to a picture in which several springs are considered connected in series. Forces acting on the adhesion complex are transmitted via this series of bonded proteins between the cytoskeleton (CSK) and the ECM, producing local deformations and stresses in the corresponding matrices that decay with distance from the adhesion site. On the intracellular side, these forces are transmitted via a complex involving vinculin, α-actinin, paxillin, and talin. Attachment to the extracellular matrix is mediated by an arginine–glycine–aspartic acid (RGD) sequence (in fibronectin, for example), which in turn, has binding sites for collagen and fibrin. If the force is sufficiently strong, above a certain threshold value F_0 say, and applied for a sufficiently long time, the bond might be severed (decoupled). Typical values of this threshold force lie in the range of 10−100 pN [31.87] but depend, as well, on the rate at which the force is increased. Under more rapid force application, the threshold is high compared with when the force is increased slowly. This simply reflects the fact that detachment is a stochastic process and that, at any given level of force, there exists a finite probability of detachment, and this probability increases with time. It has also been shown that some bonds, particularly those associated with cell–cell adhesion, strengthen when subjected to force; That is, the unbinding rate decreases with increasing force. These important phenomena are reviewed in [31.88].

We need also to consider that, in equilibrium, a fraction $\Phi = K(1+K)^{-1}$ (where K is the equilibrium constant) of the receptors will be bound at any given time, and that the receptor–ligand complexes are continually cycling between the bound and unbound states, characterized by their respective rate constants. On a larger scale, numerous adhesion sites typically act in parallel, each contributing some amount to the total adhesion force. This gives rise to an average local stress τ that can be thought of as the product of the average force per bond times the bond density. This stress is typically nonuniform. In the adhesion of a cell to a flat substrate, the bonds near the periphery of the contact zone determine the strength of the cell against detachment, and when the cell is subjected to a detaching force, the stresses are concentrated in this peripheral region. In the vicinity of the edge of adhesion, several factors will influence the stress distribution, including the mechanical properties of the membrane (in particular the bending stiffness K_b), the receptor density, the spring constants of the bond, and the bond strength.

The interplay between receptor–ligand bonding and membrane stiffness also determines whether a cell will spread over a surface or peel away from it under a given tension. Membrane bending stiffness acts to maintain the membrane and substrate within close proximity near the edge of contact. Spreading can occur only if their separation distance is within the extended length of the receptor ligand bond over a distance comparable to the linear spacing between neighboring bonds. Under high tension, the surfaces rapidly diverge and spreading is prevented; if the tension is sufficiently low, receptor–ligand bonding can occur and spreading can occur.

Transient Cell Adhesion

Concepts of transient adhesion and release are of particular importance in the case of leukocyte rolling, adhesion, and transmigration across the endothelial layer of a blood vessel. In addition, cell migration through extracellular matrix or along a substrate requires the ability of the cell to both form and release adhesions. One problem that has received considerable attention is the interaction between an adherent or rolling leuko-

cyte and the adhesion receptors on the endothelium. These studies are complicated by the three-dimensional nature of the flow, the compliance of the interacting surfaces, and receptor–ligand dynamics. In a series of studies, *Hammer* and coworkers [31.89] addressed several of these issues, computing the viscous force and torque acting upon a sphere near to a planar wall from the mobility matrix [31.90] and using the Bell model of receptor binding [31.90], but neglecting the effects of cell deformation.

A Monte Carlo method is employed at each time step in the calculation to determine bond formation or breakage. In these studies, the nature of the leukocyte–endothelial interaction is characterized as firm adhesion, rolling adhesion, bimodal adhesion or no adhesion, and mapped as a function of the two parameters of the Bell model. Most literature values for the Bell model parameters for a variety of selectin receptors (known to be instrumental in leukocyte rolling) correspond to the rolling adhesion regime for typical shear rate of $100\,s^{-1}$. An interesting, but counterintuitive, result from this study was the observation that, as the bond stiffness was increased from the value used in most calculations (100 dyn/cm), adhesiveness *decreased*, which the authors attributed to reduced deflection for a given level of force, leading subsequently to more rapid dissociation.

31.5.2 Cell Membranes

For the purpose of analysis, we treat the cell membrane as a homogeneous two-dimensional (2-D) plate or sheet completely enclosing the cytoplasm. The membrane referred to here can be thought of either as the lipid bilayer by itself, or more typically, as the bilayer plus the associated cortex of cytoskeletal filaments and the glycocalyx on the extracellular surface. In addition, though not explicitly recognized in the analysis, transmembrane proteins and their attachments to the intracellular and extracellular milieu are included in terms of their influence on the continuum properties of the model. Were it not for these, the membrane would exhibit little resistance to shear deformation.

In qualitative terms, the lipid bilayer can be thought of as a two-dimensional fluid, within which the individual lipid molecules, or other molecules embedded in the membrane, are relatively free to move about by diffusion or directed motion. Phospholipid molecules in either of the two layers resist being pulled apart, however, so each layer is highly inextensible. This also contributes to the bending stiffness, which is low in absolute terms but high for such a thin layer, since bending requires one layer to expand while the other is compressed. By contrast, the two layers readily slide relative to each other. These qualitative notions are put in more quantitative terms in the next section.

Types of Deformation

Any deformation of the membrane can be thought of, in general terms, as a superposition of several simpler deformations. For small strains for which linearization is appropriate, the principle of superposition is rigorously valid. For larger strains, however, linear theory breaks down and superposition can only be used as a rough, qualitative guide in visualizing combined influences. Here we present the three primary types of deformation: pure extension, pure bending, and pure shear.

Pure Extension. In discussing the extensional stiffness of the membrane, we need to distinguish the behavior at low tension from that at high tension. As an extensional stress is first applied at the edges of a lipid bilayer, the projected or *apparent* membrane area first increases while the actual or true membrane area remains constant. This results from the suppression of out-of-plane undulations. Forces acting to resist membrane flattening originate from entropic effects analogous to those seen in the case of a flexible polymer as its end-to-end distance is increased – many more membrane configurations exist with undulations compared with the single, perfectly flat state. Only when these undulations have been eliminated does the *true* membrane area, proportional to the surface area per molecule group, begin to increase, and this is associated with a relatively abrupt increase in extensional stiffness. For now, we consider only the stiffness of a flat membrane and leave the discussion of undulations of entropic origin to a later point in the chapter. Hence, we initially neglect all entropic effects or, equivalently, consider the membrane to be at zero temperature. Based on this assumption, consider an infinitesimal plate initially of area $A_0 = L_0^2$ that is deformed by a uniform normal stress $\tau_{11} = \sigma_1 = \tau_{22} = \sigma_2$ applied to its edges (Fig. 31.9a) to a new area A. The expressions relating stress and strain in two dimensions, and in the absence of stresses normal to the x_1–x_2 plane, can be written as

$$\sigma_\alpha = \frac{E}{1-\nu^2}(\varepsilon_\alpha + \nu\varepsilon_\beta)\,, \tag{31.18}$$

where the length of one edge is $L_\alpha = L_0(1+\varepsilon_\alpha)$; note that the subscripts α, β are used here rather than i, j to distinguish stresses and strains in two dimensions from those, more generally, in three. Thus, whereas i and j can be either 1, 2 or 3, α and β are restricted to being either 1 or 2. When this stress is uniform in the plane of the membrane (the x_1–x_2 plane) it can be replaced, without loss of generality, by a surface tension N_α (force per

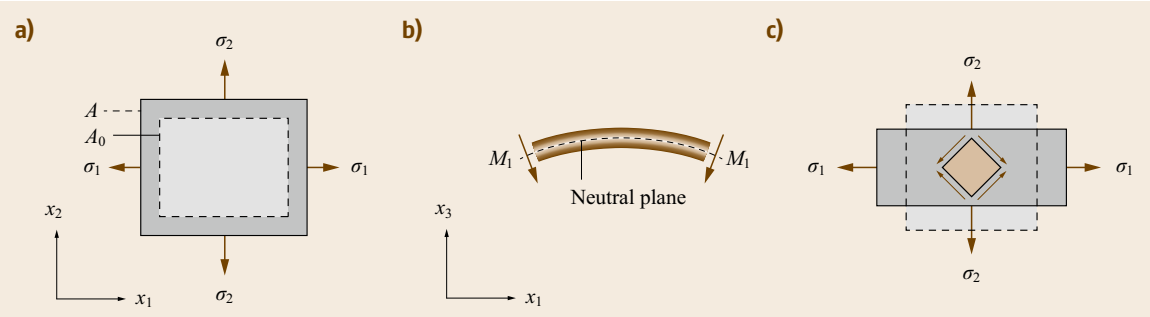

Fig. 31.9a–c Membrane mechanics. **(a)** A membrane, initially of area A_0, subjected to a uniform extensional stress along its edges ($\sigma_1 = \sigma_2$), causing an increase in area to A. **(b)** Application of equal moments M_1 at the two edges of a membrane sheet. **(c)** Shear deformations produced by the application of nonequal surface tensions on the boundaries of a membrane sheet. The inner square experiences shear strains as shown by the *arrows*

unit length) defined as $\sigma_\alpha h$, where h is the thickness of the membrane. These can be combined in the case when $N_1 = N_2 =$ constant and, consequently, $\varepsilon_1 = \varepsilon_2 = \varepsilon$ to give

$$N = \frac{Eh}{1-\nu}\varepsilon \,. \tag{31.19}$$

In terms of a plate stretched uniformly in both directions, we can define the areal strain as

$$\frac{\Delta A}{A_0} = \frac{A - A_0}{A_0} = \frac{L_0^2(1+\varepsilon)^2 - L_0^2}{L_0^2} \cong 2\varepsilon \,, \tag{31.20}$$

where the last approximation is appropriate for small strains. By combining this result with (31.19), we can define the *area expansion modulus* K_e (units of N/m) using

$$N = \frac{Eh}{2(1-\nu)}\frac{\Delta A}{A_0} \equiv K_e \frac{\Delta A}{A_0} \,. \tag{31.21}$$

Note that, although we used the continuum structural equations in our analysis, the final result can also be viewed as simply the definition of the area expansion modulus and applies regardless of whether or not the membrane can be modeled as a continuum.

Experimental measurements of K_e lie in the range of 0.1–1 N/m for various types of lipid bilayers and ≈ 0.45 N/m (450 dyn/cm) for red blood cell membranes [31.91]. These numbers suggest that cell membranes are quite resistant to extension and, for that reason, are often treated as inextensible. This discussion neglects the effects of thermal fluctuations in the membrane that give rise to a much more compliant behavior at the smallest areal strains. When surface stress is sufficient to smooth out most thermal fluctuations, the cell or vesicle will exhibit the large moduli given here.

This high resistance to area change is in large part due to the energy penalty associated with exposing the hydrophobic core of the membrane to water that occurs as the spacing between individual amphiphilic molecules is increased (for a detailed description of bilayer structure and thermodynamics, see [31.92]). Continuing to increase extensional stress, the lipid bilayer eventually ruptures, but at very small extensional strains, in the vicinity of 2–3% [31.93]. Note that a bilayer in a lipid vesicle, for example, stretches primarily by increasing the area per molecule since recruitment of additional material to the membrane occurs very slowly.

Using these expressions, the surface tension at which the membrane would rupture can be computed to be ≈ 0.06 N/m if we use a value near the higher end of the observed range $K_e = 1$ N/m. Cells also often exhibit an intrinsic surface tension. Reported values are small, however, lying in the range of $\approx 10^{-5}$–10^{-4} N/m [31.94].

Pure Bending. By contrast, lipid bilayers exhibit very low bending stiffness, so low that it is often neglected in models of membrane mechanics. It can be important in certain situations, however, and is essential, for example, in analyzing the thermal fluctuations of vesicles. Bending stiffness arises from the same type of molecular interactions that cause extensional stiffness. When an initially flat bilayer is bent, the hydrophilic head groups on the outside of the bend move further apart, while on the inside, intermolecular spacing decreases; both represent departures from the equilibrium, unstressed state and require energy.

Returning to our simple continuum plate model, consider a bending moment applied to the two ends, causing the plate to curve slightly (Fig. 31.9b). If the bending is due to moments applied at the two ends about the x_2-axis, then the bending moment per unit

length is related to the deflection by

$$M_\alpha = -\frac{Et^3}{12(1-\nu^2)}\left(\frac{\partial^2 u_3}{\partial x_\alpha^2}\right) = -K_\mathrm{b}\left(\frac{\partial^2 u_3}{\partial x_\alpha^2}\right), \tag{31.22}$$

where K_b is termed the *bending stiffness* having units of N m. Implicit in this expression are the assumptions that there exists a mid-plane (*neutral plane*) on which the in-plane stress and strain are both zero, and that straight lines perpendicular to this mid-plane remain straight and normal to this surface after deformation.

Typical values for the bending stiffness K_b lie in the range of 10^{-19} N m (10^{-12} dyn cm) for a red blood cell or lipid bilayer [31.93]. This value is larger, on the order of $(1–2)\times 10^{-18}$ N m [31.95], for other cell types (e.g., neutrophils, endothelial cells) that possess a more extensive cortex.

Pure Shear. Shear deformations arise when a membrane is stretched in one direction by a surface tension N_1 (units of force/length) while the lateral surface contracts under a lesser tension N_2, at constant surface area and in the absence of bending (Fig. 31.9c). Surfaces oriented at 45° to the boundaries experience pure shear stresses of magnitude $(N_1 - N_2)/2$. When subjected to shear stresses in the plane of the membrane, a pure lipid bilayer behaves essentially as a liquid. It exhibits a membrane viscosity in that it poses a resisting force proportional to the *rate* of shear deformation, but only a small shear modulus to *static* shear deformations. It is not clear, in fact, whether or not pure lipid bilayers exhibit a nonzero shear modulus. Typical cell membranes *do* exhibit a shear modulus, however, largely due to the cortex of cytoskeletal filaments that lie on the intracellular side of the membrane. In a red blood cell, this matrix, as discussed above, consists of interconnected filamentous spectrin and actin with attachments to the membrane via ankyrin. The equations relating shear force per unit length of membrane to shear deformation (Hooke's law) can be expressed as $N_{12} = \tau_{12}h = 2G\varepsilon_{12} = K_\mathrm{s}\varepsilon_{12}$, where we define the membrane shear modulus K_s in units of N/m. Typical values lie in the range $(6–9)\times 10^{-6}$ N/m for a red blood cell membrane. A pure lipid bilayer exhibits a *viscous* resistance to shear deformations characterized by a shear viscosity of $\approx 10^{-6}$ N s/m [31.48].

31.5.3 Cell Nuclei

Measurements based on micropipette aspiration, atomic force microscopy, and substrate strain experiments suggest that the nucleus is $\approx 2–10$ times stiffer than the surrounding cytoskeleton [31.56, 96–99]. What makes the nucleus so hard to deform? This question may in part depend on the particular mechanical load application. In cellular compression experiments, the highly condensed chromatin provides a large resistance to nuclear compression. In contrast, the nuclear lamina can act as an elastic molecular shock absorber [31.100] that seems ideally suited to sustain large strain when the cell or nucleus is stretched. This idea is supported by micropipette aspiration experiments on isolated nuclei that reveal that, in condensed nuclei, chromatin is the major contributor to nuclear stiffness, whereas the nuclear lamina carries much of the applied mechanical load in swollen nuclei that closely resemble nuclei in intact cells [31.43]. Similarly, condensed nuclei were found to be much stiffer than swollen nuclei [31.43]. Based on the nuclear structure, the mechanical contributions of the nucleus can be separated into three interconnected components: the nuclear membranes, the nuclear lamina, and the nuclear interior, which is mostly composed of chromatin but could also contain a nuclear matrix of lamins, actins, and other proteins. Each of these structural components has its own physical properties. The specific contributions have been addressed in experiments that induced osmotic swelling of isolated nuclei by varying the buffer salt concentration to separate the nuclear envelope from the underlying chromatin [31.12, 43] and in experiments on the large nuclei of *Xenopus* oocytes [31.101]. Additional insights have come from micropipette aspiration experiments, in which specific components of the nucleus (e.g., the lamina, the nuclear membrane or the chromatin) are fluorescently labeled and monitored during aspiration. These experiments have revealed that the nuclear interior behaves as a compressible, viscoelastic gel and can be compacted by more than 60% during micropipette aspiration before becoming resistant to further compression [31.46]. The reduction in nuclear volume during micropipette aspiration results in buckling of the nuclear envelope outside the pipette [31.43, 46], further demonstrating tight physical attachment between the nuclear envelope and the chromatin interior. Nucleoli and other intranuclear structures deform along with the nuclear interior in these experiments [31.45, 46], but might have slightly different mechanical stiffness. The viscoelastic nature of the chromatin also appears responsible for the persistent plastic deformations of nuclei seen after micropipette aspiration of isolated nuclei [31.45, 102]. In contrast to the gel-like nuclear interior, the nuclear lamina itself behaves as a two-dimensional elastic shell. This can be illustrated when monitoring the fluorescence intensity of green fluorescent protein (GFP)–lamin A incorporated into the nuclear lamina during micropipette aspiration experiments. While the fluorescence intensity is

very uniform in the nonaspirated section of the nucleus, the fluorescence intensity decays exponentially inside the aspirated segment, as the nuclear lamina is stretched under the aspiration pressure. Such a fluorescence intensity profile can be well fit by the predicted strain profile of a solid elastic shell [31.46, 103]. Unlike the nuclear lamina, the nuclear membranes have fluid-like characteristics; i. e., they do not show any induced strain during micropipette aspiration as they can flow in response to pressure application [31.46]. Further illustrating the fluid-like nature is the fact that small membrane vesicles continue to form blebs in the aspirated section of the nucleus as long as the suction pressure persists [31.46]. Consequently, the nuclear membrane cannot carry much of the mechanical load, leaving the nuclear interior and the nuclear lamina as the major contributors to nuclear stiffness and stability. This interpretation is further supported by recent studies that demonstrate that compression of cells using microindenters or during migration through tight spaces can result in nuclear membrane blebbing and subsequent rupture at sites of local defects in the nuclear lamina [31.104, 105].

In addition to the various structural components, the differentiation state of a cell can also modulate the mechanical properties of its nucleus. A recent study that probed nuclei from human embryonic stem cells and differentiated cells found that nuclei from embryonic stem cells were significantly more deformable than nuclei from differentiated cells and became up to sixfold stiffer relative to the cytoplasm during differentiation [31.45]. While some of this increase in nuclear stiffness could be caused by changes in chromatin structure and organization, much of it can be attributed to a stiffer lamina through increased expression of lamins A and C, as independent experiments have shown that lamins A and C are the main contributors to nuclear stiffness [31.109, 110].

Overall, micropipette aspiration has been the most widely used technique to probe nuclear mechanics, although cellular strain experiments, AFM, microbead rheology, and parallel-plate compression experiments have also been successfully applied to measure nuclear stiffness (Table 31.4). While some groups have described continuous creep of aspirated nuclei into the micropipette [31.43, 45, 100, 111], others [31.46, 97, 103] found that the nucleus stabilized after an equilibration period of $\approx 10\,\mathrm{s}$. These differences may be due to variations in the experimental setup or the particular cell type studied. Depending on the experimental technique used, various mathematical models have been applied to describe the induced nuclear deformations. For micropipette aspiration experiments, the creep compliance is often inferred from the following equation

$$J(t, \Delta P) = \Phi \frac{4\pi}{3} \frac{L}{D} \frac{1}{\Delta P} , \tag{31.23}$$

where ΔP is the applied pressure difference, L is the aspirated tongue length, and D is the micropipette diameter, and the dimensionless parameter Φ (value = 2.1) accounts for the effects of the micropipette geometry [31.112]. The challenge in finding an analytical expression for the mechanical behavior of the nucleus is that the nucleus is composed of various, structurally very different domains, as discussed above. Finite-element modeling can address some of these complex interactions, but often has to make assumptions on the specific material parameters that are difficult to verify. An alternative approach is to directly compare nuclear deformations under identical experimental conditions, e.g., the aspirated lengths of the nucleus during a constant applied pressure gradient in micropipette aspiration experiments or the induced nuclear strain under a given applied substrate strain in cell strain experiments [31.52].

31.5.4 Mechanosensing Proteins

While the complex biochemical pathways have been explored in considerable detail by biologists during the past several decades, work has only recently begun to understand the mechanical intracellular pathways for the propagation of force through the cell; For example, *Geiger* and *Bershadsky* [31.113] mapped the complex and interconnected pathways that can be

Table 31.4 Reported values for nuclear stiffness. (* Power-law rheology, not single spring constant; the nuclear envelope expansion modulus was measured to be $\approx 325\,\mathrm{mN/m}$ for these cells, after [31.43])

Cell type	Experimental method	Nuclear stiffness	Reference
Chondrocytes	Micropipette aspiration	1–2 kPa	[31.97]
Bovine endothelial cells	Parallel-plate compression	5–8 kPa	[31.96]
Monkey kidney epithelial cells	AFM and micropipette aspiration	$\approx$ 1–10 kPa*	[31.43]
Fibrosarcoma cells (HT1080)	AFM	0.2–2.5 kPa	[31.106]
Bladder cancer cell lines (RT4 and T24)	AFM	6–8 kPa	[31.98]
Mouse fibroblasts	Intranuclear particle tracking	18 Pa	[31.107]
Human cervical cancer cells (HeLa)	Magnetic tweezers	250 Pa	[31.108]

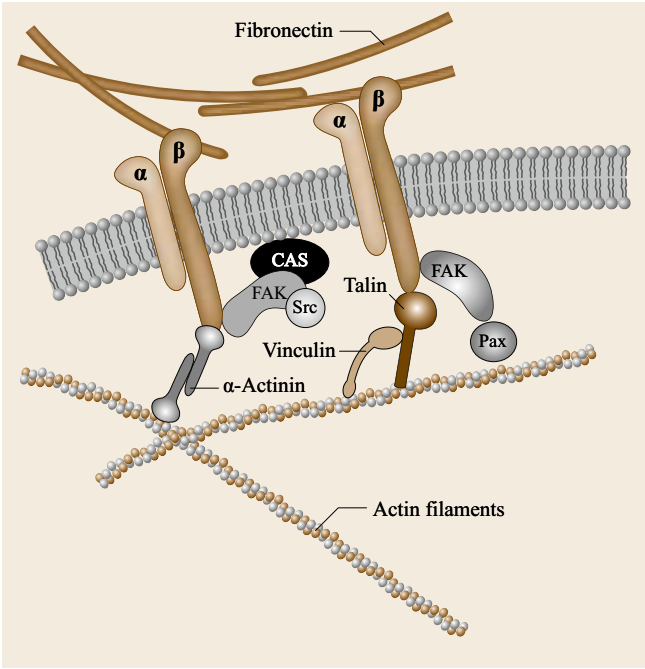

Fig. 31.10 A small sampling of the proteins found in a focal adhesion complex. Forces are typically transmitted from the extracellular matrix (e.g., fibronectin), via the integral membrane adhesion receptors (α- and β-integrins), various membrane-associated proteins (focal adhesion kinase (FAK), paxillin (Pax), talin, Crk-associated substrate (CAS)), to actin-binding proteins (α-actinin) that link the focal adhesion complex to the cytoskeleton. Note that the exact positioning of proteins with the focal adhesion is a matter of ongoing research, and be either closer to or further from the membrane than shown (after [31.113], with permission)

traced from the extracellular domain to the cytoskeletal matrix within the confines of a focal adhesion, a small portion of which is depicted in Fig. 31.10. Forces transmitted to the cell, either by tethering to the extracellular matrix or via ligand-coated beads in various in vitro experiments, are transmitted via the integrins (or other transmembrane receptors) through a collection of membrane-associated proteins, ultimately linking up with the cytoskeleton and propagated throughout the cell. Many of the proteins that form this pathway are known signaling molecules, and several have been implicated in mechanotransduction. The process by which changes in protein conformation give rise to protein clustering at a focal adhesion or initiate intracellular signaling, however, remains largely unknown. This has called for close examination of the individual proteins or protein complexes that transmit the forces throughout the cell and their interconnections. Consider one example pathway from Fig. 31.11. It can be seen that integrins bind to talin, which in turn connects with F-actin either directly or via vinculin. Talin and integrin also bind to focal adhesion kinase (FAK). This force pathway alone gives rise to several possibilities for mechanotransduction.

Even in the absence of biochemical signals, mechanical stimulation can still elicit the formation of viable focal adhesions [31.114]. These focal adhesions are produced as a result of direct molecular conformational changes in focal adhesion-forming molecules. Force-induced conformational changes in talin, vinculin, and focal adhesion kinase (FAK) initiate focal adhesion formation by anchoring integrin molecules to actin filaments and recruiting other focal adhesion-forming molecules to the site of interaction. Other mechanosensing molecules such as filamin and α-actinin stabilize actin filaments through mechanobracing and making scaffolds. The conformational changes in the focal adhesion-initiating molecules and the actin filament scaffold bracing molecules demonstrate the mechanisms of molecular mechanotransduction. In the following, we briefly review some recent work in molecular dynamics simulation of some mechanosensing proteins, namely talin interaction with vinculin, focal adhesion kinase interaction with paxillin, and molecular mechanics of actin binding proteins α-actinin and filamin.

Integrins

Integrins are signal receptors within the cell membrane that is first encountered by the cell mechanical microenvironment. Integrins act as a bridge between the cytoskeleton and ECM by transferring signals bidirectionally into and out of the cell. Several diseases, such as atherosclerosis and different types of cancer, have been linked to altered signaling patterns of integrins. Structurally, integrins are α–β heterodimeric receptors that consist of large extracellular domains (700−1000 residues), two transmembrane α-helices, and short cytosolic tails (50–70 residues). Integrin receptors reside in the cell membrane and link the cytoskeleton to ECM, making them essential for both *inside-out* and *outside-in* signaling. Signal transmission from the cell exterior to the cytoskeleton is called "outside-in signaling," whereas "inside-out signaling" occurs when a biochemical signal is relayed from the cytoskeleton outwards by inducing a cascade of conformational changes within mechanosensing proteins on the mechanical pathways that link the cytoskeleton to the ECM. Inside-out signaling is putatively triggered by separation of the two integrin subunits at their cytoplasmic and transmembrane domains, which occurs in response to association of talin to the integrin cytoplasmic β-subunit domain. A major restraint that holds

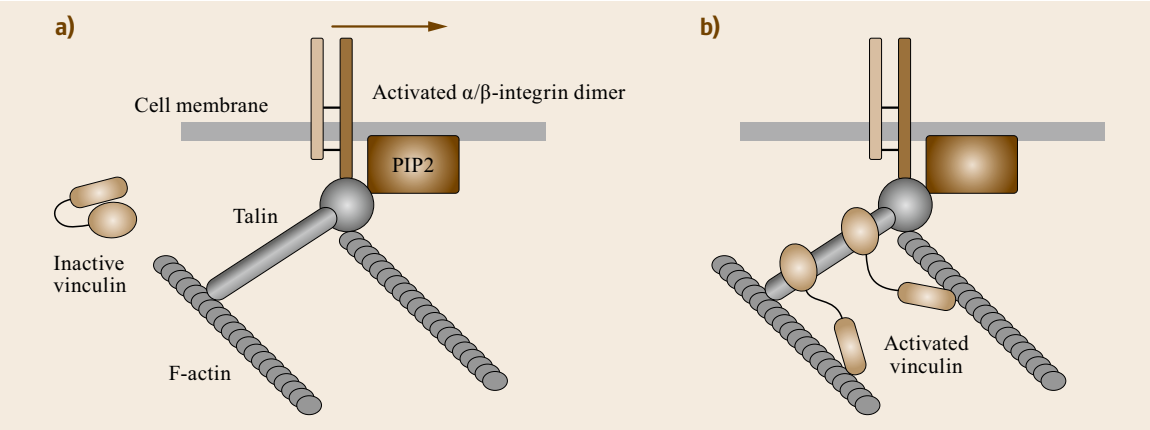

Fig. 31.11 **(a)** Model of the initial adhesion consisting of integrin–talin–F-actin linkage. Vinculin is present in the cytosol in an inactive, autoinhibitory conformation, and tensile force is applied to the integrin dimer from the outside of the cell membrane. **(b)** Transmitted force through the linkage alters the talin configuration, and recruits vinculin to reinforce the initial adhesion linkage (PIP2 – phosphatidylinositol 4,5-bisphosphate)

integrins in an inactive mode is the interaction between transmembrane and cytoplasmic domains of the α- and β-subunits. Separation of these domains is sufficient to allow unbending of the ligand-binding headpiece and conformational changes that increase ligand-binding affinity. Conversely, binding of the ligand to the integrin ectodomain results in an extended conformation of integrin whereby the legs of α- and β-subunits are separated. Hence, integrin-mediated signaling involves conformational changes of integrins leading to alterations in their binding affinity for ECM ligands and may be initiated from interacting with proteins at their cytoplasmic tail.

Talin and Vinculin

Talin interacts with the membrane-bound integrin molecule at its head domain, and with vinculin in its tail domain. It has been implicated as a site of molecular activation by external force. The forces acting on the cells from the ECM are transmitted from the integrin molecules to the talin head and then to all regions of the talin tail (Fig. 31.11). The talin tail has 11 vinculin binding sites (VBSs), some of which are on amphipathic α-helices and are buried in the hydrophobic core of the talin tail. VBS1 is one of the cryptic binding sites buried in the hydrophobic core of the TAL5 region of talin's tail. TAL5 has several surface polar residues that are sites of hydrogen bonding with other secondary structures in the rod domain. Transduced external forces from the ECM are applied to the TAL5 domain via these residues [31.115]. In order to simulate the force transduction through the cryptic VBS1 of TAL5, *Lee* et al. [31.116] applied forces averaging 21.2 pN at the residues near the N-terminal near the talin head while

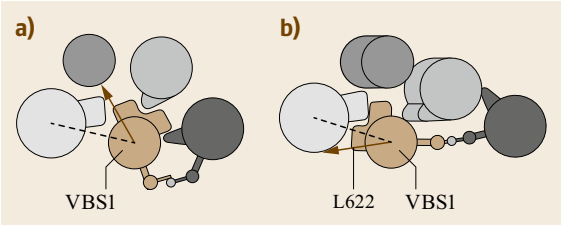

Fig. 31.12a,b With external force applied to the polar residues in the TAL5 region of the talin rod, domain activation of the VBS1 is achieved through rotation of the buried VBS residues to the surface of the molecule. **(a)** TAL5 region before application of external force. The VBS1 is buried in the hydrophobic patch. **(b)** After the external force is applied, TAL5 undergoes a conformational change and the VBS residues are exposed to the surface. In this representation, movement of the VBS to the surface is shown by the movement of the *arrow* (edge of VBS) past the *dotted lines*

constraining fixed the polar residues at the C-terminal, which interact with the adjacent secondary structure domain. The external locally applied force caused TAL5 to elongate, H1 to move in the direction of the pulling force, H1 to apply torque to H4 via its hydrogen bonds, and H4 to rotate, exposing the VBS1 (Fig. 31.12). Once exposed to solvent, the VBS1 is activated and can interact with vinculin. The force-induced activation of VBS sites in the talin tail together with force-induced activation of vinculin can anchor the stimulated integrin molecules to the actin cytoskeleton and thereby initiate focal adhesions.

An alternative mechanism was recently proposed by *Hytönen* and *Vogel* [31.117], which involves the unfold-

ing of the rod domain in order to expose the vinculin binding site VBS1. Using steered molecular dynamics, Hytönen and Vogel demonstrated that the talin rod can be fragmented into three helix subbundles, which is followed by the sequential exposure of vinculin-binding helices to water. The unfolding of a vinculin-binding helix into a completely stretched polypeptide might then inhibit further binding of vinculin.

The conformational changes that enable the recruitment of vinculin to ECM-bound talin can go beyond the exposure of cryptic vinculin binding sites. The orientation of the talin dimer itself can be affected by its mechanical environment. Recent molecular dynamics simulations [31.118] have probed these possible dimer orientation changes. Molecular dynamics has shown that the talin dimer will adopt either an elongated conformation, when bound to two integrins under extension, or a compact conformation, when bound to two integrins free of external strain. The elongated conformation then allows for further recruitment of vinculin by exposure of additional regions on the talin rod domain with cryptic binding sites. The combined reorientation of the dimer and the exposure of the cryptic binding sites vastly enhances the recruitment of vinculin to the growing focal adhesion.

The mechanisms via which vinculin reinforces contacts between the ECM and F-actin through interaction with talin have also been explored [31.119–121]. Vinculin is natively in an autoinhibited conformation in which the VBS binding region of vinculin head domain (Vh) prevents interaction with the vinculin tail domain (Vt) by steric hindrance. Competing hypotheses have been suggested for how vinculin is activated via interaction with talin and actin: (A) vinculin activation after simultaneous interaction with talin and actin, or (B) vinculin activation solely by interaction with talin VBS. Recent molecular dynamics models seem to suggest vinculin is more likely to become activated through simultaneous interaction rather than through talin VBS insertion alone [31.122, 123]. It has been postulated that the activation of vinculin and its binding with talin's VBS could involve the following mechanism:

1. VBS links to D1 via surface hydrophobic interactions.
2. Vinculin undergoes activation, and D1 is moved away from the vinculin tail.
3. Helices in D1 undergo conformational change to allow VBS binding.
4. VBS inserts itself into the hydrophobic core of D1.

One major actin filament cross-linker is α-actinin, which maintains dynamic rearrangement of actin filaments and serves as a scaffold for parallel actin filaments, such as those in stress fibers or in muscle z-disk formations. α-Actinin is an antiparallel homodimer with three major domains: an actin binding domain, a calmodulin homology domain, and a central rod domain [31.124]. In order to act as a molecular scaffold, cross-linking actin filaments in a stressed cytoskeletal network α-actinin must have a semiflexible structure. By exploring the natural frequencies of α-actinin and its response to external forces, *Golji* et al. [31.119] characterized the flexible and rigid regions of α-actinin and demonstrated the molecular conformational changes that underlie the semiflexible cross-linking and mechanical bracing of α-actinin. Besides its cross-linking role for filamentous actin, α-actinin binds with integrin as well and is speculated to play a role in the activation and clustering of integrins and thus focal adhesion formation. However, it is debated whether α-actinin plays an inhibitory or facilitating role in integrin activation. Detailed molecular interactions of α-actinin and integrin cytoplasmic tail have been probed in order to reconcile this controversy [31.120]. While talin is essential for focal adhesion formation, it does not play a significant role in focal adhesion maturation, and other molecules such as α-actinin are responsible for that. Since α-actinin is an antiparallel dimer and each monomer contains an integrin-binding site at the N-terminal end of its rod domain, it can bind to two integrin tails simultaneously, which may give rise to integrin clustering. Integrin clustering may occur via maintaining the distance between two α-actinin-bound integrins, allowing them to interact more effectively. Integrins diffuse freely in the lipid membrane, thus the probability of assembling individual integrins is only related to their concentration in the membrane. Directional motion of integrins may highly influence the time scale of their clustering, leading to adhesion maturation. α-Actinin may play a role in this by binding to actins at both ends and transmitting actomyosin forces to the plasma membrane through their interaction with integrins, which leads to directional migration of integrins governed by cytoskeletal forces [31.121, 125].

Microtubules

As yet another mechanosensing protein system, one can name the microtubule filaments [31.126]. The microtubule cytoskeleton, which is composed of individual microtubules typically nucleated from a microtubule organizing center near the nucleus, usually forms a radial network that radiates outward to the cell periphery. These microtubules are inherently polarized due to their head-to-tail assembly, and this allows for processive movement of cargo via motor proteins that move specifically towards either the plus or the minus end.

Microtubular filaments resist mechanical deformation and facilitate transport of intracellular cargo via coupling to molecular motors. These filaments are typically in compression, effectively balancing the tensile forces exhibited by the actin–myosin system [31.84].

Stretch-Sensitive Ion Channels

Another class of mechanosensing proteins are the mechanosensitive ion channels, e.g., the mechanosensitive channel of large conductance (MscL), which has been studied extensively [31.127, 128]; molecular dynamics simulation has been used to show how stresses in the cell membrane act directly on the channel and cause it to change its conductance [31.129]. A recently discovered cation channel, Piezo2, is present in mechanosensory neurons and important for proprioception [31.130]. These channels have emerged as another potential gateway for the cell to sense and respond to environmental stimuli.

The Nucleus as a Cellular Mechanosensor

The nucleus has long been speculated to serve as a cellular mechanosensor, and functional loss of nuclear envelope proteins such as lamins and nesprins results in impaired activation of mechanosensitive genes [31.32, 131]. Force-induced deformation of the nucleus could modulate gene expression through a variety of mechanisms, including:

1. Changing the accessibility of chromatin to transcriptional regulators
2. Causing conformational changes in nuclear envelope proteins that alter their interaction with chromatin and other binding partners
3. Increasing/decreasing the permeability of nuclear pores
4. Perturbing mobility and interaction of nuclear proteins and intranuclear structures (reviewed in [31.132, 133]).

Nuclear swelling and associated nuclear membrane strain have also been shown to activate proinflammatory signals in response to tissue damage, possibly by stretch-induced changes in the nuclear lipid membrane that facilitate recruitment of cytosolic phospholipase A2 ($cPLA_2$) to the nuclear envelope [31.134]. The most striking evidence for nuclear mechanosensing comes from studies on isolated nuclei subjected to nanonewton forces by magnetic beads attached via nesprin-1. Repeated force application resulted in rapid nuclear stiffening and recruitment of lamins A/C to the LINC complex, mediated by phosphorylation of the nuclear envelope protein emerin through Src kinase [31.135]. Understanding the mechanisms of force transmission and the stability of LINC complexes is critically important in unravelling the cellular mechanotransduction pathways.

31.6 Current Understanding and Future Needs

Progress is rapidly being made on both the experimental and computational fronts to further understand the nanomechanics of the cell. Using either AFM or optical tweezers, controlled force applications in the pN range and displacement measures in the nm range are already within current capabilities. Both methods have been used extensively to measure the rupture force of two bound proteins [31.136] or the force needed to unfold a protein and change its binding or signaling properties. In addition, single-molecule fluorescence measurements provide the opportunity to monitor single binding events. On a larger scale, new entirely noninvasive methods are being developed to probe the mechanical properties of subcellular structures. Since we know cells are exquisitely sensitive to mechanical force, these methods will help us to distinguish the passive and active mechanical responses. On the computational side, technical and technological barriers are being slowly surmounted. Molecular dynamics can be applied to proteins to predict their conformational change under force, and docking simulations provide a means for determining binding affinities in different conformational states. The barriers to progress lie primarily in our lack of atomistic models capable of simulating interactions between proteins such as those located in the force transmission pathway, at focal adhesions or nuclear pore complexes, for example. These proteins also tend to be difficult to crystallize, so few structures are available. Cryoelectron microscopy (cryo-EM) is emerging as a promising approach to yield structural information without the requirement to form crystals, which makes it particularly attractive to study filaments and large, complex structures such as the nuclear pore complex. For computational modeling, due to their size, simulations are computationally intensive, especially if the presence of water molecules is included explicitly. Despite these constraints, some progress can be made by using subdomains of the proteins of interest or coarse-graining and multiscale approaches, although these need to be adequately evaluated [31.137].

32. Nanomechanical Properties of Nanostructures and Scale Effects

Bharat Bhushan

Structural integrity is of paramount importance in all devices. Load applied during the use of devices can result in component failure. Cracks can develop and propagate under tensile stresses, leading to failure. Knowledge of the mechanical properties of nanostructures is necessary for the design of realistic micro/nanoelectromechanical systems (MEMS/NEMS) and biological micro/nanoelectromechanical systems (bioMEMS/bioNEMS) devices. Elastic and inelastic properties are needed to predict deformation from an applied load in the elastic and inelastic regimes respectively. The strength property is needed to predict the allowable operating limit. Some properties of interest are hardness, elastic modulus, bending strength, fracture toughness, and fatigue strength. Many of the mechanical properties are scale dependent. Therefore, these should be measured at relevant scales. Atomic force microscopy and nanoindenters can be used to evaluate the mechanical properties of micro/nanoscale structures.

Commonly used materials in MEMS/NEMS are single-crystal silicon and silicon-based materials, e.g., SiO_2 and polysilicon films deposited by low-pressure chemical vapor deposition. Single-crystal SiC deposited on large-area silicon substrates is used for high-temperature micro/nanosensors and actuators. Amorphous alloys can be formed on both metal and silicon substrates by sputtering and plating techniques, providing more flexibility in surface integration. Electroless deposited Ni-P amorphous thin films have been used to construct microdevices, especially using the so-called Lithographie, Galvanoformung, Abformung (LIGA) techniques. Micro/nanodevices need conductors to provide power, as well as electrical/magnetic signals to make them functional. Electroplated gold films have found wide application in electronic devices because of their ability to make thin films and because they process simply. Polymers, such as poly(methyl methacrylate) (PMMA), poly(dimethylsiloxane) (PDMS), and polystyrene are commonly used in BioMEMS/BioNEMS such as micro/nanofluidic devices because of the ease of manufacturing and reduced cost. Many polymers are biocompatible, so they may be integrated into biomedical devices.

This chapter presents a review of mechanical property measurements on the micro/nanoscale of various materials of interest and stress and deformation analyses of nanostructures.

Microelectromechanical systems (MEMS) refer to microscopic devices that have a characteristic length of less than 1 mm but more than 100 nm (or 1 μm), and nanoelectromechanical systems (NEMS) refer to nanoscopic devices that have a characteristic length of less than 100 nm (or 1 μm). These are referred to as an intelligent miniaturized system comprising of sensing, processing, and/or actuating functions and combine electrical and mechanical components. The acronym MEMS originated in the USA. The term commonly used in Europe is micro/nanosystem technology (MST/NST), and in Japan it is micro/nanomachines. Another term generally used is micro/nanodevices. MEMS/NEMS terms are also now used in a broad sense and include electrical, mechanical, optical, biological, and/or fluidic functions. To put the dimensions in perspective, individual atoms are typically a fraction of a nanometer in diameter, DNA molecules are about 2.5 nm wide, biological cells are in the range of thousands of nm in diameter, and human hair is about 75 μm in diameter. The mass of a micromachined silicon structure can be as low as 1 nN, and NEMS can be built with mass as low as 10^{-20} N with cross-sections of about 10 nm. In comparison, the mass of an eyelash is about 100 nN, and the mass of a drop of water is about 10 μN.

A wide variety of MEMS, including Si-based devices, chemical and biological sensors and actuators, and miniature nonsilicon structures (e.g., devices made from plastics or ceramics) have been fabricated with dimensions in the range of a couple to a few thousand microns (see e.g., [32.1–11]). A variety of NEMS have also been produced (see e.g., [32.12–18]). MEMS/NEMS technology and fabrication processes have found a variety of applications in biology and biomedicine, leading to the establishment of an entirely new field known as BioMEMS/BioNEMS [32.19–26]. The ability to use micro/nanofabrication processes to develop precision devices that can interface with biological environments at the cellular and molecular level has led to advances in the fields of biosensor technology [32.26–30], drug delivery [32.31–34], and tissue engineering [32.35–37]. The miniaturization of fluidic systems using micro/nanofabrication techniques has led to new and more efficient devices for medical diagnostics and biochemical analysis [32.38]. The largest industrial applications of MEMS include accelerometers, pressure sensors, thermal and piezoelectric-type inkjet printer heads, and digital micromirror devices. BioMEMS and BioNEMS are increasingly used in commercial applications. The largest applications of BioMEMS and BioNEMS include a variety of biosensors and drug delivery devices.

Structural integrity is of paramount importance in all devices. Load applied during the use of devices can result in component failure. Cracks can develop and propagate under tensile stresses leading to failure. Friction/stiction and wear limit the lifetimes and compromise the performance and reliability of devices involving relative motion [32.3, 39–41]. Most MEMS/NEMS applications demand extreme reliability. Stress and deformation analyses are carried out for an optimal design. MEMS/NEMS designers require information about mechanical properties at the nanoscale. Elastic and inelastic properties are needed to predict deformation from an applied load in the elastic and inelastic regimes respectively. Understanding of the strength property is needed to predict the allowable operating limit. Some of the properties of interest are hardness, elastic modulus, creep, bending strength (fracture stress), fracture toughness, and fatigue strength. Micro/nanostructures have some surface topography and local scratches dependent upon the manufacturing process. Surface roughness and local scratches may compromise the reliability of the devices, and their effect needs to be studied.

Most mechanical properties are scale dependent [32.40, 41]. Several researchers have measured the mechanical properties of silicon and silicon-based milli- to microscale structures. These include tensile tests and bending tests [32.42–51], resonant structure tests for the measurement of elastic properties [32.52], fracture toughness tests [32.43, 45, 53–57], and fatigue tests [32.55, 58, 59]. Nanomechanical properties of nanoscale structures have been measured using atomic force microscopy (AFM) [32.60, 61] and nanoindentation [32.62–65]. For stress and deformation analyses of simple geometries and boundary conditions, analytical models can be used. For analysis of complex

geometries, numerical models are needed. The conventional finite element method (FEM) can be used down to a few tens of nanometers scale, although its applicability is questionable at the nanoscale. FEM has been used for simulation and prediction of residual stresses and strains induced in MEMS devices during fabrication [32.66], to perform fault analysis in order to study MEMS faulty behavior [32.67], to compute mechanical strain resulting from doping of silicon [32.68], analyze micromechanical experimental data [32.45, 69, 70], and nanomechanical experimental data [32.61]. FEM analysis of nanostructures has been performed to analyze the effect of types of surface roughness and scratches on stresses in nanostructures [32.71, 72].

Commonly used materials for MEMS/NEMS are single-crystal silicon and silicon-based materials (e.g., SiO_2 and polysilicon films deposited by the low-pressure chemical vapor deposition (LPCVD) process) [32.10]. An early study showed silicon to be a mechanically resilient material, in addition to its favorable electronic properties [32.73]. Single-crystal 3C-SiC (cubic or β-SiC) films, deposited by the atmospheric-pressure chemical vapor deposition (APCVD) process on large-area silicon substrates, are produced for high-temperature micro/nanosensor and actuator applications [32.74–76]. Amorphous alloys can be formed on both metal and silicon substrates by sputtering and plating techniques, providing more flexibility in surface integration. Electroless deposited Ni-P amorphous thin films have been used to construct microdevices, especially using the so-called LIGA techniques [32.10, 63]. Micro/nanodevices need conductors to provide power, as well as electrical/magnetic signals to make them functional. Electroplated gold films have found wide applications in electronic devices because of their ability to make thin films and process simplicity [32.63].

As the field of MEMS/NEMS has progressed, alternative materials, especially polymers, have established an important role in their construction. This trend has been driven by the reduced cost associated with polymer materials. Polymer microfabrication processes, including micromolding and hot embossing techniques [32.77], can be orders of magnitude less expensive than traditional silicon photolithography processes. Many polymers are biocompatible, so these can be integrated into biomedical devices with minimal detrimental effects to the host or on the biofluids. An improvement in device functionality (relative to silicon) is also possible due to the mechanical properties of the polymer used, which have properties much closer to biological tissues. Polymer BioMEMS structures involving microbeams have been designed to measure cellular forces [32.64, 65]. Polymer materials most commonly used for biomedical applications include poly(methyl methacrylate) (PMMA), poly(dimethylsiloxane) (PDMS), and polystyrene [32.65, 77–79]. Another material of interest due to ease of fabrication is poly(propyl methacrylate) (PPMA), which has a lower glass transition temperature (T_g) (35−43 °C) [32.80] than PMMA (104−106 °C) [32.81, 82], permitting low-temperature thermal processing [32.64, 65, 79].

This chapter presents a review of mechanical property measurements on the nanoscale of various materials of interest and stress and deformation analyses of nanostructures.

32.1 Experimental Techniques for Measurement of Mechanical Properties of Nanostructures

32.1.1 Indentation and Scratch Tests Using Micro/Nanoindenters

A nanoindenter is commonly used to measure hardness, elastic modulus, and fracture toughness, and to perform micro/nanoscratch studies to get a measure of scratch/wear resistance of materials [32.83].

Hardness and Elastic Modulus

The nanoindenter monitors and records the dynamic load and displacement of the three-sided pyramidal diamond (Berkovich) indenter during indentation with a force resolution of about 75 nN and displacement resolution of about 0.1 nm. Hardness and elastic modulus are calculated from the load-displacement data [32.83]. The peak indentation load depends on the mechanical properties of the specimen; a harder material requires a higher load for reasonable indentation depth.

Fracture Toughness

The indentation technique for fracture toughness measurement of brittle samples on the microscale is based on the measurement of the lengths of median-radial cracks produced by indentation. A Vickers indenter (a four-sided diamond pyramid) is used in a microhardness tester. A load on the order of 0.5 N is typically used in making the Vickers indentations. The

indentation impressions are examined using an optical microscope with Nomarski interference contrast to measure the length of median-radial cracks, c. The fracture toughness (K_{IC}) is calculated by the following relation [32.84],

$$K_{IC} = \alpha \left(\frac{E}{H}\right)^{1/2} \left(\frac{P}{c^{3/2}}\right) , \tag{32.1}$$

where α is an empirical constant depending on the geometry of the indenter, H and E are hardness and elastic moduli, and P is the peak indentation load. For Vickers indenters, α has been empirically found based on experimental data and is equal to 0.016 [32.83]. Both E and H values are obtained from the nanoindentation data. The crack length is measured from the center of the indent to the end of crack using an optical microscope. For one indent, all crack lengths are measured. The crack length c is obtained from the average value of several indents.

Indentation Creep

For an indentation creep test of polymer samples, the test is performed using a continuous stiffness measurements (CSMs) technique [32.83]. In a study by *Wei* et al. [32.64], the indentation load was typically 30 μN, and the loading rate was 3 μN/s. The tip was held typically for 600 s after the indentation load reached 30 μN. To measure the mean stress and contact stiffness, during the hold segment the indenter was oscillated at a peak-to-peak load amplitude of 1.2 μN and a frequency of 45 Hz.

Scratch Resistance

In micro/nanoscratch studies, in a nanoindenter, a conical diamond indenter having a tip radius of about 1 μm and an included angle of 60° is drawn over the sample surface, and the load is ramped up until substantial damage occurs [32.83]. The coefficient of friction is monitored during scratching. In order to obtain scratch depths during scratching, the surface profile of the sample surface is first obtained by translating the sample at a low load of about 0.2 mN, which is insufficient to damage a hard sample surface. The 500 μm long scratches are made by translating the sample while ramping the loads on the conical tip over different loads dependent upon the material hardness. The actual depth during scratching is obtained by subtracting the initial profile from the scratch depth measured during scratching. In order to measure the scratch depth after the scratch, the scratched surface is profiled at a low load of 0.2 mN and is subtracted from the actual surface profile before scratching.

32.1.2 Bending Tests of Nanostructures Using an AFM

Quasistatic bending tests of fixed nanobeam arrays in the normal direction are carried out using an AFM [32.61, 85]. A three-sided pyramidal diamond tip (with a radius of about 200 nm) mounted on a rectangular stainless steel cantilever is used for the bending tests. The beam stiffness is selected based on the desired load range. The stiffness of the cantilever beams for application of a normal load up to 100 μN is about 150–200 N/m.

For the bending test, the tip is brought over the nanobeam array with the help of the sample stage of the AFM and a built-in high magnification optical microscope (Fig. 32.1) [32.61]. For the fine positioning of the tip over a chosen beam, the array is scanned in contact mode at a contact load of about 2–4 μN, which results in negligible damage to the sample. After scanning, the tip is located at one end of a chosen beam. To position the tip at the center of the beam span, the tip is moved to the other end of the beam by giving the x-piezoelectric electrode an offset voltage. The value of this offset is determined after several such attempts have been made in order to minimize the effects of piezoelectric drift. Half of this offset is then applied to the x-piezoelectric electrode after the tip is positioned at one end of the beam, which usually results in the tip being moved to the center of the span. Once the tip is positioned over the center of the beam span, the tip is held stationary without scanning, and the z-piezoelectric electrode is extended by a known distance, typically about 2.5 μm, at a rate of 10 nm/s, as shown in Fig. 32.1. During this time, the vertical deflection signal (dV_{AFM}), which is proportional to the deflection of the cantilever (D_{tip}), is monitored. The displacement of the piezoelectric tube scanner is equal to the sum of the displacements of the cantilever and the nanobeam. Hence the displacement of the nanobeam (D_{beam}) under the point of load can be determined as

$$D_{beam} = D_{piezo} - D_{tip} . \tag{32.2}$$

The load (F_{beam}) on the nanobeam is the same as the load on the tip/cantilever (F_{tip}) and is given by

$$F_{beam} = F_{tip} = D_{tip} k , \tag{32.3}$$

where k is the stiffness of the tip/cantilever. In this manner, a load displacement curve for each nanobeam can be obtained.

The photodetector sensitivity of the cantilever needs to be calibrated to obtain D_{tip} in nm. For this calibration, the tip is pushed against a smooth diamond sample by moving the z-piezoelectric electrode over

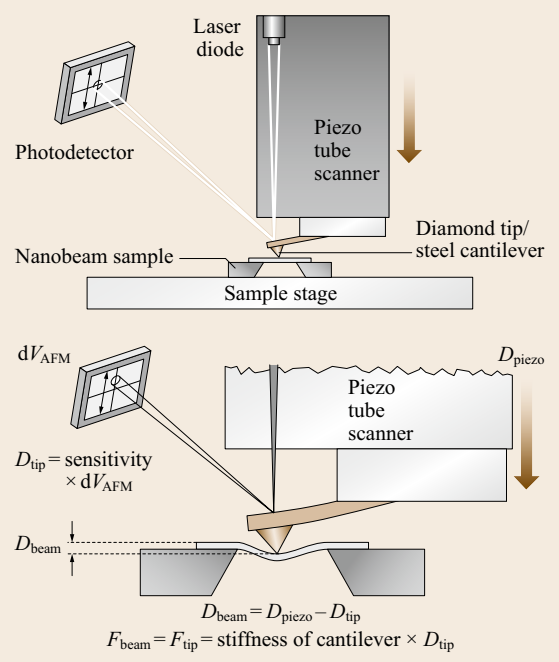

Fig. 32.1 Schematic showing the details of a nanoscale bending test using an AFM. The AFM tip is brought to the center of the nanobeam and the piezoelectric tube scanner is extended over a known distance. By measuring the tip displacement, a load displacement curve of the nanobeam can be obtained (after [32.61])

a known distance. For the hard diamond material, the actual deflection of the tip can be assumed to be the same as the z-piezoelectric electrode travel (D_{piezo}), and the photodetector sensitivity (S) for the cantilever setup is determined as

$$S = \frac{D_{piezo}}{dV_{AFM}} \frac{nm}{V} . \tag{32.4}$$

In the measurements, D_{tip} is given as $dV_{AFM}S$.

Since a sharp tip would result in an undesirable large local indentation, *Sundararajan* and *Bhushan* [32.61] used a diamond tip that was worn (blunt). Indentation experiments using this tip on a silicon substrate yielded a residual depth of less than 8 nm at a maximum load of 120 μN, which is negligible compared to displacements of the beams (several hundred nm). Hence we can assume that negligible local indentation or damage is created during the bending process of the beams and that the displacement calculated from (32.2) is from the beam structure.

Elastic Modulus and Bending Strength

Elastic modulus and bending strength (fracture stress) of the beams can be estimated by equations based on

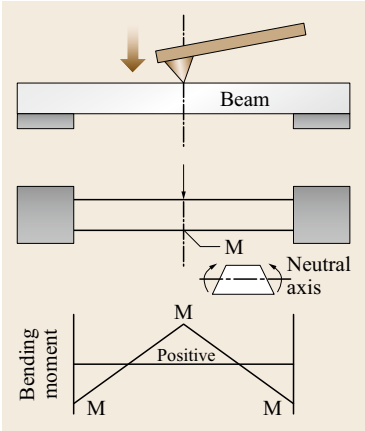

Fig. 32.2 Schematic of the bending moments generated in the beam during a quasistatic bending experiment, with the load at the center of the span. The maximum moments occur under the load and at the fixed ends. Due to the trapezoidal cross-section, the maximum tensile bending stresses occur at the top surfaces at the fixed ends

the assumption that the beams follow the linear elastic theory of an isotropic material. This is probably valid since the beams have high length-to-width ℓ/w and length-to-thickness ℓ/t ratios and also since the length direction is along the principal stress direction during the test. For a fixed elastic beam loaded at the center of the span, the elastic modulus is expressed as

$$E = \frac{\ell^3}{192I} m , \tag{32.5}$$

where ℓ is the beam length, I is the area moment of inertia for the beam cross-section, and m is the slope of the linear region of the load–displacement curve during bending [32.86]. The area moment of inertia for a beam with a trapezoidal cross-section is calculated from the following equation

$$I = \frac{4w_1w_2 + w_1^2 + w_2^2}{36\,(w_1 + w_2)} t^3 , \tag{32.6}$$

where w_1 and w_2 are the upper and lower widths respectively, and t is the thickness of the beam. According to linear elastic theory, for a centrally loaded beam, the moment diagram is shown in Fig. 32.2. The maximum moments are generated at the ends (negative moment) and under the loading point (positive moment) as shown in Fig. 32.2. The bending stresses generated in the beam are proportional to the moments and are compressive or tensile about the neutral axis (line of zero stress). The maximum tensile stress (σ_b, which is the bending strength or fracture stress) is produced on the top sur-

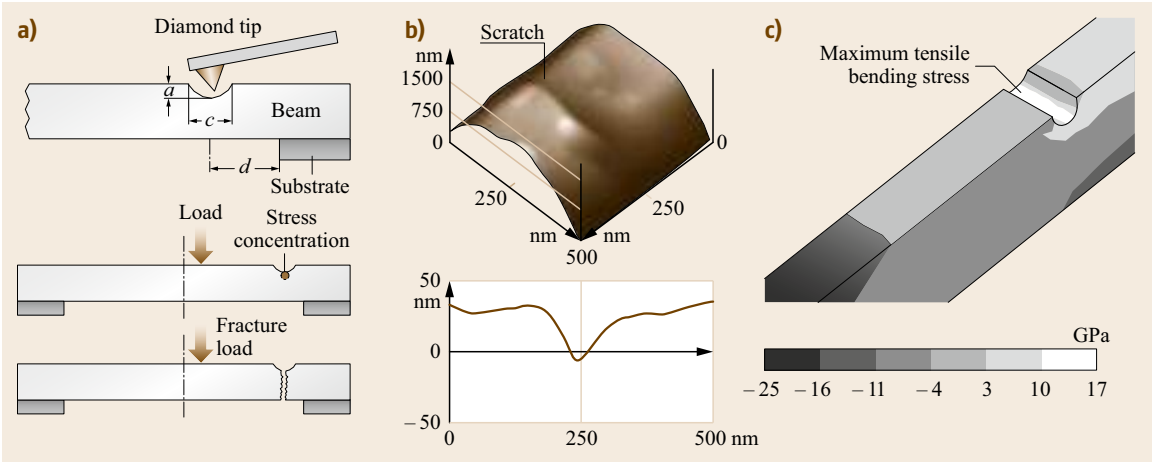

Fig. 32.3 **(a)** Schematic of technique to generate a defect (crack) of known dimensions in order to estimate fracture toughness. A diamond tip is used to generate a scratch across the width of the beam. When the beam is loaded as shown, a stress concentration is formed at the bottom of the scratch. The fracture load is then used to evaluate the stresses using FEM. **(b)** AFM three-dimensional (3-D) image and two-dimensional (2-D) profile of a typical scratch. **(c)** Finite element model results verifying that the maximum bending stress occurs at the bottom of the scratch (after [32.61])

face at both the ends and is given by [32.86]

$$\sigma_b = \frac{F_{max}\ell e_1}{8I} , \tag{32.7}$$

where F_{max} is the applied load at failure, and e_1 is the distance of the top surface from the neutral plane of the beam cross-section and is given by [32.86]

$$e_1 = \frac{t\,(w_1 + 2w_2)}{3\,(w_1 + w_2)} . \tag{32.8}$$

Although the moment value at the center of the beam is the same as at the ends, the tensile stresses at the center (generated on the bottom surface) are less than those generated at the ends (per (32.7)) because the distance from the neutral axis to the bottom surface is less than e_1. This is because of the trapezoidal cross-section of the beam, which results in the neutral axis being closer to the bottom surface than the top Fig. 32.2.

In the preceding analysis, the beams were assumed to have fixed ends. However, in the nanobeams used by *Sundararajan* and *Bhushan* [32.61], the underside of the beams was pinned over some distance on either side of the span. Hence a finite element model of the beams was created to see if the difference in the boundary conditions affected the stresses and displacements of the beams. It was found that the difference in the stresses was less than 1%. This indicates that the boundary conditions near the ends of the actual beams are not that different from that of fixed ends. Therefore the bending strength values can be calculated from (32.7).

Fracture Toughness

Fracture toughness is another important parameter for brittle materials such as silicon. In the case of the nanobeam arrays, these are not best suited for fracture toughness measurements because they do not possess regions of uniform stress during bending. *Sundararajan* and *Bhushan* [32.61] developed a methodology, which is outlined schematically in Fig. 32.3a. First, a crack of known geometry is introduced in the region of maximum tensile bending stress, i. e., on the top surface near the ends of the beam. This is achieved by generating a scratch at high normal load across the width (w_1) of the beam using a sharp diamond tip (radius < 100 nm). A typical scratch thus generated is shown in Fig. 32.3b. By bending the beam as shown, a stress concentration will be formed under the scratch. This will lead to failure of the beam under the scratch once a critical load (fracture load) is attained. The fracture load and relevant dimensions of the scratch are input into the FEM model, which is used to generate the fracture stress plots. Figure 32.3c shows an FEM simulation of one such experiment, which reveals that the maximum stress does occur under the scratch.

If we assume that the scratch tip acts as a crack tip, a bending stress will tend to open the crack in Mode I. In this case, the stress field around the crack tip can be described by the stress intensity parameter K_I (for Mode I) for linear elastic materials [32.87]. In particular

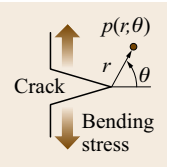

Fig. 32.4 Schematic of crack tip and coordinate systems used in (32.9) to describe a stress field around the crack tip in terms of the stress intensity parameter, K_I (after [32.61])

the stresses corresponding to the bending stresses are described by

$$\sigma = \frac{K_I}{\sqrt{2\pi r}} \cos\left(\frac{\theta}{2}\right)\left[1 + \sin\left(\frac{\theta}{2}\right)\sin\left(\frac{3\theta}{2}\right)\right] \tag{32.9}$$

for every point $p(r, \theta)$ around the crack tip as shown in Fig. 32.4. If we substitute the fracture stress (σ_f) into the left-hand side of (32.9), then the K_I value can be substituted by its critical value, which is the fracture toughness K_{IC}. Now, the fracture stress can be determined for the point ($r = 0, \theta = 0$), i. e., right under the crack tip as explained above. However, we cannot substitute $r = 0$ in (32.9). The alternative is to substitute a value for r that is as close to zero as possible. For silicon, a reasonable number is the distance between neighboring atoms in the (111) plane, the plane along which silicon exhibits the lowest fracture energy. This value was calculated from silicon unit cell dimensions of 0.5431 nm [32.88] to be 0.4 nm (half of the face diagonal). This assumes that Si displays no plastic zone around the crack tip, which is reasonable since in tension silicon is not known to display much plastic deformation at room temperature. *Sundararajan* and *Bhushan* [32.61] used values $r = 0.4–1.6$ nm (i. e., distances up to four times the distance between the nearest neighboring atoms) to estimate the fracture toughness for both Si and SiO_2 according to the following equation

$$K_{IC} = \sigma_f\sqrt{2\pi r}\,, \quad r = 0.4–1.6\,\text{nm}\,. \tag{32.10}$$

Fatigue Strength

In addition to the properties mentioned so far that can be evaluated from quasistatic bending tests, the fatigue properties of nanostructures are also of interest. This is especially true for MEMS/NEMS involving vibrating structures such as oscillators and comb drives [32.89] and hinges in digital micromirror devices [32.90]. To study the fatigue properties of the nanobeams, *Sundararajan* and *Bhushan* [32.61] applied monotonic cyclic stresses using an AFM (Fig. 32.5a). Similar to the bending test, the diamond tip is first positioned at the center of the beam span. In order to ensure that the tip is always in contact with the beam (as opposed to impacting it), the piezoelectric tube scanner is first extended by a distance D_1, which ensures a minimum stress on the beam. After this extension, a cyclic

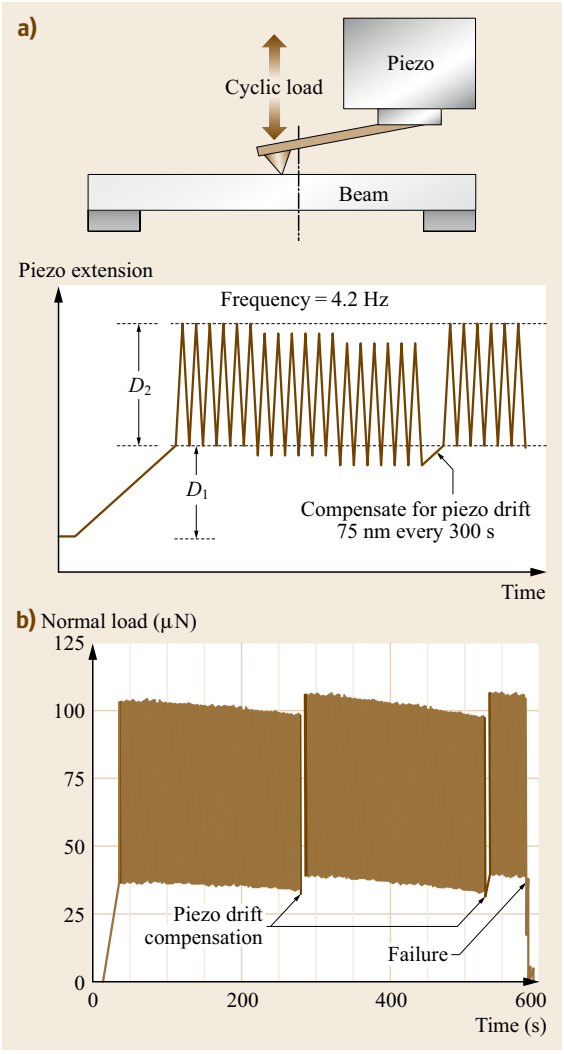

Fig. 32.5 **(a)** Schematic showing the details of the technique to study fatigue behavior of the nanobeams. The diamond tip is located at the middle of the span and a cyclic load at 4.2 Hz is applied to the beam by forcing the piezoelectric tube scanner to move in the pattern shown. An extension is made every 300 s to compensate for the piezoelectric drift, ensuring that the load on the beam is kept fairly constant. **(b)** Data from a fatigue experiment on a nanobeam until failure. The normal load is computed from the raw vertical deflection signal. The compensations for piezoelectric drift keep the load fairly constant (after [32.61])

displacement of amplitude D_2 is applied continuously until failure of the beam occurs. This results in the application of a cyclic load to the beam. The maximum frequency of the cyclic load that could be attained using the AFM by *Sundararajan* and *Bhushan* [32.61] was

4.2 Hz. The vertical deflection signal of the tip is monitored throughout the experiment. The signal follows the pattern of the piezoelectric input up to failure, which is indicated by a sudden drop in the signal. During initial runs, piezoelectric drift was observed that caused the piezoelectric tube scanner to gradually move away from the beam (i. e., to retract), resulting in a continuous decrease in the applied normal load. In order to compensate for this, the piezoelectric tube scanner is given a finite extension of 75 nm every 300 s as shown in Fig. 32.5a. This results in keeping the applied loads fairly constant. The normal load variation (calculated from the vertical deflection signal) from a fatigue test is shown in Fig. 32.5b. The cyclic stress amplitudes (corresponding to D_2) and fatigue lives are recorded for every sample tested. Values for D_1 are set such that minimum stress levels are about 20% of the bending strengths.

32.1.3 Bending Tests of Micro/Nanostructures Using a Nanoindenter

Quasistatic bending tests of micro/nanostructures in both normal and lateral directions are carried out using a nanoindenter (Fig. 32.6) [32.62–65]. The advantage of a nanoindenter is that loads up to about 400 mN, higher than that in AFM (up to about 100 μN), can be used for structures requiring high loads for experiments. Bending experiments in the normal direction have been carried out on the suspended beams using the nanoindenter fitted with a conical tip that has a 1 μm radius of curvature and a 60° included angle. Figure 32.6a shows the schematic of the beam bending experimental setup. To avoid the indenter tip pushing into the specimen, a blunt tip is used in the bending and fatigue tests. For ceramic and metallic beam samples, *Li* et al. [32.63] used a diamond conical indenter with a radius of 1 μm and an included angle of 60°. For polymer beam samples, *Wei* et al. [32.64] and *Palacio* et al. [32.65] reported that the diamond tip penetrated the polymer beams easily and caused considerable plastic deformation during the bending test, which led to significant errors in the measurements. To avoid this issue, the diamond tip was dip-coated with PMMA (about 1–2 μm thick) by dipping the tip in the 2 wt% PMMA solution for about 5 s. Load position used was at the center of the span for the bridge beams and at 10 μm off from the free end of cantilever beams. An optical microscope with a magnification of 1500× or an in situ AFM is used to locate the loading position. Then the specimen is moved under the indenter location with a resolution of about 200 nm in the longitudinal direction and less than 100 nm in the lateral direction.

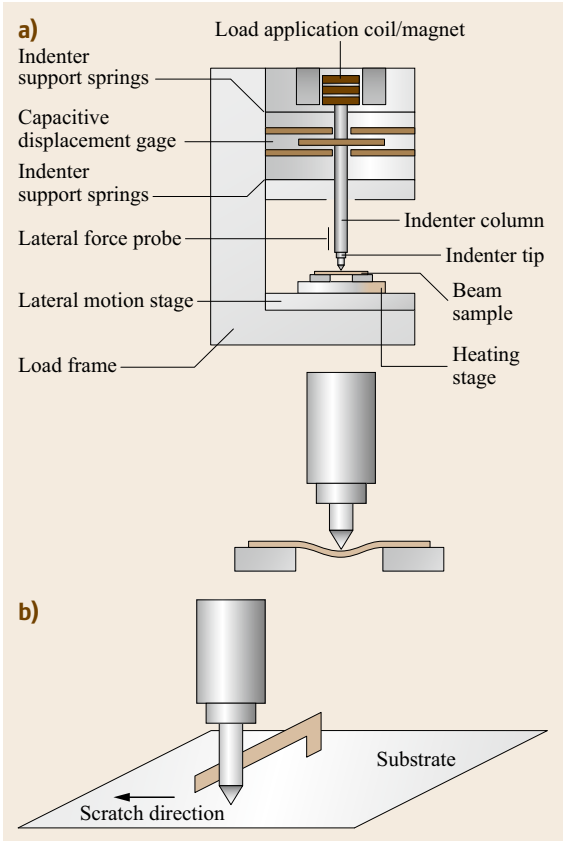

Fig. 32.6a,b Schematic of micro/nanoscale bending experimental setup using a nanoindenter **(a)** in the normal direction, and **(b)** in the lateral direction

Using the analysis presented earlier, elastic modulus and bending strength of the beams can be obtained from the load displacement curves [32.63–65]. For fatigue tests, an oscillating load is applied and contact stiffness is measured during the tests. A significant drop in the contact stiffness during the test is a measure of the number of cycles to failure [32.62].

A schematic of the lateral bending experimental setup is shown in Fig. 32.6b. The nanoindenter was fitted with a conical tip, which has a 1 μm radius of curvature and a 60° included angle. The tip was positioned at 200–300 μm away from the beam anchor and 20 μm from the edge of the beam length. The indenter was programmed to perform a scratch at a constant load of 400 μN, and the stage was moved at a rate of 10 μm/s. Since the lateral force contribution of the substrate surface is constant, any additional force recorded comes from the cantilever beam response. From the linear elastic regime in the measured lateral force as a function of lateral displacement, the elastic modulus can be evaluated. For a cantilever beam with one end clamped, it is

expressed as [32.86],

$$E = \frac{\ell^3}{3I} m \,, \tag{32.11}$$

where, as described earlier, ℓ is the beam length, I the area moment of inertia for the beam cross-section, and m is the slope of the linear region of the force displacement curve.

32.2 Experimental Results and Discussion

32.2.1 Indentation and Scratch Tests of Various Ceramic and Metals Using Micro/Nanoindenter

Studies have been conducted on six different materials: undoped single-crystal Si(100), undoped polysilicon film, SiO_2 film, SiC film, electroless deposited Ni-11.5 wt% P amorphous film, and electroplated Au film [32.63, 75, 76]. A 3 μm-thick polysilicon film was deposited by a low-pressure chemical vapor deposition (LPCVD) process on a Si(100) substrate. The 1 μm-thick SiO_2 film was deposited by a plasma-enhanced chemical vapor deposition (PECVD) process on a Si(111) substrate. A 3 μm-thick 3C-SiC film was epitaxially grown using an atmospheric-pressure chemical vapor deposition (APCVD) process on a Si(100) substrate. A 12 μm-thick Ni-P film was electroless plated on a 0.8 mm-thick Al-4.5 wt% Mg alloy substrate. A 3 μm-thick Au film was electroplated on a Si(100) substrate.

Hardness and Elastic Modulus

Hardness and elastic modulus measurements are made using a nanoindenter [32.63]. The hardness and elastic modulus values of various materials at a peak indentation depth of 50 nm are summarized in Fig. 32.7 and Table 32.1. The SiC film exhibits the highest hardness among the samples examined, of about 25 GPa, with an elastic modulus of about 395 GPa, followed by the undoped Si(100), undoped polysilicon film, SiO_2 film, Ni-P film, and Au film. The hardness and elastic modulus data of the undoped Si(100) and undoped polysilicon film are comparable. For the metal alloy films, the Ni-P film exhibits higher hardness and elastic modulus than the Au film.

Fracture Toughness

The optical images of Vickers indentations made using a microindenter at a normal load of 0.5 N held for 15 s on the undoped Si(100), undoped polysilicon film, and SiC film are shown in Fig. 32.8 [32.76]. The SiC film exhibits the smallest indentation mark, followed by the undoped polysilicon film and undoped Si(100). These Vickers indentation depths are smaller than one-third of the film thickness. Thus, the influence of substrate on the fracture toughness of the films can be ignored. In addition to the indentation marks, radial

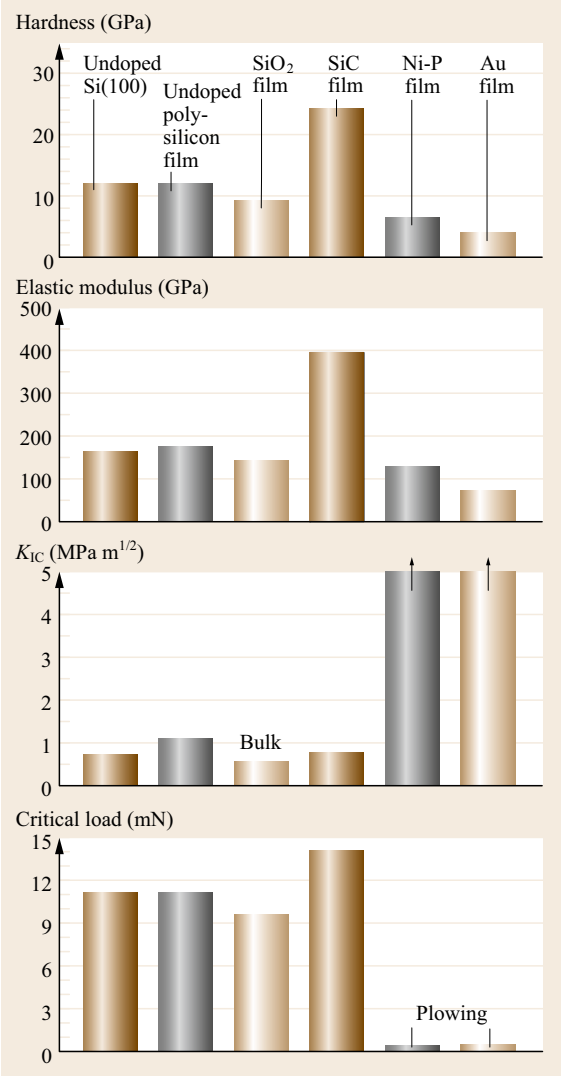

Fig. 32.7 Bar chart summarizing the hardness, elastic modulus, fracture toughness, and critical load (from scratch tests) results of the bulk undoped single-crystal Si(100) and thin films of undoped polysilicon, SiO_2, SiC, Ni-P, and Au (after [32.63])

Table 32.1 Hardness, elastic modulus, fracture toughness, and critical load results of bulk single-crystal Si(100) and thin films of undoped polysilicon, SiO_2, SiC, Ni-P, and Au

Samples	Hardness (GPa)	Elastic modulus (GPa)	Fracture toughness ($MPa\,m^{1/2}$)	Critical load (mN)
Undoped Si(100)	12	165	0.75	11
Undoped polysilicon film	12	167	1.11	11
SiO_2 film	9.5	144	0.58 (bulk)	9.5
SiC film	24.5	395	0.78	14
Ni-P film	6.5	130		0.4 (plowing)
Au film	4	72		0.4 (plowing)

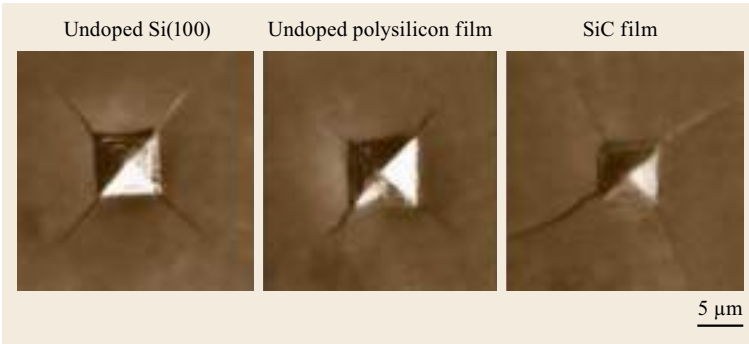

Fig. 32.8 Optical images of Vickers indentations made at a normal load of 0.5 N held for 15 s on the undoped Si(100), undoped polysilicon film, and SiC film (after [32.76])

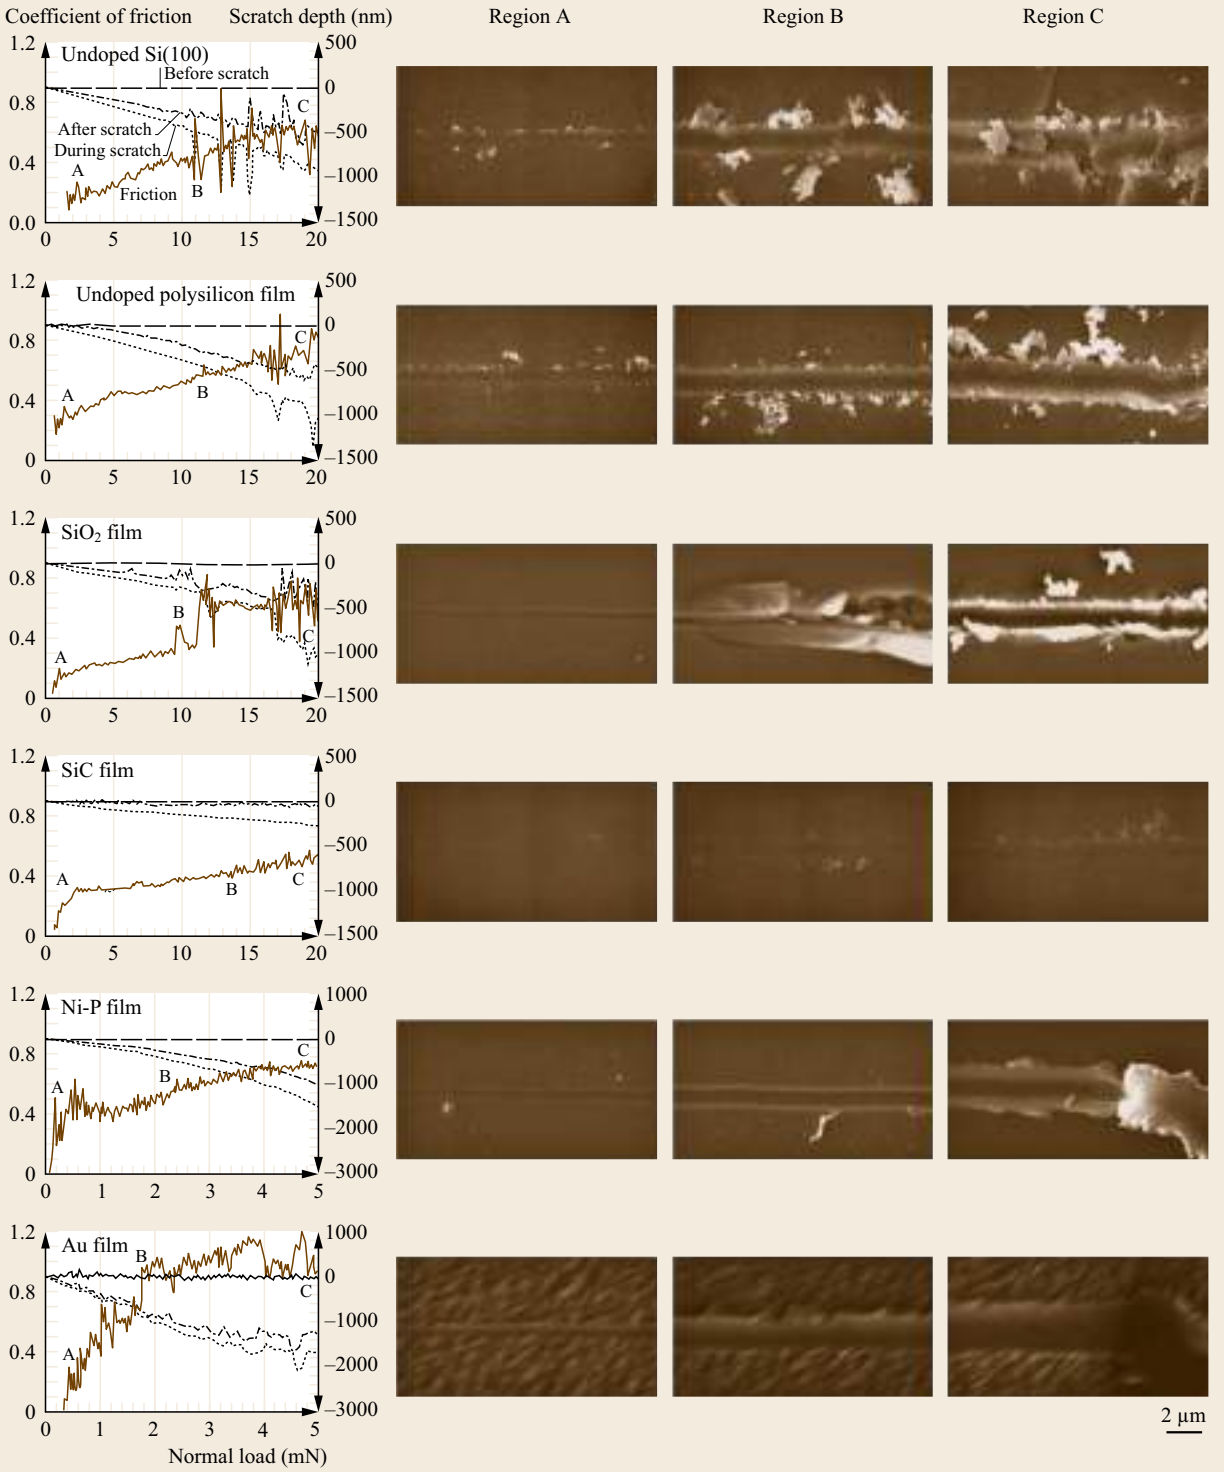

cracks are observed, emanating from the indentation corners. The SiC film shows the longest radial crack length, followed by the undoped Si(100) and undoped polysilicon film. The radial cracks for the undoped Si(100) are straight whereas those for the SiC, undoped polysilicon film are not straight but go in a zigzag manner. The fracture toughness (K_{IC}) is calculated using (32.1).

The fracture toughness values of all samples are summarized in Fig. 32.7 and Table 32.1. The SiO_2 film used in this study is about 1 μm thick, which is not thick enough for fracture toughness measurement. The fracture toughness value of bulk silica is listed instead for a reference. The Ni-P and Au films exhibit very high fracture toughness values that cannot be measured by indentation methods. For other samples, the undoped polysilicon film has the highest value, followed by the undoped Si(100), SiC film, and SiO_2 film. For the undoped polysilicon film, the grain boundaries can stop the radial cracks and change the propagation directions of the radial cracks, making the propagation of these cracks more difficult. Values of fracture toughness for the undoped Si(100) and SiC film are comparable. Since the undoped Si(100) and SiC film are single crystal, no grain boundaries are present to stop the radial cracks and change the propagation directions of the radial cracks. This is why the SiC film shows a lower fracture toughness value than the bulk polycrystal SiC materials of 3.6 $MPa\,m^{1/2}$ [32.91].

Scratch Resistance

The scratch resistance of various materials has been studied using a nanoindenter by *Li* et al. [32.63]. Figure 32.9 compares the coefficient of friction and scratch depth profiles as a function of increasing normal load and optical images of three regions over scratches: at the beginning of the scratch (indicated by A on the friction profile), at the point of initiation of damage at which the coefficient of friction increases to a high value or increases abruptly (indicated by B on the friction profile), and towards the end of the scratch (indicated by C on the friction profile) for all samples. Note that the ramp loads for the Ni-P and Au range are from 0.2 to 5 mN whereas the ramp loads for other samples are from 0.2 to 20 mN. All samples exhibit a continuous increase in the coefficient of friction with increasing normal load from the beginning of the scratch. The continuous increase in the coefficient of friction during scratching is attributed to the increasing

Fig. 32.9 Coefficient of friction and scratch depth profiles as a function of increasing normal load and optical images of three regions over scratches: at the beginning of the scratch (indicated by A on the friction profile), at the point of initiation of damage at which the coefficient of friction increases to a high value or increase abruptly (indicated by B on the friction profile), and towards the end of the scratch (indicated by C on the friction profile) for all samples (after [32.63]) ►

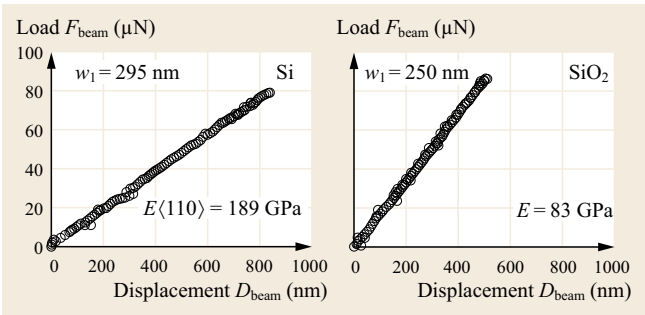

Fig. 32.11 Typical load displacement curves of silicon and SiO_2 nanobeams. The *curves* are linear until sudden failure, indicative of brittle fracture of the beams. The elastic modulus (E) values calculated from the *curves* are shown. The dimensions of the Si beam were $w_1 = 295\,\text{nm}$, $w_2 = 484\,\text{nm}$ and $t = 255\,\text{nm}$, while those of the SiO_2 beam were $w_1 = 250\,\text{nm}$, $w_2 = 560\,\text{nm}$ and $t = 425\,\text{nm}$ (after [32.85])

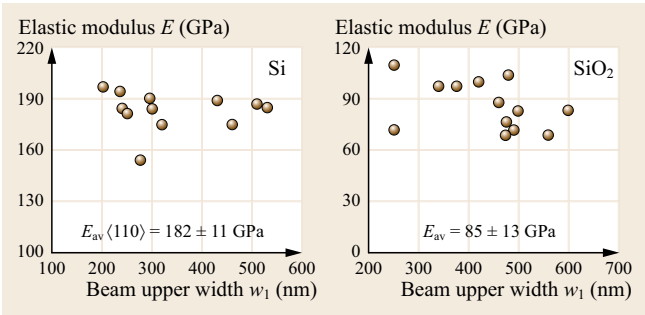

Fig. 32.12 Elastic modulus values measured for Si and SiO_2. The average values are shown. These are comparable to bulk values, which demonstrates that elastic modulus shows no specimen-size dependence (after [32.61])

plowing of the sample by the tip with increasing normal load, as shown in the scanning electron microscopy (SEM) images in Fig. 32.9. The abrupt increase in the coefficient of friction is associated with catastrophic failure as well as significant plowing of the tip into the sample. Before the critical load, the coefficient of friction of the undoped polysilicon, SiC, and SiO_2 films increased at a slower rate, and was smoother than that of the other samples. The undoped Si(100) exhibits some bursts in the friction profiles before the critical load. At the critical load, the SiC and undoped polysilicon films exhibit a small increase in the coefficient of friction whereas the undoped Si(100) and undoped polysilicon film exhibit a sudden increase in the coefficient of friction. The Ni-P and Au films show a continuous increase in the coefficient of friction, indicating the behavior of a ductile metal. The bursts in the friction profile might result from the plastic deformation and material pileup in front of the scratch tip. The Au film exhibits a higher coefficient of friction than the Ni-P film. This is because the Au film has lower hardness and elastic modulus values than the Ni-P film.

The SEM images show that below the critical loads the undoped Si(100) and undoped polysilicon film were damaged by plowing, associated with the plastic flow of the material and formation of debris on the sides of the scratch. For the SiC and SiO_2 films, in region A, a plowing scratch track was found without any debris on the side of the scratch, which is probably responsible for the smoother curve and slower increase in the coefficient of friction before the critical load. After the critical load, for the SiO_2 film, delamination of the film from the substrate occurred, followed by cracking along the scratch track. For the SiC film, only several small debris particles were found without any cracks on the side of the scratch, which is responsible for the small increase in the coefficient of friction at the critical load. For the undoped Si(100), cracks were found on the side of the scratch right from the critical load and up, which is probably responsible for the big bursts in the friction profile. For the undoped polysilicon film, no cracks were found on the side of the scratch at the critical load. This might result from grain boundaries, which can stop

Table 32.2 Summary of measured parameters from quasistatic bending tests

Sample	Elastic modulus E (GPa)		Bending strength σ_b (GPa)		Fracture toughness K_{IC} (MPa m$^{1/2}$)		
	Measured	Bulk value	Measured	Reported (microscale)	Estimated	Reported (microscale)	Bulk value
Si	182±11	169[a]	18 ± 3	< 10[c]	1.67 ± 0.4	0.6–1.65[e]	0.9[f]
SiO_2	85±13	73[b]	7.6 ± 2	< 2[d]	0.60 ± 0.2	0.5–0.9[d]	–

[a] Si[110] [32.92], [b] [32.93], [c] [32.42, 43, 45–48, 70, 94, 95], [d] [32.57], [e] [32.53–56], [f] [32.88]

the propagation of cracks. At the end of the scratch, some of the surface material was torn away and cracks were found on the side of the scratch in the undoped Si(100). A couple of small cracks were found in the undoped polysilicon and SiO_2 films. No crack was found in the SiC film. Even at the end of the scratch, less debris was found in the SiC film. A curly chip was found at the end of the scratch in both Ni-P and Au films. This is a typical characteristic of ductile metal alloys. The Ni-P and Au films were damaged by plowing right from the beginning of the scratch with material pileup at the side of the scratch.

The scratch depth profiles obtained during and after the scratch on all samples with respect to initial profile, after the cylindrical curvature is removed, are plotted in Fig. 32.9. Reduction in scratch depth is observed after scratching as compared to that of during scratching. This reduction in scratch depth is attributed to an elastic recovery after removal of the normal load. The scratch depth after scratching indicates the final depth, which reflects the extent of permanent damage and plowing of the tip into the sample surface, and is probably more relevant for visualizing the damage that can occur in real applications. For the undoped Si(100), undoped polysilicon film, and SiO_2 film, there is a large scatter in the scratch depth data after the critical loads, which is associated with the generation of cracks, material removal, and debris. The scratch depth profile is smooth for the SiC film. It is noted that the SiC film exhibits the lowest scratch depth among the samples examined. The scratch depths of the undoped Si(100), undoped polysilicon film and SiO_2 film are comparable. The Ni-P and Au films exhibit much larger scratch depth than other samples. The scratch depth of the Ni-P film is smaller than that of the Au film.

The critical loads estimated from friction profiles for all samples are compared in Fig. 32.7 and Table 32.1. The SiC film exhibits the highest critical load of about 14 mN, as compared to other samples. The undoped Si(100) and undoped polysilicon film show comparable critical load of about 11 mN whereas the SiO_2 film shows a low critical load of about 9.5 mN. The Ni-P and Au films were damaged by plowing right from the beginning of the scratch.

32.2.2 Bending Tests of Ceramic Nanobeams Using an AFM

Bending tests have been performed on Si and SiO_2 nanobeam arrays [32.61, 85]. The single-crystal silicon bridge nanobeams were fabricated by bulk micromachining incorporating enhanced-field anodization using an AFM [32.60]. The Si nanobeams are oriented along the [110] direction in the (001) plane. Subsequent thermal oxidation of the beams results in the formation of SiO_2 beams. The cross-section of the nanobeams is trapezoidal owing to the anisotropic wet etching process. SEM micrographs of Si and SiO_2 nanobeam arrays and a schematic of the shape of a typical nanobeam are shown in Fig. 32.10. The actual widths and thicknesses of nanobeams were measured using an AFM in tapping mode prior to tests using a standard Si tapping-mode tip (tip radius < 10 nm). Surface roughness measurements of the nanobeam surfaces in tapping mode yielded a σ of 0.7±0.2 nm and peak-to-valley (P–V) distance of 4±1.2 nm for Si and a σ of 0.8±0.3 nm and a P-V distance of 3.1±0.8 nm for SiO_2. Prior to testing, the Si nanobeams were cleaned by immersing them in a *piranha etch* solution (3:1 solution by volume of 98% sulphuric acid and 30% hydrogen peroxide) for ten minutes to remove any organic contaminants.

Bending Strength

Figure 32.11 shows typical load displacement curves for Si and SiO_2 beams that were bent to failure [32.61, 85]. The upper width (w_1) of the beams is indicated in the figure. Also indicated in the figure are the elastic modulus values obtained from the slope of the load displacement curve (32.5). All the beams tested showed linear elastic behavior followed by abrupt failure, which is suggestive of brittle fracture. Figure 32.12 shows the scatter in the values of elastic modulus obtained for both Si and SiO_2 along with the average values (± standard deviation). The scatter in the values may be due to differences in orientation of the beams with respect to the trench and the loading point being a little off center with respect to the beam span. The average values are a little higher than the bulk values (169 GPa for Si[110] and 73 GPa for SiO_2 in Table 32.2). However the values of E

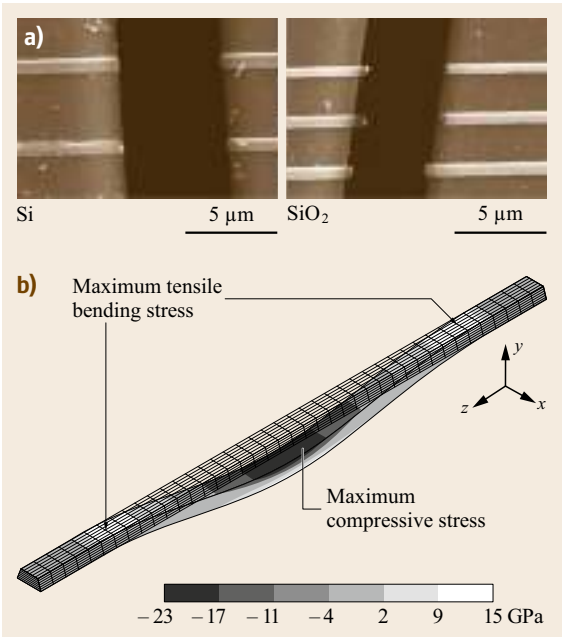

Fig. 32.13 **(a)** SEM micrographs of nanobeams that failed during quasistatic bending experiments. The beams failed at or near the ends, which is the location of maximum tensile bending stress (after [32.85]), and **(b)** bending stress distribution for silicon nanobeam indicating that the maximum tensile stresses occur on the top surfaces near the fixed ends

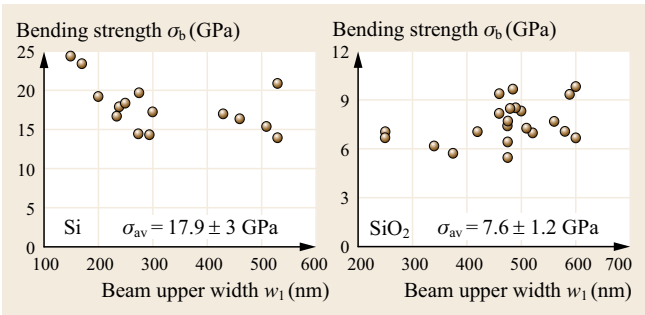

Fig. 32.14 Bending strength values obtained from bending experiments. Average values are indicated. These values are much higher than values reported for microscale specimens, indicating that bending strength shows a specimen-size effect (after [32.61])

obtained from (32.5) have an error of about 20% due to the uncertainties in beam dimensions and spring constant of the tip/cantilever (which affects the measured load). Hence the elastic modulus values on the nanoscale can be considered to be comparable to bulk values.

Most of the beams when loaded quasistatically at the center of the span broke at the ends as shown in Fig. 32.13a, which is consistent with the fact that maximum tensile stresses occur on the top surfaces near the ends. (See FEM stress distribution results in Fig. 32.13b.) Figure 32.14 shows the values of bending strength obtained for different beams. There appears to be no trend in bending strength with the upper width (w_1) of the beams. The large scatter is expected for the strength of brittle materials, since they are dependent on preexisting flaw populations in the material and hence are statistical in nature. The Weibull distribution, a statistical analysis, can be used to describe the scatter in the bending strength values. The means of the Weibull distributions were found to be 17.9 and 7.6 GPa for Si and SiO_2 respectively. Previously reported numbers of strengths range from 1–6 GPa for silicon [32.42, 43, 45–48, 50, 70, 94, 95] and about 1 GPa for SiO_2 [32.57] microscale specimens. This clearly indicates that bending strength shows a specimen-size dependence. Strength of brittle materials is dependent on preexisting flaws in the material. Since for nanoscale specimens the volume is smaller than for micro- and macroscale specimens, the flaw population will be smaller as well, resulting in higher values of strength.

Fracture Toughness

Estimates of fracture toughness calculated using (32.10) for Si and SiO_2 are shown in Fig. 32.15 [32.61]. The results show that the K_{IC} estimate for Si is about 1–2 MPa $m^{1/2}$, whereas for SiO_2 the estimate is about 0.5–0.9 MPa $m^{1/2}$. These values are comparable to values reported by others on larger specimens for Si [32.53–56] and SiO_2 [32.57]. The high values obtained for Si could be due to the fact that the scratches, despite being quite sharp, still have a finite radius of about 100 nm. The bulk value for silicon is about 0.9 MPa $m^{1/2}$ (Table 32.2). Fracture toughness is considered to be a material property and is believed to be independent of specimen size. The values obtained in this study, given its limitations, appear to show that fracture toughness is comparable, if not a little higher on the nanoscale.

Fatigue Strength

Fatigue strength measurements of Si nanobeams have been carried out by *Sundararajan* and *Bhushan* [32.61] using an AFM and *Li* and *Bhushan* [32.62] using a nanoindenter. Various stress levels were applied to nanobeams by *Sundararajan* and *Bhushan* [32.61]. The minimum stress was 3.5 GPa for Si beams and 2.2 GPa for SiO_2 beams. The frequency of applied load was 4.2 Hz. In general, the fatigue life decreased with increasing mean stress as well as increasing stress amplitude. When the stress amplitude was less than 15% of the bending strength, the fatigue life was greater than 30 000 cycles for both Si and SiO_2. However, the mean

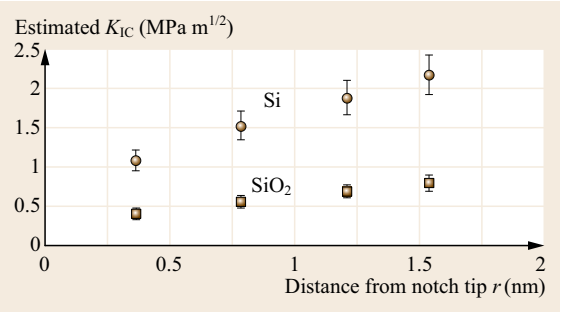

Fig. 32.15 Fracture toughness (K_{IC}) values for increasing values of r corresponding to distance between neighboring atoms in {111} planes of silicon (0.4 nm). Hence r values between 0.4 and 1.6 nm are chosen. The K_{IC} values thus estimated are comparable to values reported by others for both Si and SiO_2 (after [32.61])

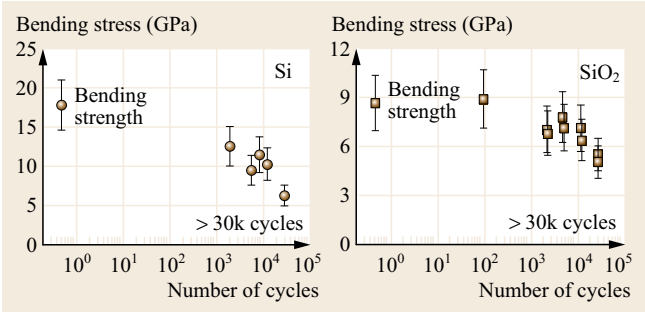

Fig. 32.16 Fatigue test data showing applied bending stress as a function of number of cycles. A single load-unload sequence is considered as one cycle. The bending strength data points are therefore associated with 1/2 cycle, since failure occurs upon loading (after [32.61])

stress had to be less than 30% of the bending strength for a life of greater than 30 000 cycles for Si whereas even at a mean stress of 43% of the bending strength, SiO_2 beams showed a life greater than 30 000 cycles. During fatigue, the beams broke under the loading point or at the ends when loaded at the center of the span. This was different from the quasistatic bending tests, where the beams broke at the ends almost every time. This could be due to the fact that the stress levels under the load and at the ends are not that different and fatigue crack propagation could occur at either location. Figure 32.16 shows a nanoscale *S–N* curve, with bending stress (*S*) as a function of fatigue in number of cycles (*N*) with an apparent endurance life at lower stress. This study clearly demonstrates that fatigue properties of nanoscale specimens can be studied.

SEM Observations of Fracture Surfaces

Figure 32.17 shows SEM images of the fracture surfaces of nanobeams broken during quasistatic bending as well as fatigue [32.61]. In the quasistatic cases, the maximum tensile stresses occur on the top surface, so it is reasonable to assume that fracture initiated at or near the top surface and propagated downward. The fracture surfaces of the beams suggest a cleavage type of fracture. Silicon beam surfaces show various ledges or facets, which is typical for crystalline brittle materials. Silicon usually fractures along the (111) plane due to this plane having the lowest surface energy to overcome by a propagating crack. However, failure has also been known to occur along the (110) planes in microscale specimens, despite the higher energy required as compared to the (111) planes [32.70]. The plane normal to the beam direction in these samples is the (110) plane while (111) planes will be oriented at 35° from the (110) plane. The presence of facets and irregularities on the silicon surface in Fig. 32.17a suggest that it is a combination of these two types of fractures that has occurred. Since the stress levels are very high for these specimens, it is reasonable to assume that crack-propagating forces will be high enough to result in (110)-type failures.

In contrast, the silicon fracture surfaces under fatigue, shown in Fig. 32.17b, appear very smooth without facets or irregularities. This is suggestive of low energy fracture, i. e., of (111)-type fracture. We do not see evidence of fatigue crack propagation in the form of steps or striations on the fracture surface. We believe that for the stress levels applied in these fatigue experiments, failure in silicon occurred via cleavage associated with *static fatigue* type of failures.

SiO_2 shows very smooth fracture surfaces for both quasistatic bending and fatigue. This is in contrast to the irregular surface one might expect for the brittle failure of an amorphous material on the macroscale. However, in larger-scale fracture surfaces for such materials, the region near the crack initiation usually appears smooth or mirror-like. Since the fracture surface here is so small and very near the crack initiation site, it is not unreasonable to see such a smooth surface for SiO_2 on this scale. There appears to be no difference between the fracture surfaces obtained by quasistatic bending and fatigue for SiO_2.

Summary of Mechanical Properties Measured Using Quasistatic Bending Tests

Table 32.2 summarizes the various properties measured via quasistatic bending in this study [32.61]. Also shown are bulk values of the parameters along with values reported on larger-scale specimens by other researchers. Elastic modulus and fracture toughness values appear to be comparable to bulk values and show no dependence on specimen size. However, bending

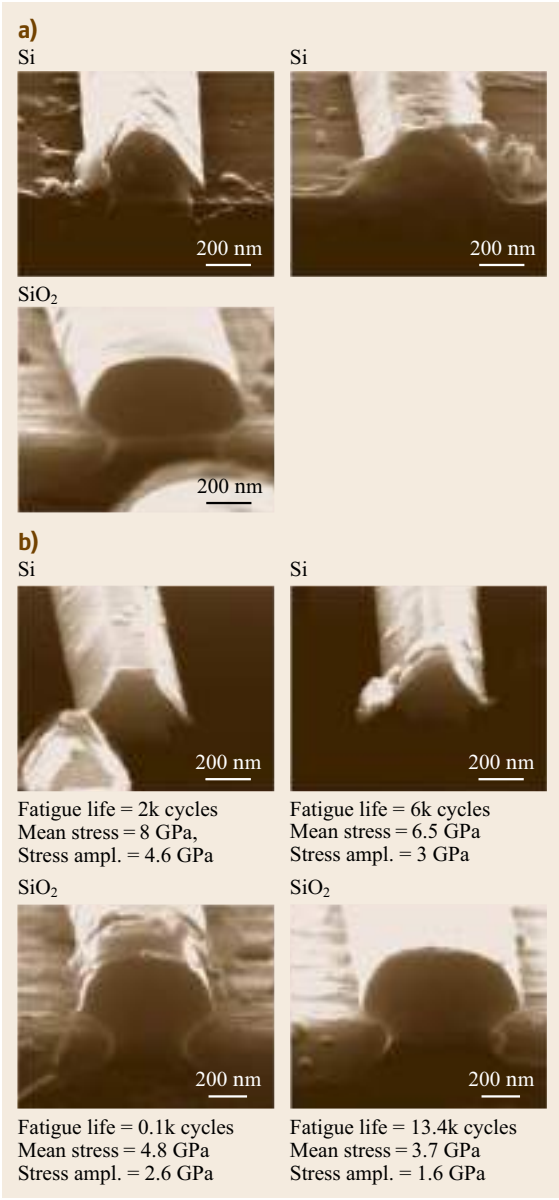

Fig. 32.17a,b SEM micrographs of fracture surfaces of silicon and SiO_2 beams subjected to **(a)** quasistatic bending and **(b)** fatigue (after [32.61])

strength shows a clear specimen-size dependence with nanoscale numbers being twice as large as numbers reported for larger-scale specimens.

32.2.3 Bending Tests of Metallic Microbeams Using a Nanoindenter

Bending tests have been performed on Ni-P and Au microbeams [32.63]. The Ni-P cantilever microbeams were fabricated by a focused ion beam machining technique. The dimensions were $10 \times 12 \times 50\,\mu m^3$. Notches with a depth of $3\,\mu m$ and a tip radius of $0.25\,\mu m$ were introduced in the microbeams to facilitate failure at a lower load in the bending tests. The Au bridge microbeams were fabricated by an electroplating technique.

Figure 32.18 shows the SEM images, load displacement curve, and FEM stress contour for the notched Ni-P cantilever microbeam that was bent to failure [32.63]. The distance between the loading position and the fixed end is $40\,\mu m$. The $3\,\mu m$ deep notch is $10\,\mu m$ from the fixed end. The notched beam showed linear behavior followed by abrupt failure. The FEM stress contour shows that there is a higher stress concentration at the notch tip. The maximum tensile stress σ_m at the notch tip can be analyzed by using the Griffith fracture theory as follows [32.84],

$$\sigma_m \approx 2\sigma_o \left(\frac{c}{\rho}\right)^{1/2} , \qquad (32.12)$$

where σ_o is the average applied tensile stress on the beam, c is the crack length, and ρ is the crack tip radius. Therefore, elastic-plastic deformation will first occur locally at the end of the notch tip, followed by abrupt fracture failure after σ_m reaches the ultimate tensile strength of Ni-P, even though the rest of the beam is still in the elastic regime. The SEM image of the fracture surface shows that the fracture started right from the notch tip with plastic deformation characteristics. This indicates that although local plastic deformation occurred at the notch tip area, the whole beam failed catastrophically. The present study shows that FEM simulation can predict well the stress concentration, and helps in understanding the failure mechanism of the notched beams.

Figure 32.19 shows the SEM images, load displacement curve, and FEM stress contour for the Au bridge microbeam that was deformed by the indenter [32.63]. The recession gap between the beam and substrate is about $7\,\mu m$, which is not large enough to break the beam at the load applied. From the load-displacement curve, we note that the beam experienced elastic-plastic deformation. The FEM stress contour shows that the maximum tensile stress is located at the fixed ends whereas the minimum compressive stress is located around the center of the beam. The SEM image shows that the beam has been permanently deformed. No crack was found on the beam surface. The present study shows a possibility for mechanically forming the Au film into the shape as needed. This may help in designing/fabricating functionally complex smart micro/nanodevices that need conductors for power supply and input/output signals.

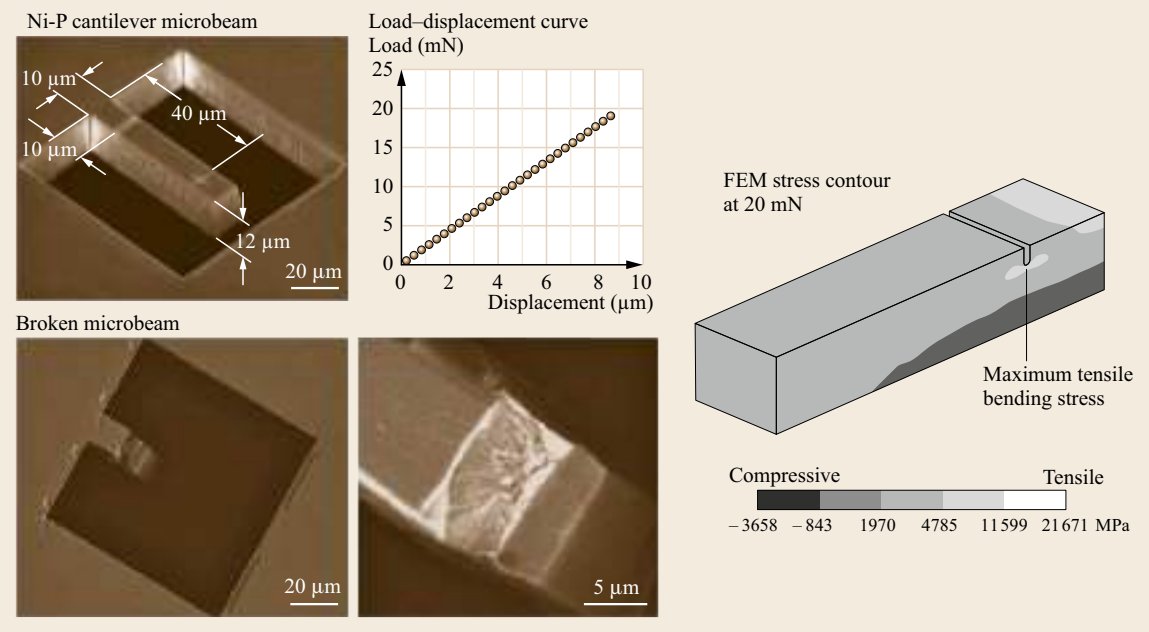

Fig. 32.18 SEM micrographs of the new and broken beams, load displacement curve and FEM stress contour for the notched Ni-P cantilever microbeam (after [32.63])

32.2.4 Indentation and Scratch Tests of Polymeric Microbeams Using a Nanoindenter

Four potential structural materials for BioMEMS devices were selected for this study, namely poly(propyl methacrylate) (PPMA), poly(methyl methacrylate) (PMMA), polystyrene (PS) and a polystyrene-nanoclay composite (PS/clay) [32.65]. The physical properties of PPMA, PMMA and PS are summarized in Table 32.3. PMMA and PS are widely used engineering polymers for a number of commercial applications. Historically, PMMA was the polymer of choice in ophthalmologic devices due to its high refractive index, hardness, and biocompatibility. Its surface can be functionalized with proteins, which promotes the bonding of tissues for in vivo implants [32.96]. PMMA is also employed in chips and valve components for immunosensors and other lab-on-a-chip applications [32.26, 97]. PPMA has a lower glass transition temperature (T_g) (35–43 °C) [32.80] than PMMA (104–106 °C) [32.81, 82], which allows for easier processing at a lower temperature.

Polystyrene is particularly desirable for BioMEMS due to its ubiquitous use in tissue culture applications. Plasma-treated polystyrene is the most commonly used material for in vitro cell biology studies of adherent cells. Thus, there is a wealth of knowledge about cellular behavior on polystyrene. In addition to tissue culture polystyrene, various surface modification techniques can be employed for functionalizing the PS surface in order to promote cell attachment and proliferation [32.96]. Oxygen plasma-modified polystyrene has been shown to improve cell growth, proliferation, and

Table 32.3 Summary of the physical properties of PPMA, PMMA and PS

	Structure	Density (g/cm^3)	T_g (°C)	Water absorption after 24 h (%)	Thermal expansion coefficient (K^{-1})	Thermal conductivity (0–50 °C) (W/(m K))	Heat capacity (0–100 °C) (kJ/(kg K))
PPMA		–	35–43[a]	–	–	–	–
PMMA		1.188[b]	104–106[b,c]	0.3–0.4[d] 0.1–0.3[e]	$2.0–3.0\times10^{-4}$ [c] ($< T_g$) 6.0×10^{-4} [c] ($> T_g$)	0.193[b]	1.255–1.720[b]
PS		1.040–1.065[c] (amorphous) 1.111–1.127[c] (crystalline)	100[b,c]	0.03–0.1[d]	$1.7–2.1\times10^{-4}$ [c] ($< T_g$) $5.1–6.0\times10^{-4}$ [c] ($> T_g$)	0.105–0.116[b]	1.185–1.838[b]

[a] [32.80], [b] [32.81], [c] [32.82], [d] [32.98], [e] [32.99]

expression of cellular adhesion protein proportional to the surface oxygen concentration [32.100]. The previous knowledge of cellular interactions with polystyrene makes it a logical choice to use in BioMEMS devices for cellular interactions.

Clay nanoparticles in a polymer matrix act to improve the mechanical and thermal properties as compared to the native polymer [32.101, 102]. Nanoclay composites can also be used to improve barrier resistance and improve ionic conductivity. The extent to which polymer properties are affected is determined by the clay content, polymer/clay interfacial strength, and dispersion of the clay particles. The fabrication procedure for the double-anchored and cantilever beams is presented in Appendix 32.A. SEM images of the two types of beams are shown in Fig. 32.20.

The hardness (H), elastic modulus (E) and creep of the beams were measured at the supported region of the beams [32.64, 65]. The indentation location, where the H, E and creep were measured, is indicated by an arrow in Fig. 32.20a.

Since the fabricated polymer beams were too narrow (width about 5 µm) to perform nanoscratch tests, the nanoscratch experiments were conducted on thin films of polymeric materials. PPMA, PMMA, PS and PS/clay were dissolved in anisole at various concentrations and spin coated for 1 min at 3000 RPM to achieve the desired film thickness of 500 nm. All film samples were then baked at 95 °C for 2 min to remove any residual solvent.

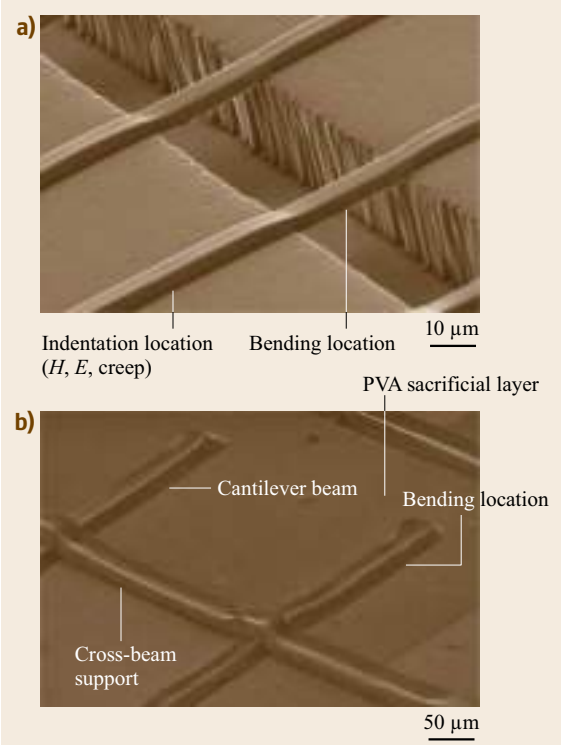

Fig. 32.20 SEM images of polystyrene **(a)** double-anchored beams, and **(b)** cantilever beams (after [32.65])

Hardness and Elastic Modulus

Figure 32.21a shows the H and E of various beams as a function of contact depth [32.65]. Five beams in one wafer sample were indented once, and the average values of H and E at a contact depth of 100 nm are reported in Table 32.4. Among the materials examined, the PS/clay nanocomposite exhibited the highest hardness and elastic modulus (of 390±50 MPa and 5.1±0.4 GPa

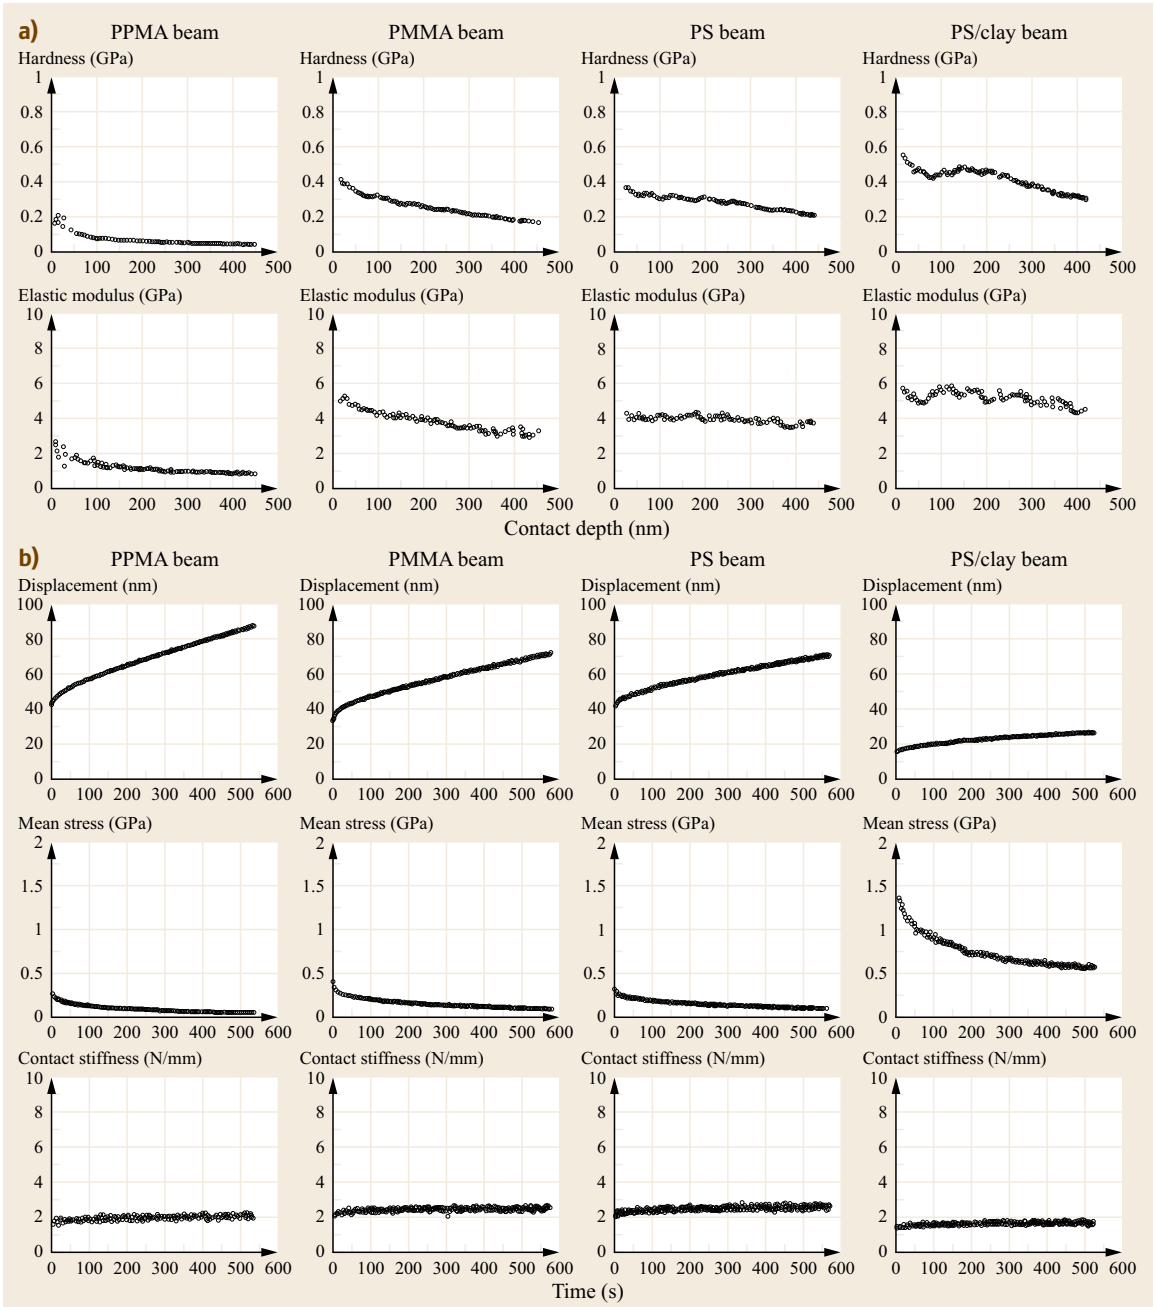

Fig. 32.21 **(a)** Hardness and elastic modulus of PPMA, PMMA, PS and PS/clay beams as a function of contact depth, **(b)** creep displacement, mean stress and contact stiffness as a function of time for PPMA, PMMA, PS and PS/clay, and **(c)** scratch depth profiles and coefficient of friction as a function of increasing normal loads for thin films of PPMA, PMMA, PS and PS/clay. SEM images were taken at three regions: at the beginning of the scratch (A), in the middle of the scratch (B) and at the end of the scratch (C) (after [32.65])

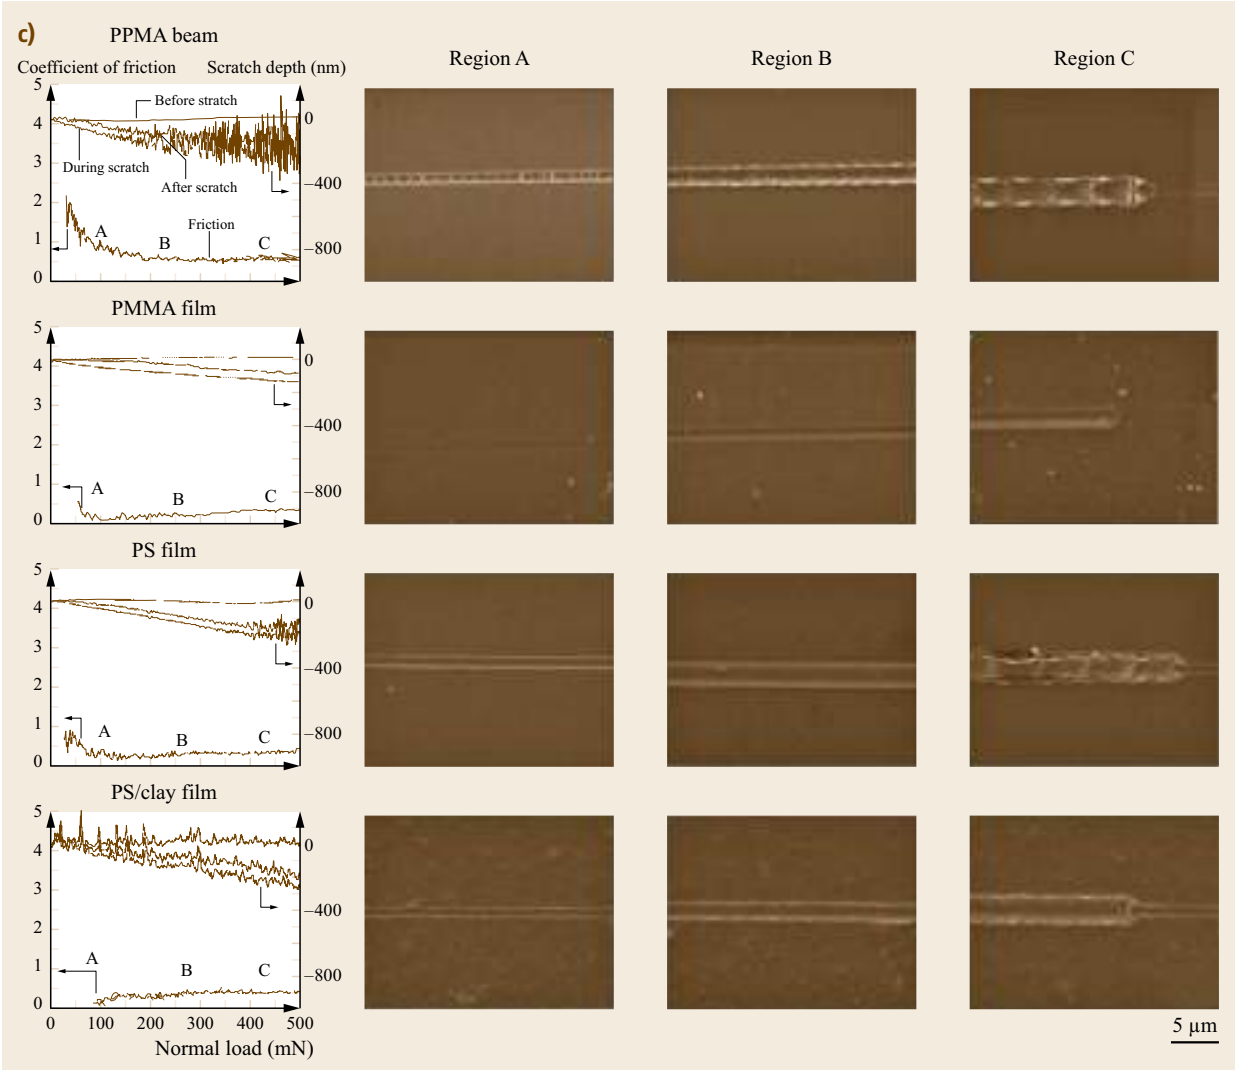

Fig. 32.21 (continued)

respectively), followed by PMMA (340±30 MPa, 4.8±0.5 GPa), PS (290±20 MPa, 3.6±0.4 GPa) and PPMA (110±30 MPa, 1.7±0.5 GPa). The standard deviation was calculated from the five indents performed.

Indentation Creep

Creep is an important aspect of polymer mechanical behavior. Figure 32.21b shows representative creep data for the supported polymer beams using CSM indentation, where the change in displacement, mean stress and contact stiffness was monitored while holding the tip at the maximum imposed load [32.65]. Conclusions on the creep response of the materials are based mainly on the displacement change at constant loading, which is directly measured in the experiment. For each material, three beams on one sample were tested, and it was found that the variation in creep response was no more than 15%. As expected for polymers, the indentation displacement increases with time. The material with the lowest hardness and modulus (PPMA) exhibited the fastest rate of displacement change (i. e., mostly creep), while the PS/clay nanocomposite (which has the highest H and E value) showed minimal creep. This shows a direct correlation between the hardness, modulus, and creep resistance. The mean stress exerted by the tip decreases with time as the polymer deforms viscoelastically underneath the tip during the hold segment. For the PS/clay nanocomposite, it is observed that this quantity decreases more rapidly during the first few seconds of the measurement compared to the other ma-

terials. This could be attributed to the presence of an additional phase (the clay filler). The filler-matrix interface could exhibit yield without necessarily causing further penetration into the material.

Scratch Resistance

The scratch behavior of thin films of the four polymers studied is presented in Fig. 32.21c. Plots on the left side show the depth profile before, during, and after a scratch, along with the coefficient of friction. SEM images were taken at three areas: at the beginning of the scratch (indicated by A on the friction profile), middle of the scratch (B) and towards the end of the scratch (C). Among the three homogeneous films, PMMA had the greatest scratch resistance as it exhibited the least penetration as well as the absence of bursts in the scratch depth profile. PMMA is followed by PS, then PPMA. This order is consistent with the observed trend for the elastic modulus and hardness. The features in the scratch depth profiles can be correlated to the morphology of the scratches. In the PPMA depth profile, the tip jumped up and down during the scratch instead of continuously ramping down. This is accounted for by the SEM images, which reveal deformation bands that are convex with respect to the scratch direction. The bands indicate plastic deformation and material pileup in front of the tip. In PS, the oscillation in the depth profile occurs only towards the end of the scratch, and the deformation bands are observed only in Region C. For PMMA, the smooth depth profile corresponds to a clear scratch track, indicating that minimal pileup occurred. The nanocomposite exhibits enhanced scratch resistance relative to the unfilled PS. The peaks and valleys in the depth profile come from the roughness of the surface and not from scratch-induced material displacement, which is confirmed from the SEM images.

32.2.5 Bending Tests of Polymeric Microbeams Using a Nanoindenter

Suspended Beams

For each material, five suspended beams in one sample were measured, and representative load-displacement data are presented in Fig. 32.22. In this case, the displacement is due to beam bending. The loading profile can be fit into a straight line, indicating that bending at this load range is fully elastic. From the slope of this line and (32.5), the calculated elastic moduli are 0.7±0.2, 1.9±0.3, 1.9±0.1 and 4.6±0.3 GPa for PPMA, PMMA, PS and PS/clay respectively. The standard deviation was based on five measurements.

The elastic moduli from beam bending are compared to values from nanoindentation and the available

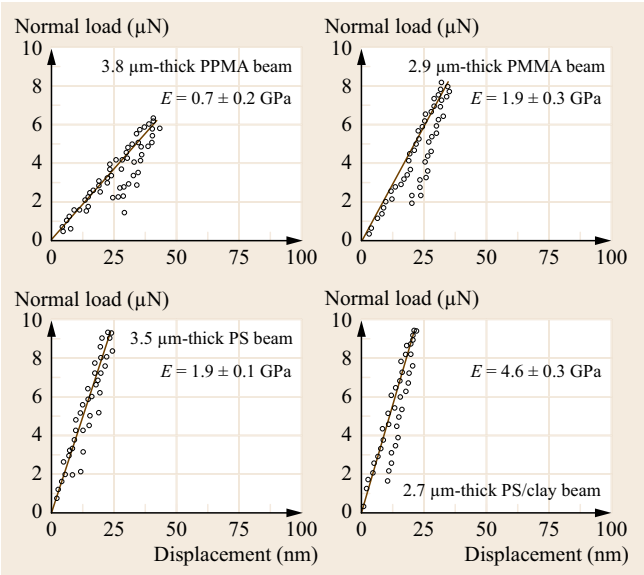

Fig. 32.22 Normal beam bending results for PPMA, PMMA, PS and PS/clay at a maximum load of 10 μN (after [32.65])

bulk literature values. The consistency in the obtained trend in E for the four materials using the three methods provides validation for the beam bending technique. In addition, the beam bending method has been successfully employed on various metal and ceramic materials, as presented earlier [32.63]. The slightly lower elastic moduli calculated from beam bending tests (relative to nanoindentation and bulk literature data) can be attributed to several reasons. Some deformation may have occurred in the boundary between the supported and the suspended region of the beam due to stress concentration at this junction. A small amount of plastic deformation of the beam surface may occur even though the indenter tip was coated with PMMA. This could reduce the slope of the loading curve.

Effect of Soaking and Temperature. The effects of aqueous medium and human body temperature (37.5 °C) were investigated on both the suspended and supported beams. Figure 32.23a is a summary of the effects of beam soaking and elevated temperature on the hardness and elastic modulus as obtained by nanoindentation on the supported part of the beam. Among the four materials studied, soaking had the greatest effect on PPMA. On the other hand, the H and E of the other materials (PMMA, PS and PS/clay) were not significantly affected. The properties of the PPMA beam were adversely affected when the indentation temperature was increased to 37.5 °C. This is because the glass transition temperature (T_g) of PPMA is within 35–43 °C [32.80], such that the glassy to rubbery tran-

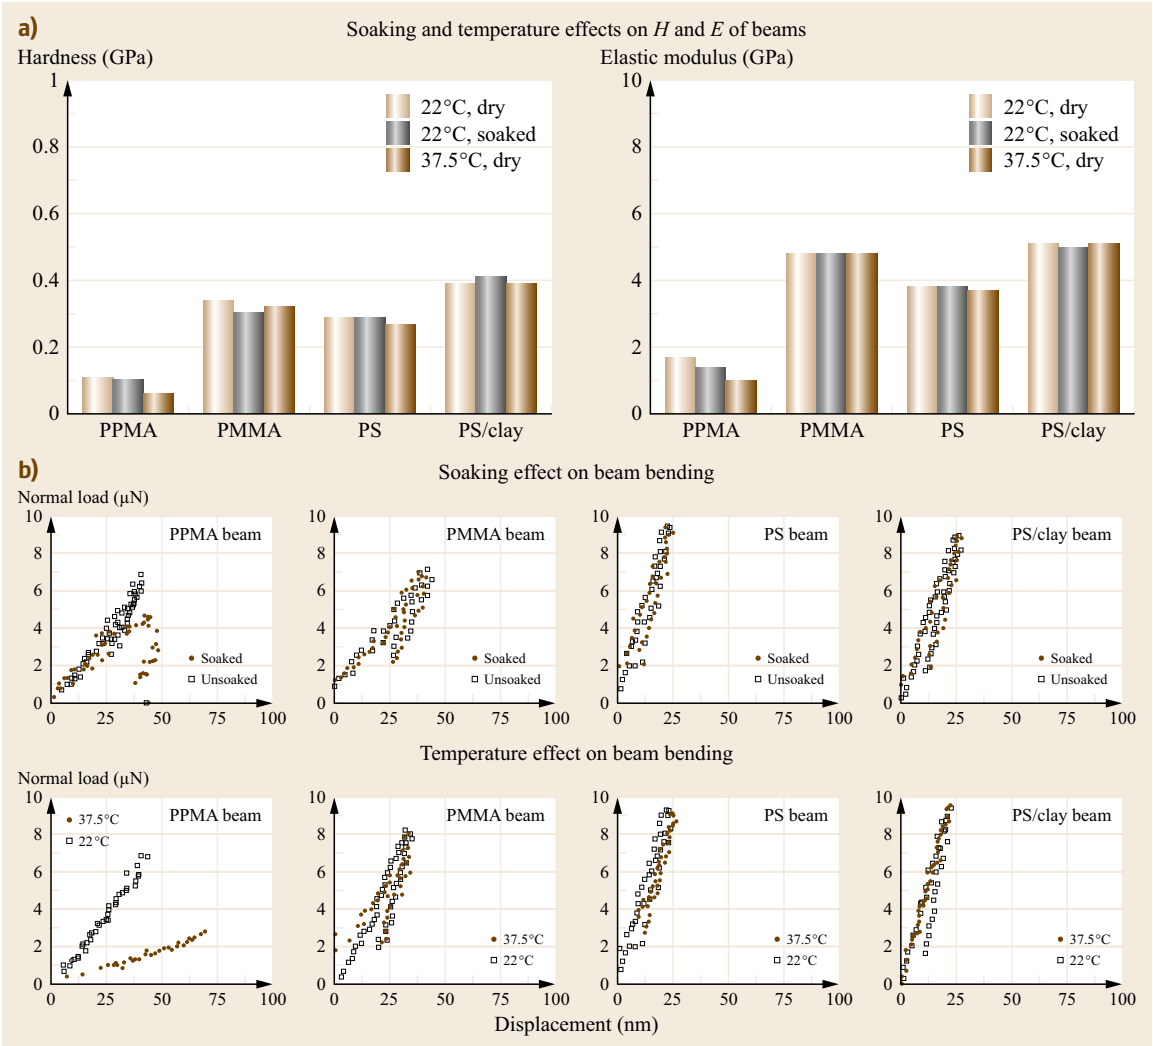

Fig. 32.23 **(a)** Effect of soaking and elevated temperature on suspended beams and **(b)** effect of soaking and elevated temperature on the hardness and elastic modulus of supported beams (after [32.65])

sition is being observed here. On the other hand, no significant decrease in H and E was observed on the other three materials since their values of T_g are much higher, such that the indent was performed well within the glassy regime.

In Fig. 32.23b, beam bending data are shown for each of the four polymers investigated. The PPMA beam is affected by soaking in deionized (DI) water, as shown by the appearance of a large amount of hysteresis in the load-displacement data. Human body temperature has an adverse effect on the stiffness of the PPMA beam. These are consistent with results from indentation. From a materials selection standpoint, these are important findings as they imply that the performance of PPMA structures would be compromised if they were in a device subjected to either soaking in an aqueous medium or above ambient temperatures.

Normal Beam Bending at Elevated Loads. Bending experiments were performed with applied loads in the millinewton range in order to investigate the behavior of polymer beams beyond the elastic deformation regime. The upper half of Fig. 32.24 shows normal load-displacement profiles at maximum imposed loads of 0.5, 1.5 and 3.0 mN applied on three different beams in one wafer sample. For PPMA, PMMA and PS, the loading portion overlaps, indicating uniform beam quality. Slight variability in the loading profile is observed in the PS/clay composite, which is attributed to variable

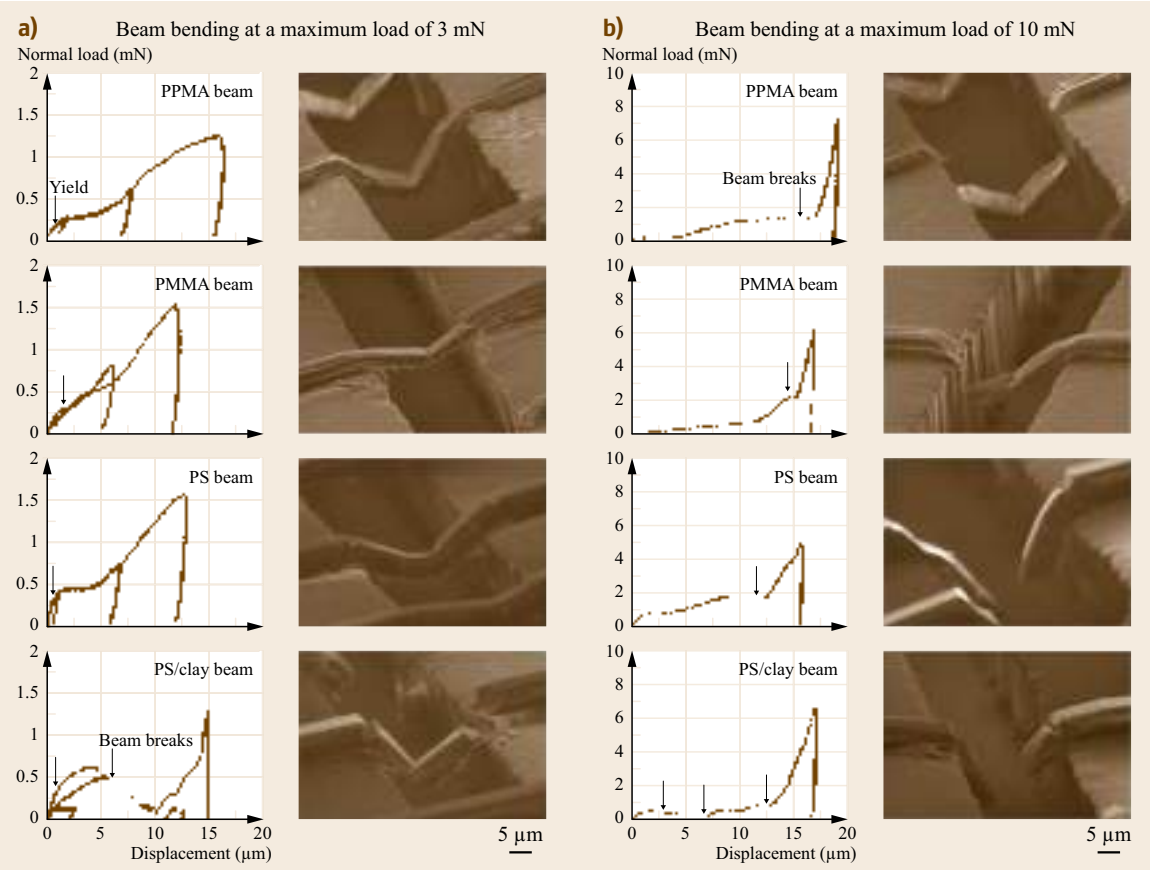

Fig. 32.24a,b Normal beam bending at elevated loads. **(a)** Normal load-displacement profiles at a maximum load of 0.5, 1.5 and 3.0 mN, *arrows* indicate the onset of yield and breaking of the beams. For plots with multiple profiles **(a)**, the SEM image corresponds to the beam subjected to the highest load (3 mN). **(b)** Normal load-displacement profiles and SEM images for beams subjected to 10 mN maximum load (after [32.65])

interfacial adhesion between the filler and the matrix and inhomogeneities in the dispersion of the clay particles.

The first inflection in the load-displacement profiles implies the onset of yield, and its location is indicated by arrows. The three unfilled polymers (PPMA, PMMA and PS) exhibit ductility, as seen in the SEM images for the beams tested with an applied load of 3 mN. The beams stretch at the ends and underneath the center of the beam. These correspond to regions subjected to maximum tensile stress [32.63]. It is worth noting that the beams deformed symmetrically, indicating that the load was applied equidistant from the clamping points. The PS/clay nanocomposite beam exhibited slight yielding, followed by breaking, as indicated by an arrow in the load-displacement profile. After breaking, the load continued to increase because a predefined load is imposed by the nanoindenter. The corresponding SEM image for PS/clay shows a flat fracture surface, indicating that the crack propagated perpendicular to the direction of the applied stress.

From the load-displacement curves, the yield strength was evaluated using the following equation [32.86]

$$\sigma = \frac{3}{4}\frac{Fl}{bh^2}\,, \tag{32.13}$$

where F is the load corresponding to yield of the beam (as indicated by arrows in the load–displacement profile), and l, b and h are the beam's length, width and height respectively. It is assumed that the beam ends are clamped. The yield strength values listed in Table 32.4 are in the same order of magnitude as the bulk yield strength data in the literature.

Bending data at a maximum load of 10 mN are shown in the lower half of Fig. 32.24. As with the bending tests performed at 3 mN, symmetric deformation and failure is observed in the beams. The three unfilled

[a] [32.99], [b] [32.103], [c] [32.81], [d] [32.82], [e] [32.104], [f] Values may be an overestimate due to limitations of the technique and the geometry of the beams

polymers stretched considerably prior to fracture, and the PS/clay nanocomposite beam exhibited brittle failure as observed in the lower-load experiment.

For brittle materials, the elastic regime is immediately followed by breaking, and the breaking strength can be evaluated using (32.13). Even though plastic deformation was observed in all materials, (32.13) was assumed valid, and the force corresponding to breaking is taken as the load observed prior to the abrupt jump in displacement. The calculated breaking strength (as shown in Table 32.4) is higher and does not appear to correlate with the trends observed for the other mechanical properties reported. This can be attributed to a number of reasons. The load-displacement response may not purely be from beam bending. A higher load can be imposed without beam breaking due to plastic deformation on the beam surface. At elevated loads, a larger contact area between the tip and beam is expected such that permanent deformation on the surface can be significant. In addition, the compliant trench material (SU-8) can help to accommodate a higher stress prior to breaking of the beam.

Lateral Bending of the Cantilever Beams

Figure 32.25 presents the results of the lateral bending experiments on PS and PS/clay cantilever beams. In the left column are the plots for the lateral force recorded as a function of the lateral displacement. From the linear elastic regime (as indicated by the straight line drawn through the data points), the modulus can be evaluated using (32.11). The resulting elastic modulus of PS/clay is three times that of PS, as shown in Table 32.4. This was obtained from measurements on two beams for each material. However, the elastic modulus values obtained from this experiment are lower than those obtained from nanoindentation and beam bending in the normal direction. This is attributed to the applied pressure coming from the addition of the crossbeam reinforcement, inducing deformation on the anchor. In addition, a small curvature is observed on the beam. This diminishes the beam width, which is the dominant term in the equation for evaluating the modulus ((32.5) and (32.11)).

From the load-displacement curves, the yield strength was evaluated using [32.86]

$$\sigma = \frac{6Fl}{bh^2}\,, \tag{32.14}$$

where F, l, b and h are defined similarly as in (32.13). The force used for calculating the yield strength was taken at the point where a change in slope was observed (as indicated by the arrows on the left). The results are listed in Table 32.4. They are lower than the values obtained from normal bending, and this could be attributed to the same causes mentioned above.

For PS, a steady decrease in the lateral load was observed at 160 μm, while for the PS/clay beam, the drop at 80 μm was abrupt (as indicated by the arrows on the right). SEM images reveal that for PS, this corresponds to crack formation at the base of the beam that did not run throughout the entire thickness of the beam. However, for PS/clay, the beam broke. This implies that the addition of the nanoclay filler induces embrittlement of the beam.

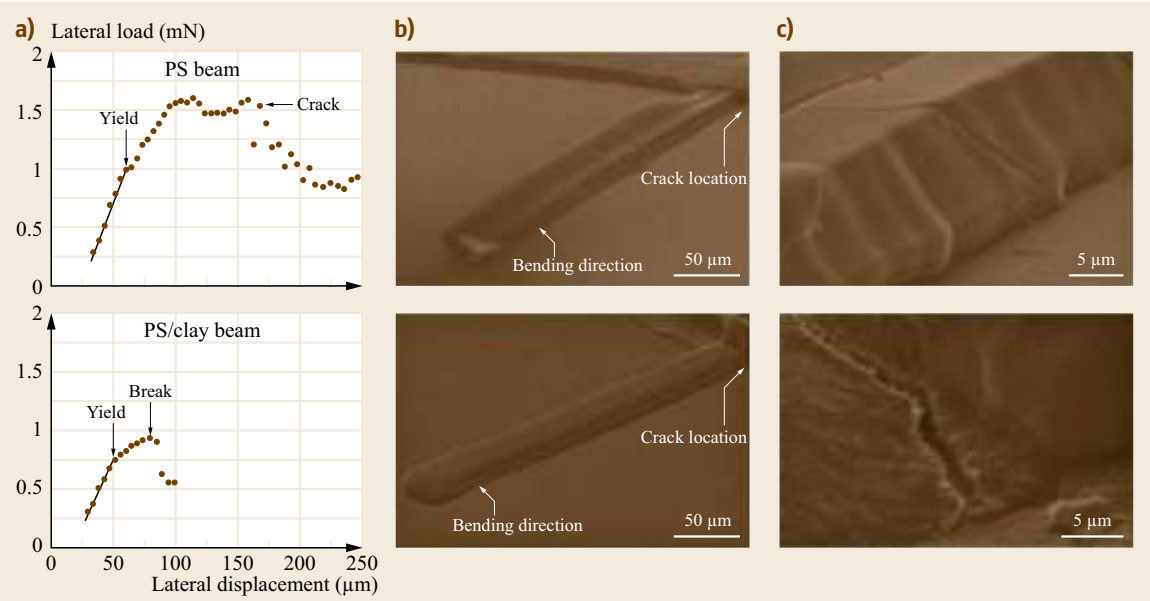

Fig. 32.25a–c Lateral bending of PS and PS/clay cantilever beams. **(a)** Lateral force plotted as a function of the lateral displacement; *arrows* indicate the onset of yield for both PS and PS/clay, cracking for PS and breaking for PS/clay. **(b)** SEM images of the cantilever beams indicate the bending direction and the location of the cracks. The images in **(c)** show the cracks at a higher magnification (after [32.65])

Equation (32.14) is assumed valid for evaluating the breaking strength of this beam. The force used in the calculation was the load prior to the abrupt decrease. The breaking strength for PS/clay obtained from this technique (listed in Table 32.4) is lower than the value from the normal bending experiment. This is possibly due to the beam geometry and processing conditions, as described earlier. However, the large difference in the calculated yield strength between the unfilled and filled PS demonstrates that the technique can adequately differentiate between material compositions.

32.3 Finite Element Analysis of Nanostructures with Roughness and Scratches

Micro/nanostructures have some surface topography and local scratches dependent upon the manufacturing process. Surface roughness and local scratches may compromise the reliability of the devices, and their effect needs to be studied. Finite element modeling is used to perform parametric analysis to study the effect of surface roughness and scratches in different well-defined forms on tensile stresses, which are responsible for crack propagation [32.71, 72]. The analysis has been carried out on trapezoidal beams supported at the bottom whose data (on Si and SiO_2 nanobeams) have been presented earlier in Table 32.2.

The finite element analysis has been carried out by using the static analysis of the ANSYS 5.7 model, which calculates the deflections and stresses produced by applied loading. The type of element selected for the study was SOLID95 type, which allows the use of different shapes without much loss of accuracy. This element is 3-D with 20 nodes, each node having three degrees of freedom, which implies translation in the x, y and z directions. The nanobeam cross-section is divided into six elements each along the width and the thickness and forty elements along the length. SOLID95 has plasticity, creep, stress stiffening, large deflection and large strain capabilities. The large displacement analysis is used for large loads. The mesh is kept finer near the asperities and the scratches in order to take into account variation in the bending stresses. The beam materials studied are made of single-crystal silicon (110) and SiO_2 films whose data have been presented earlier. Based on the bending experiments presented earlier, the beam materials can be assumed to be linearly elastic isotropic materials. Young's modulus of elasticity (E) and Poisson's ratio (ν) for Si and SiO_2 are

169 GPa [32.92] and 0.28 [32.88], and 73 GPa [32.93] and 0.17 [32.93] respectively. A sample nanobeam of silicon was chosen for performing most of the analysis as silicon is the most widely used MEMS/NEMS material. The cross-section of the fabricated beams used in the experiment is trapezoidal and supported at the bottom so nanobeams with trapezoidal cross-section are modeled (Fig. 32.10). The following dimensions are used: $w_1 = 200\,\text{nm}$, $w_2 = 370\,\text{nm}$, $t = 255\,\text{nm}$, and $P = 6\,\mu\text{m}$. In the boundary conditions, the displacements are constrained in all directions on the bottom surface for 1 μm from each end. A point load applied at the center of the beam is simulated with the load being applied at three closely located central nodes on the beam used. It has been observed from the experimental results that the Si nanobeam breaks at around 80 μN. Therefore, in this analysis, a nominal load of 70 μN is selected. At this load, deformations are large, and a large displacement option is used.

To study the effect of surface roughness and scratches on the maximum bending stresses the following cases were studied. First, the semicircular and grooved asperities in the longitudinal direction with defined geometrical parameters are analyzed (Fig. 32.26a). Next, semicircular asperities and scratches placed along the transverse direction at a distance c from the end and separated by pitch p from each other are analyzed (Fig. 32.26b). Lastly, the beam material is assumed to be either purely elastic, elastic-plastic, or elastic-perfectly plastic. In the following, we begin with the stress distribution in smooth nanobeams followed by the effect of surface roughness in the longitudinal and transverse directions and scratches in the transverse direction.

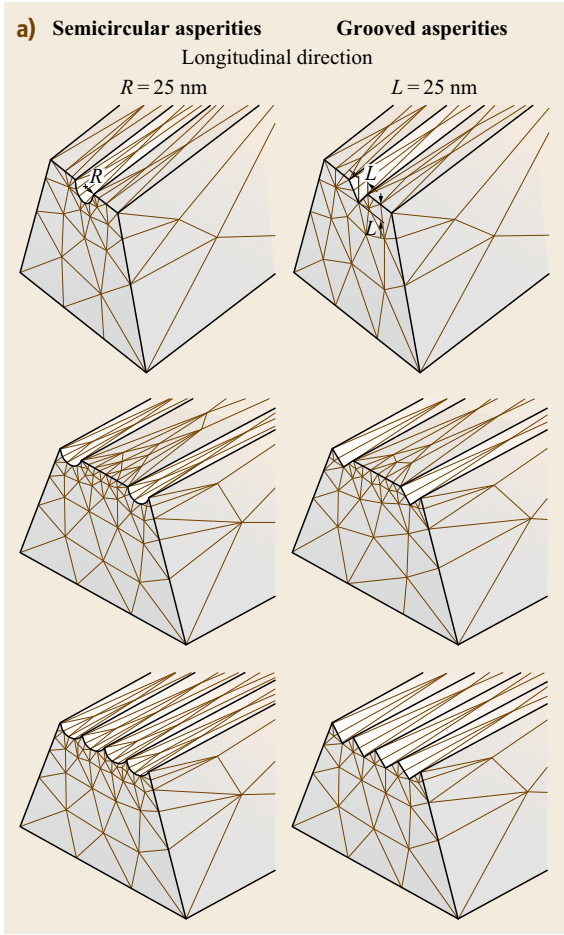

Fig. 32.26 (a) Plots showing the geometries of modeled roughness – semicircular and grooved asperities along the nanobeam length with defined geometrical parameters. (b) Schematic showing semicircular asperities and scratches in the transverse direction followed by the illustration of the mesh created on the beam with fine mesh near the asperities and the scratches. Also shown are the semicircular asperities and scratches at different pitch values

32.3.1 Stress Distribution in a Smooth Nanobeam

Figure 32.27 shows the stress and vertical displacement contours for a nanobeam supported at the bottom and loaded at the center [32.71, 72]. As expected, the maximum tensile stress occurs at the ends while the maximum compressive stress occurs under the load at the center. Stress contours obtained at a section of the beam from the front and side are also shown. In the beam cross-section, the stresses remain constant at a given vertical distance from one side to another and change with a change in vertical location. This can be explained due to the fact that the bending moment is constant at a particular cross-section, so the stress is only dependent on the distance from the neutral axis. However, in cross-section A–A the high tensile and compressive stresses are localized near the end of the beam at top and bottom respectively, whereas the lower values are spread out away from the ends. High values of tensile stresses occur near the ends because of high bending moment.

32.3.2 Effect of Roughness in the Longitudinal Direction

The roughness in the form of semicircular and grooved asperities in the longitudinal direction on the maximum bending stresses are analyzed [32.72]. The radius R and depth L are kept fixed at 25 nm while the number of asperities is varied, and their effect is observed on the maximum bending stresses. Figure 32.28 shows

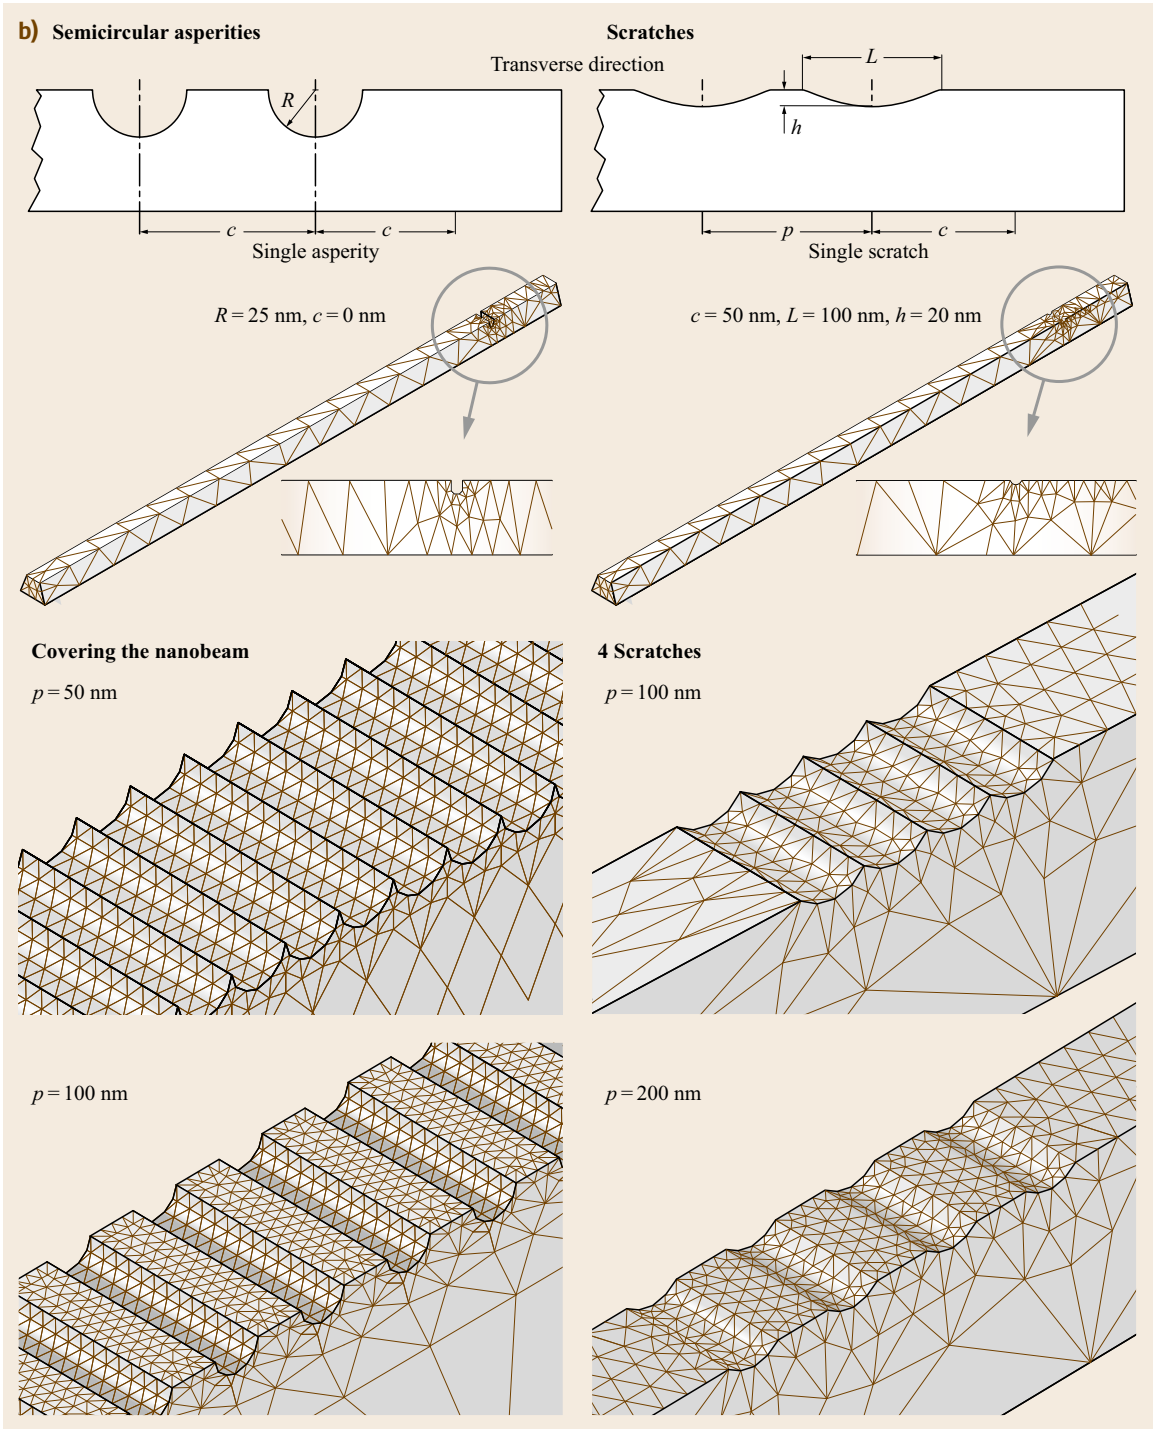

Fig. 32.26 (continued)

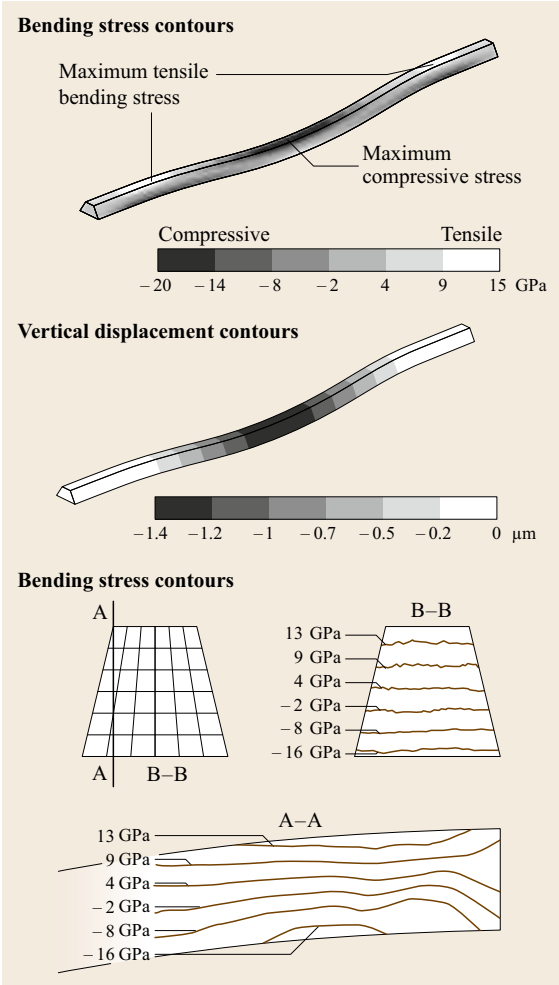

Fig. 32.27 Bending stress contours, vertical displacement contours, and bending stress contours after loading trapezoidal Si nanobeams ($w_1 = 200\,\text{nm}$, $w_2 = 370\,\text{nm}$, $t = 255\,\text{nm}$, $\ell = 6\,\mu\text{m}$, $E = 169\,\text{GPa}$, $\nu = 0.28$) at $70\,\mu\text{N}$ load (after [32.72])

the variation of maximum bending stresses as a function of asperity shape and the number of asperities. The maximum bending stresses increase as the asperity number increases for both semicircular and grooved asperities. This can be attributed to the fact that as asperity number increases, the moment of inertia decreases for that cross-section. Also the distance from the neutral axis increases because the neutral axis shifts downwards. Both these factors lead to the increase in the maximum bending stresses, and this effect is more pronounced in the case of a semicircular asperity as it exhibits a higher value of maximum bending stress

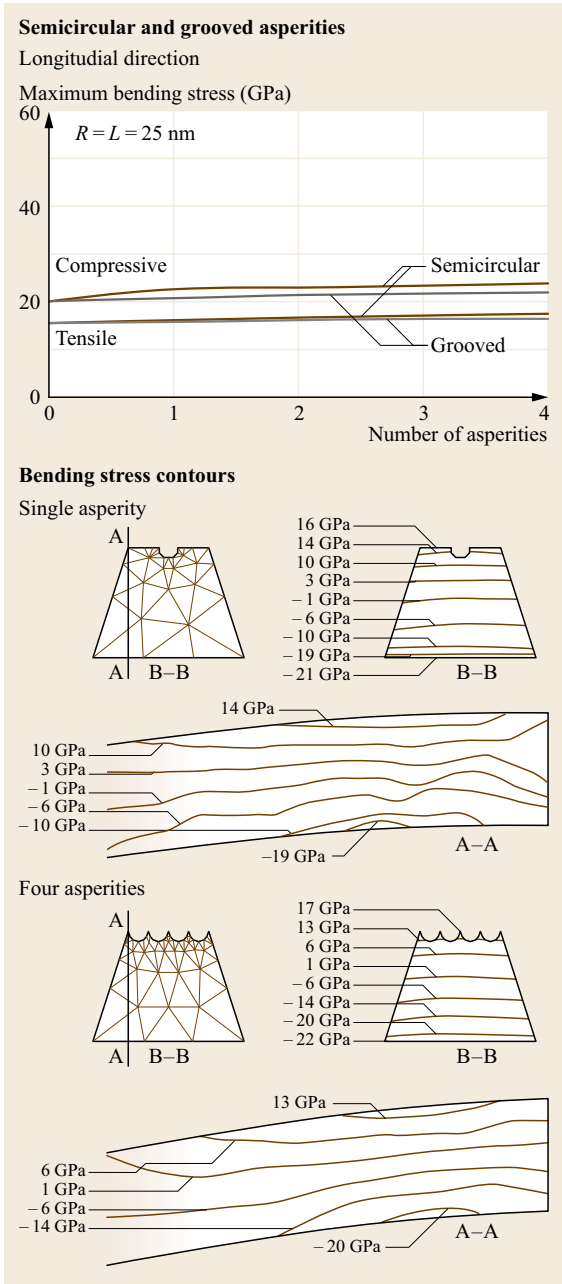

Fig. 32.28 Effect of longitudinal semicircular and grooved asperities in different numbers on maximum bending stresses after loading trapezoidal Si nanobeams ($w_1 = 200\,\text{nm}$, $w_2 = 370\,\text{nm}$, $t = 255\,\text{nm}$, $\ell = 6\,\mu\text{m}$, $E = 169\,\text{GPa}$, $\nu = 0.28$, load $= 70\,\mu\text{N}$). Bending stress contours obtained in the beam with semicircular single asperity and four adjacent asperities of $R = 25\,\text{nm}$ (after [32.72])

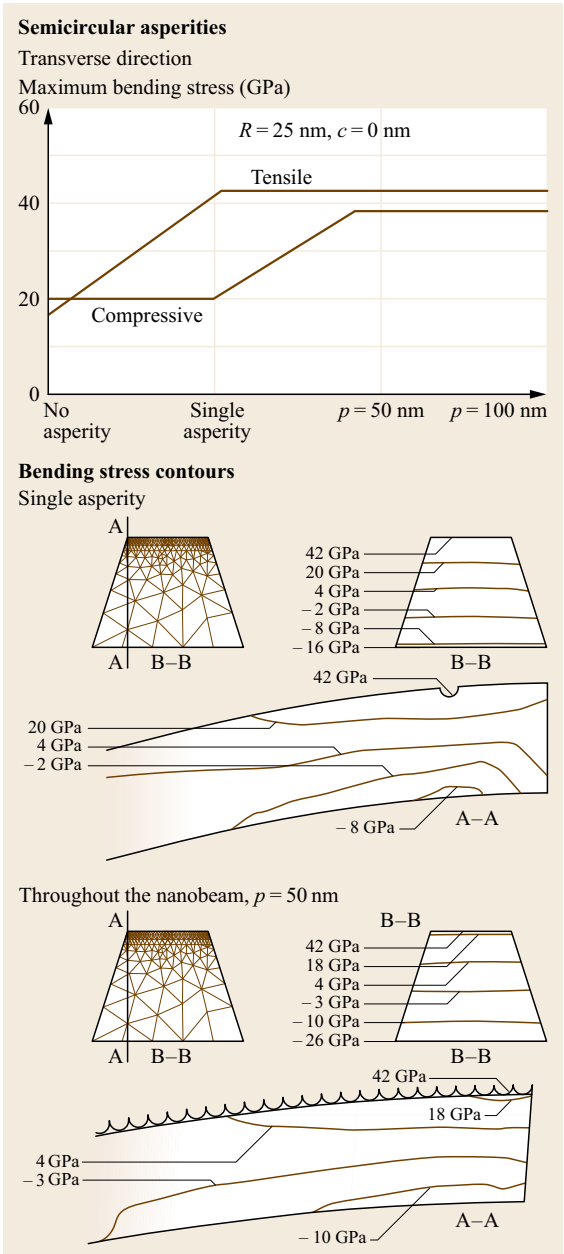

Fig. 32.29 Effect of transverse semicircular asperities located at different pitch values on the maximum bending stresses after loading trapezoidal Si nanobeams ($w_1 = 200\,\text{nm}$, $w_2 = 370\,\text{nm}$, $t = 255\,\text{nm}$, $\ell = 6\,\mu\text{m}$, $E = 169\,\text{GPa}$, $\nu = 0.28$, load $= 70\,\mu\text{N}$). Bending stress contours obtained in the beam with semicircular single asperity and semicircular asperities throughout the nanobeam surface at $p = 50\,\text{nm}$ (after [32.72])

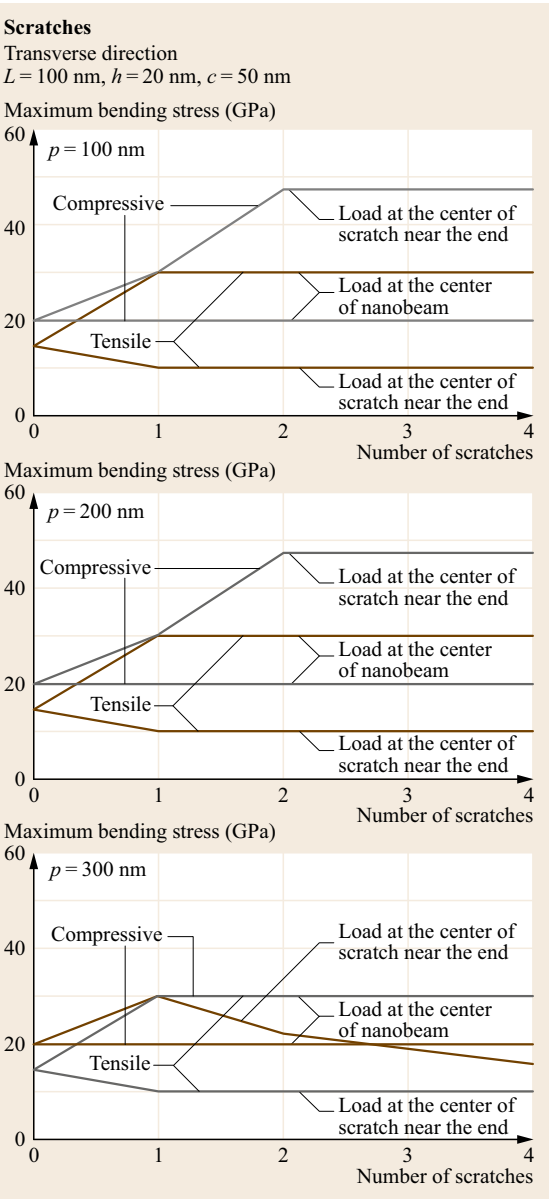

Fig. 32.30 Effect of number of scratches along with the variation in the pitch on the maximum bending stresses after loading trapezoidal Si nanobeams ($w_1 = 200\,\text{nm}$, $w_2 = 370\,\text{nm}$, $t = 255\,\text{nm}$, $\ell = 6\,\mu\text{m}$, $E = 169\,\text{GPa}$, $\nu = 0.28$, load $= 70\,\mu\text{N}$). Also shown is the effect of load when applied at the center of the beam and at the center of the scratch near the end (after [32.72])

than that in a grooved asperity. Figure 32.28 shows the stress contours obtained at a section of the beam from the front and from the side for both cases when we have a single semicircular asperity and when four adjacent semicircular asperities are present. Trends are similar to that observed earlier for a smooth nanobeam (Fig. 32.27).

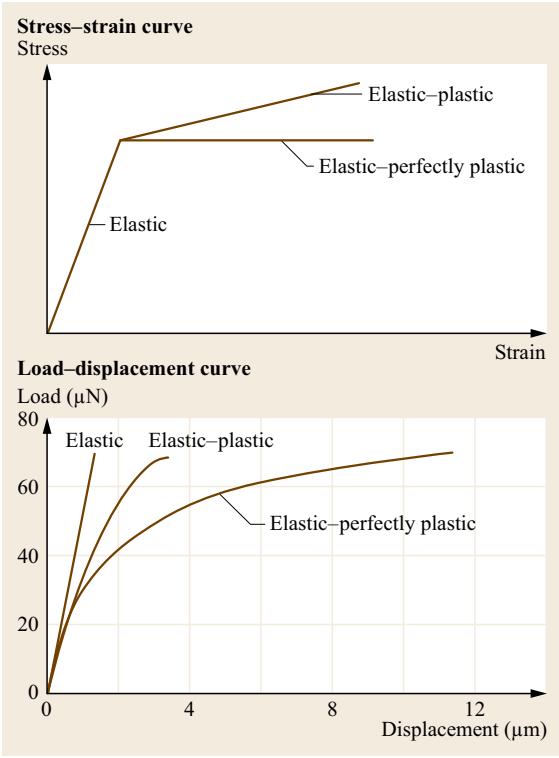

Fig. 32.31 Schematic representation of stress-strain curves and load-displacement curves for material when it is elastic, elastic-plastic, or elastic-perfectly plastic for a Si nanobeam ($w_1 = 200\,\text{nm}$, $w_2 = 370\,\text{nm}$, $t = 255\,\text{nm}$, $\ell = 6\,\mu\text{m}$, $E = 169\,\text{GPa}$, tangent modulus in plastic range $= 0.5\,\text{E}$, $\nu = 0.28$) (after [32.72])

32.3.3 Effect of Roughness in the Transverse Direction and Scratches

We analyze semicircular asperities when placed along the transverse direction followed by the effect of scratches on the maximum bending stresses in varying numbers and different pitch [32.72]. In the analysis of semicircular transverse asperities three cases were considered, which included a single asperity, asperities throughout the nanobeam surface separated by pitch equal to 50 nm and pitch equal to 100 nm. In all of these cases, the c value was kept equal to 0 nm. Figure 32.29 shows that the value of maximum tensile stress is 42 GPa, which is much larger than the maximum tensile stress value with no asperity of 16 GPa or when the semicircular asperity is present in the longitudinal direction. It is also observed that the maximum tensile stress does not vary with the number of asperities or the pitch, while the maximum compressive stress does increase dramatically for the asperities present throughout the beam surface from its value when a single asperity is present. Maximum tensile stress occurs at the ends. An increase in p does not add any asperities at the ends whereas asperities are added in the central region where compressive stresses are maximum. The semicircular asperities present at the center cause the local perturbation in the stress distribution at the center of the asperity where load is being applied leading to a high value of maximum compressive stress [32.105]. Figure 32.29 also shows the stress contours obtained at a section of the beam from front and from the side for both cases when there is a single semicircular asperity and when asperities are present throughout the beam surface at a pitch equal to 50 nm. Trends are similar to that observed earlier for a smooth nanobeam (Fig. 32.27).

In the study pertaining to scratches, the number of scratches are varied along with the variation in the pitch. Furthermore the load is applied at the center of the beam and at the center of the scratch near the end for all the cases. In all of these cases, the c value was kept equal to 50 nm, and the L value was equal to 100 nm with the h value being 20 nm. Figure 32.30 shows that the value of maximum tensile stress remains almost the same with the number of scratches for both types of loading, that is, when load is applied at the center of the beam and at the center of the scratch near the end. This is because the maximum tensile stress occurs at the beam ends, no matter where the load gets applied. But the presence of a scratch does increase the maximum tensile stress as compared to its value for a smooth nanobeam, although the number of scratches no longer matters as the maximum tensile stress occurring at the nanobeam end is unaffected by the presence of more scratches beyond the first scratch in the direction towards the center. The value of the tensile stress is much lower when the load is applied at the center of the scratch, and it can be explained as follows. The negative bending moment at the end near the load applied decreases with load offset after two-thirds of the length of the beam [32.106]. Since this negative bending moment is responsible for tensile stresses, their behavior with the load offset is the same as the negative bending moment. Also, the value of maximum compressive stress when load is applied at the center of the nanobeam remains almost the same, as the center geometry is unchanged due to the number of scratches, and hence the maximum compressive stress occurring below the load at the center is same. On the other hand when the load is applied at the center of the scratch we observe that the maximum compressive stress increases dramatically because the local perturbation in the stress distribution at the center of the scratch where load is being applied leads to a high value of maximum compressive

Table 32.5 Stresses and displacements for materials which are elastic, elastic-plastic or elastic-perfectly plastic (load = 70 μN, $w_1 = 200$ nm, $w_2 = 370$ nm, $t = 255$ nm, $\ell = 6$ μm, $R = 25$ nm, $E = 169$ GPa, tangent modulus in plastic range $= 0.5E$, $\nu = 0.28$)

	Elastic		Elastic–plastic		Elastic–perfectly plastic	
	Smooth nanobeam	Single semicircular longitudinal asperity	Smooth nanobeam	Single semicircular longitudinal asperity	Smooth nanobeam	Single semicircular longitudinal asperity
Maximum von Mises stress (GPa)	18.2	19.3	13.5	15.2	7.8	9.1
Maximum displacement (μm)	1.34	1.40	3.35	3.65	11.5	12.3

stress [32.105]. It increases further with the number of scratches and then levels off. This can be attributed to the fact that when there is another scratch present close to the scratch near the end, the stress concentration is more, as the effect of local perturbation in the stress distribution is more significant. However, this effect is insignificant when more than two scratches are present.

Now we address the effect of pitch on the maximum compressive stress when the load is applied at the center of the scratch near the end. When the pitch is up to a value of 200 nm the maximum compressive stress increases with the number of scratches, as discussed earlier. On the other hand, when the pitch value goes beyond 225 nm this effect is reversed. This is because the presence of another scratch no longer affects the local perturbation in the stress distribution at the scratch near the end. Instead more scratches at a fair distance distribute the maximum compressive stress at the scratch near the end, and the stress starts going down. Such observations of maximum bending stresses can help in identifying the number of asperities and scratches allowed, separated by an optimum distance from each other.

32.3.4 Effect on Stresses and Displacements for Materials Which are Elastic, Elastic–Plastic or Elastic–Perfectly Plastic

This section deals with the beam modeled as elastic, elastic-plastic and elastic-perfectly plastic to observe the variation in the stresses and displacements from an elastic model used so far [32.72]. Figure 32.31 shows the typical stress-strain curves for the three types of deformation regimes and their corresponding load-displacement curves obtained from the model of an Si nanobeam, which are found to exhibit same trends.

Table 32.5 shows the comparison of the maximum von Mises stress and maximum displacements for both a smooth nanobeam and a nanobeam with a defined roughness, which is a single semicircular longitudinal asperity of R value equal to 25 nm for the three different models. It is observed that the maximum value of stress is obtained at a given load for elastic material whereas the displacement is maximum for elastic-perfectly plastic material. Also the pattern that the maximum bending stress value increases for a rough nanobeam still holds true in the other models as well.

32.4 Summary

Mechanical properties of nanostructures at relevant scales are required to design realistic MEMS/NEMS and BioMEMS/BioNEMS devices. Most mechanical properties are scale dependent. Micro/nanomechanical properties, hardness, elastic modulus, and scratch resistance of bulk materials of undoped single-crystal silicon (Si) and thin films of undoped polysilicon, SiO_2, SiC, Ni-P, and Au were presented. It was found that the SiC film exhibits higher hardness, elastic modulus, and scratch resistance as compared to other materials.

Bending tests have been performed on the Si and SiO_2 nanobeams and Ni-P, Au, PPMA and PMMA, PS and PS/clay microbeams using an AFM and a depth-sensing nanoindenter respectively. The bending tests were used to evaluate elastic modulus, bending strength (fracture stress), fracture toughness (K_{IC}), and fatigue strength of the beam materials. The Si and SiO_2 nanobeams exhibited an elastic linear response with sudden brittle fracture. The notched Ni-P beam showed linear deformation behavior followed by abrupt failure. The Au beam showed elastic-plastic deformation

behavior. Measured elastic modulus values for Si(110) and SiO_2 were comparable to bulk values. Measured bending strength for Si and SiO_2 were twice as large as the values reported on larger-scale specimens. This indicates that bending strength shows a specimen-size dependence. Measured fracture toughness values for Si and SiO_2 were also comparable to values obtained on larger specimens. At stress amplitudes less than 15% of their bending strength and at mean stresses of less than 30% of the bending strength, Si and SiO_2 displayed an apparent endurance life of greater than 30 000 cycles. SEM observations of the fracture surfaces revealed a cleavage type of fracture for both materials when subjected to bending as well as fatigue.

The hardness, elastic modulus, and creep behavior of the PPMA, PMMA, PS and a PS/clay nanocomposite microbeams were evaluated using nanoindentation in continuous stiffness mode. The H, E, and creep resistance decreased in the following order: PS/clay, PMMA, PS, PPMA. The scratch resistance was observed to decrease in the following order: PMMA, PS/clay, PS, PPMA.

The elastic modulus of the double-anchored beams obtained from normal beam bending was lower than the E measured from nanoindentation due to stress concentration at the beam ends. The test environment affected the mechanical properties as well. After 36 hours of soaking in DI water, the hardness and elastic modulus of PPMA was affected, while the properties of the other three polymers were unaffected due to their low water absorption properties. Similarly, for tests conducted at human body temperature (37.5 °C), only PPMA exhibited a decrease in the hardness and modulus. The other materials did not exhibit any change because while this temperature is within the glass transition temperature range of PMMA, it is well below the T_g of the other polymers. By performing bending experiments at higher imposed loads, permanent deformation can be attained such that the yield and breaking strength can be evaluated. Adding nanoclay filler improved bending strength. It also modified the fracture behavior of the polymer microbeams. The unfilled polymers deformed in a ductile manner while the PS/clay nanocomposite exhibited minimal yielding followed by brittle failure.

Lateral bending has been demonstrated to provide a measure for the elastic, plastic and fracture properties of cantilever beams.

The AFM and nanoindenters used in this study can be satisfactorily used to evaluate the mechanical properties of micro/nanoscale structures for use in MEMS/NEMS.

FEM simulations were used to predict stress and deformation in nanostructures. FEM has been used to analyze the effect of the type of surface roughness and scratches on stresses and deformation of nanostructures. We found that roughness affects the maximum bending stresses. The maximum bending stresses increased as the asperity number increased for both semicircular and grooved asperities in the longitudinal direction. When the semicircular asperity was present in the transverse direction, the value of the maximum tensile stress was much larger than the maximum tensile stress value with no asperity or when the semicircular asperity was present in the longitudinal direction. This observation suggests that an asperity in the transverse direction is more detrimental. The presence of scratches increased the maximum tensile stress. The maximum tensile stress remained almost the same with the number of scratches for two types of loading, that is, when load was applied at the center of the beam or at the center of the scratch near the end, although the value of the tensile stress was much lower when the load was applied at the center of the scratch. This means that the load applied at the ends was less damaging. This analysis shows that FEM simulations can be useful to designers for development of the most suitable geometry for nanostructures.

32.A Appendix: Fabrication Procedure for the Double-Anchored and Cantilever Beams

The starting materials for the polymer microbeams are PPMA (molecular weight 250 000, Scientific Polymer Products), PMMA (molecular weight 75 000, Sigma-Aldrich), PS (melt flow index 4.0, Sigma-Aldrich) and PS/clay solutions in anisole (Acros Organics). The clay additive in PS/clay is Cloisite 20A surface modified natural montmorillonite (Southern Clay Products, Inc.) with a thickness of approximately 1 nm and lateral dimensions of 70–150 nm. The surface modification of the clay additive improves the dispersion of the nanoparticles in the polymer matrix, thus improving the properties of the composite. To prepare the nanocomposite, the clay was first dispersed in the PS matrix by melt compounding at a concentration of 10 wt% (clay/PS). The composite was then dissolved in anisole and sonicated for at least eight hours to dissolve the polymer and redisperse the particles.

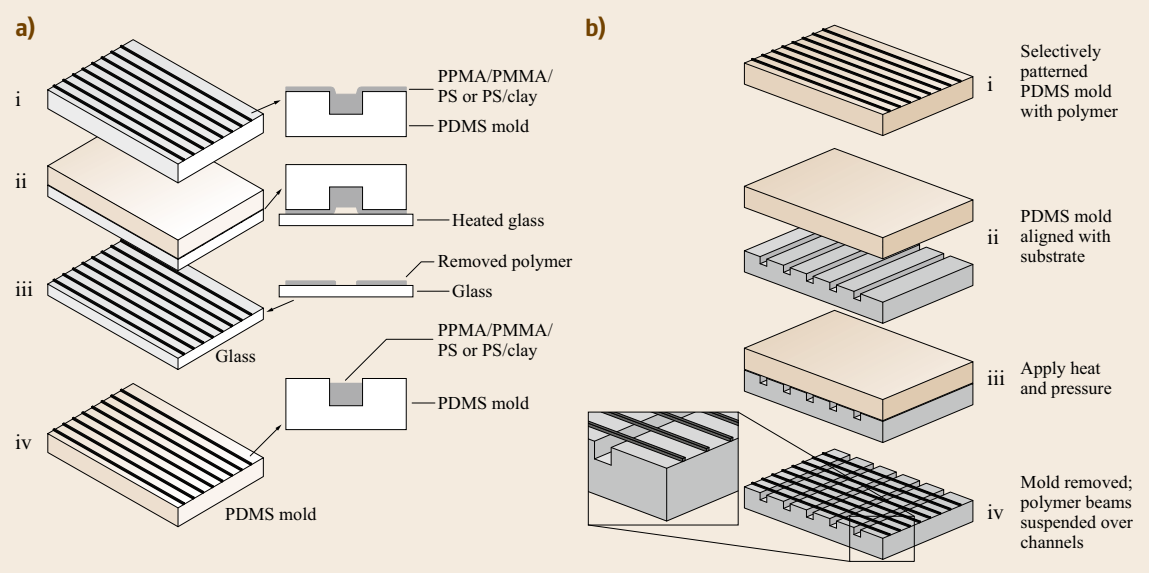

Fig. 32.32a,b Schematic of the micromolding process used in polymer double-anchored beam fabrication. **(a)** Selective patterning of PDMS mold: (i) mold is spin coated with a polymer layer; (ii) mold is inverted and brought into contact with a heated glass plate; (iii) mold is removed from the plate, transferring the surface polymer onto the glass; and (iv) mold is left with polymer only in the recessed features. **(b)** Stamping of the polymer beams: (i) selectively patterned mold; (ii) mold is inverted and aligned with the photolithographically patterned substrate; (iii) mold and substrate are brought into contact under heat and pressure; and (iv) polymer is transferred onto the photoresist and mold is removed (after [32.65])

Double-anchored polymer microbeams were fabricated using a soft lithography-based micromolding process along with standard photolithography [32.65]. The process involves selectively filling a poly(dimethyl siloxane) (PDMS) mold with the polymer of interest followed by transfer of the resulting structures to a prefabricated substrate. This substrate is a silicon wafer with a layer of SU-8 25 negative tone photoresist (MicroChem Corp.) patterned by photolithography to create 25 μm-wide channels, which is the resulting length of the suspended beams. (The second number 25 in the SU-8 designation relates to a viscosity appropriate for a given thickness.)

A patterned PDMS mold with the desired polymer beam geometry was fabricated from a photoresist master. Briefly, a layer of SU-8 5 photoresist was spin coated on silicon, and photolithography was used to define 5 μm-wide photoresist features separated by 45 μm gaps. A 10:1 ratio of T-2 PDMS translucent base and curing agent (Dow Corning) was mixed thoroughly and poured over the photoresist master to transfer the pattern into the PDMS. The mold was then placed in a vacuum desiccator to remove bubbles. The sample was removed from the vacuum periodically, and a razor blade was used to remove surface bubbles. After the bubbles were completely removed, the PDMS mold was allowed to cure at room temperature for 48 h before removing it from the wafer.

Next, the PDMS mold was selectively coated with the polymer solution to form the microbeams and then transferred to the substrate. Figure 32.32 is a schematic of the fabrication process used for making the polymer microbeams. As shown in Fig. 32.32a, the polymer solutions were spin coated on the PDMS mold for one minute. A 10% solution of polymer was spin coated on a mold with 5.3 μm-deep features at 3000 rpm for fabrication of the beams in the bending experiments. After spin coating, the mold was brought into contact with a heated glass plate to promote adhesion of the contacting polymer materials. This process removed the polymer material from the raised surfaces of the mold, resulting in the polymer remaining only in the recessed portions of the PDMS mold. The glass plate was heated to 175 °C for all four materials. As shown in Fig. 32.32b, the selectively coated mold was then aligned with the photolithographically patterned silicon substrate so that the beams of interest (PPMA, PMMA, PS, PS/clay) ran perpendicular to the channels defined in the photoresist. The substrate was then heated and pressure was applied to the top of the mold to transfer the material onto the substrate. The transfer temperatures for PPMA, PS, PS/clay and PMMA were 95, 125,

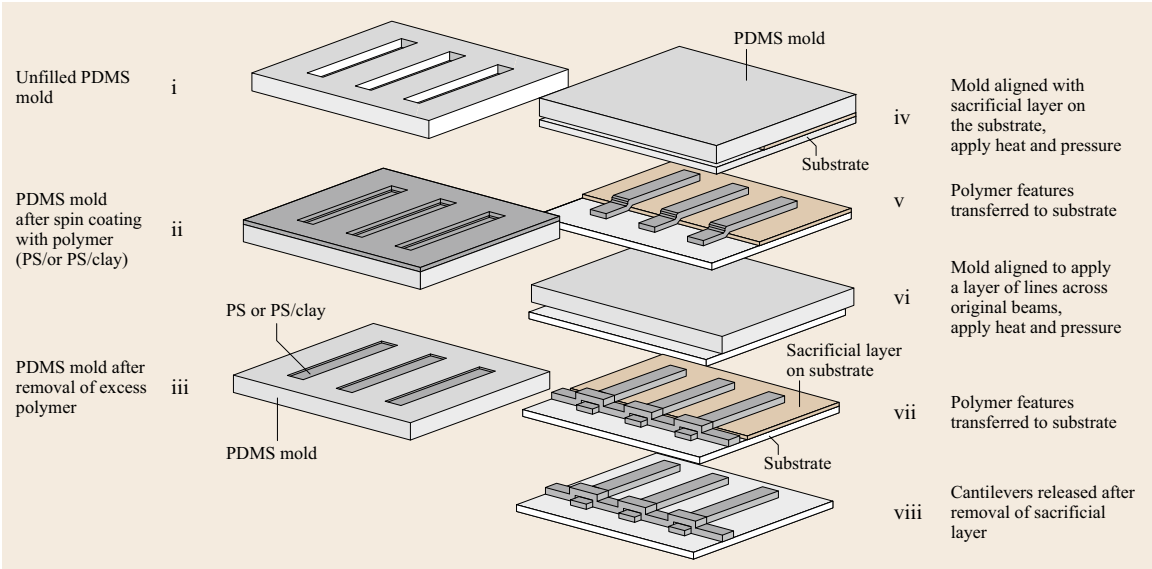

Fig. 32.33 Schematic of the polymer cantilever beam fabrication process: (i) PDMS mold; (ii) mold spin coated with the polymer of interest; (iii) selectively filled mold after removal of surface polymer; (iv) mold aligned with sacrificial layer; (v) polymer features transfer to the substrate using heat and pressure; (vi) mold aligned for a second time to add another layer of lines across original beams for reinforcement; (vii) polymer features transfer to the substrate using heat and pressure; and (viii) cantilever structures after removal of the sacrificial layer (after [32.65])

125, and 175 °C respectively, and the transfer pressure for all materials was around 0.21 MPa.

After removal of the mold, two types of polymer beams were transferred onto the wafer sample. The first type is supported beams, which was used to determine the hardness, elastic modulus, and creep response. The second type is suspended beams, on which the bending experiments were performed. The double-anchored beam samples studied by *Palacio* et al. [32.65] were 3–5 μm thick, 5 μm wide and nominally 25 μm long.

The process for fabrication of the polymer cantilever for lateral bending tests is shown in Fig. 32.33 [32.65]. A PDMS mold was first cast from a photolithographically patterned SU-8/silicon master. The resulting molds consisted of 50 μm-wide channels that were approximately 27 μm deep. The PDMS mold was then coated with the polymer of interest (PS or PS/clay). The polymers were spin coated on the mold at 3000 rpm for one minute at concentrations of 15 and 10% for PS and PS/clay respectively. The polymer on the raised surface of the mold was removed by contacting the surface with a glass slide heated to 180 °C. The mold was then inverted and manually aligned with a silicon substrate coated with patches of polyvinyl alcohol (PVA), which acts as the sacrificial layer. The PVA was patterned using photolithography and reactive ion etching with an oxygen plasma. The substrate was heated and pressure was applied to the top side of the mold to transfer the polymer from the recessed features of the mold onto the substrate such that a 350 μm portion of it is attached to the PVA and the remainder is attached to the bare silicon surface. Transfer temperatures for PS and PS/clay were 150 and 175 °C respectively. The process was repeated to apply another layer of beams across the length of the original layer. This was performed to provide reinforcement as it was observed that the one-layer design was not robust. The cantilever beam samples studied by *Palacio* et al. [32.65] were 12–27 μm thick, 60–80 μm wide and 350 μm long.

33. Nanotribology of Ultrathin and Hard Amorphous Carbon Films

Bharat Bhushan

One of the best materials to use in applications that require very low wear and reduced friction is diamond, especially in the form of a diamond coating. Unfortunately, true diamond coatings can be deposited only at high temperatures and on selected substrates, and they require surface finishing. However, the mechanical, thermal, and optical properties of hard, amorphous carbon – commonly known as a diamond-like carbon (DLC) coating – can be tailored to be similar to those of diamond. It can also be deposited at a wide range of thicknesses using a variety of deposition processes on various substrates at or near room temperature. The coatings reproduce the topography of the substrate, removing the need for surface finishing. Various physical and chemical characterization techniques have been used to study the structure, stoichiometry, and mechanical and tribological properties. The friction and wear properties of some DLC coatings make them very attractive for some tribological applications. The most significant current industrial applications of DLC coatings are in magnetic storage devices, micro/nanoelectromechanical systems, and various other consumer products including razor blades, sunglasses, and optical windows.

In this chapter, the state-of-the-art in the chemical, mechanical, and tribological characterization of ultrathin amorphous carbon coatings as thin as 5 nm is presented.

Carbon exists in both crystalline and amorphous forms and exhibits both metallic and nonmetallic characteristics [33.1–3]. Crystalline carbon includes graphite, diamond, and a family of fullerenes (Fig. 33.1). Graphite and diamond are infinite periodic network solids with a planar structure, whereas the fullerenes are a molecular form of pure carbon with a finite network and a nonplanar structure. Graphite has a hexagonal, layered structure with weak interlayer bonding forces, and exhibits excellent lubrication properties. The graphite crystal may be visualized as infinite parallel layers of hexagons stacked 0.34 nm apart with a 0.1415 nm interatomic distance between the carbon atoms in the basal plane. The atoms lying in the basal planes are trigonally coordinated and closely packed with strong σ (covalent) bonds to its three carbon neighbors using the hybrid sp^2 orbitals. The fourth electron lies in a p_z orbital lying normal to the σ bonding plane. It forms a weak π bond by overlapping side-to-side with a p_z orbital of an adjacent atom to which carbon is attached by a σ bond. The layers (basal planes) themselves are relatively far apart and the forces that bond them are weak van der

Waals forces. These layers can align themselves parallel to the direction of the relative motion, and slide over one another with relative ease, providing low friction. Strong interatomic bonding and packing in each layer is thought to help reduce wear. Operating environment has a significant influence on the lubrication properties, i. e., low friction and low wear, of graphite. It lubricates better in a humid environment than a dry one which results from adsorption of water vapor and other gases from the environment. This further weakens the interlayer bonding forces, resulting in easy shear and transfer of the crystallite platelets to the mating surface. Thus, transfer plays an important role in controlling friction and wear. Graphite oxidizes at high operating temperatures, and can be used up to about 430 °C.

One of the fullerene molecules is C_{60}, commonly known as a Buckyball. Since the C_{60} molecules are very stable and do not require additional atoms to satisfy chemical bonding requirements, they are expected to have low adhesion to the mating surface and low surface energy. Since C_{60} molecules with a perfect spherical symmetry are weakly bonded to other molecules, C_{60} clusters get detached readily, similar to other layered-lattice structures. They either transfer to the mating surface by mechanical compaction, or are present as a loose wear particle that may roll like a tiny ball bearing in a sliding contact, resulting in low friction and wear. The wear particles are expected to be harder than as-deposited C_{60} molecules because of their phase transformation at the high asperity contact pressures present in a sliding interface. The low surface energy, spherical shape of C_{60} molecules, weak intermolecular bonding, and high load-bearing capacity offer potential for various mechanical and tribological applications. Sublimed C_{60} coatings and fullerene particles as an additive to mineral oils and greases, have been reported to be good solid lubricants comparable to graphite and MoS_2 [33.4–6].

Diamond crystallizes in a modified face-centered cubic (fcc) structure with an interatomic distance of 0.154 nm. The diamond cubic lattice consists of two interpenetrating fcc lattices displaced by one-quarter of the cube diagonal. Each carbon atom is tetrahedrally coordinated, making strong σ (covalent) bonds to its four carbon neighbors using the hybrid sp^3 atomic orbitals. This accounts for its hardness (80–104 GPa) and thermal conductivity (900–2100 W/mK, on the order of five times that of copper), the highest of any known solid, and a high electrical resistivity, optical transmission, and large optical bandgap. It is relatively chemically inert, and it exhibits poor adhesion with other solids with consequent low friction and wear. Its high thermal conductivity allows dissipation of frictional heat during sliding and protects the interface. The dangling carbon bonds on the surface react with the environment to form hydrocarbons, which act as good lubrication films. These are some of the reasons for the low friction and wear of diamond. Diamond and its coatings find many industrial applications: tribological applications (low friction and wear), optical applications (exceptional optical transmission, high abrasion resistance), and thermal management or heat sink applications (high thermal conductivity). Diamond can be used to high temperatures and its starts to become graphite at about 1000 °C in ambient air and at about 1400 °C in vacuum. Diamond is an attractive material for cutting tools, as an abrasive for grinding wheels and lapping compounds, and other extreme-wear applications.

Natural diamond, particularly in large sizes, is very expensive and its coatings, a low-cost alternative, are attractive. True diamond coatings are deposited by chemical vapor deposition (CVD) processes at high substrate temperatures (on the order of 800 °C). They adhere best on a silicon substrate and require an interlayer for other substrates. A major roadblock to the widespread use of

true diamond films in tribological, optical, and thermal management applications is surface roughness. Growth of the diamond phase on a nondiamond substrate is initiated by nucleation either at randomly seeded sites or at thermally favored sites due to statistical thermal fluctuation at the substrate surface. On the basis of growth temperature and pressure conditions, favored crystal orientations dominate the competitive growth process. As a result, the grown films are polycrystalline in nature with relatively large grain size ($> 1\,\mu m$), and terminate in very rough surfaces with RMS (root mean square) roughnesses ranging from a few tenths of a micron to tens of microns. Techniques for polishing these films have been developed. It has been reported that the laser-polished films exhibit friction and wear properties almost comparable to that of bulk polished diamond [33.7, 8].

Amorphous carbon has no long-range order and the short-range order of carbon atoms can have one or more of three bonding configurations – sp^3 (diamond), sp^2 (graphite), or sp^1 (with two electrons forming strong σ bonds and the remaining two electrons left in orthogonal p_y and p_z orbitals to form weak π bonds). Short-range order controls the properties of amorphous materials and coatings. Hard amorphous carbon (a-C) coatings are commonly known as diamond-like carbon or DLC (implying high hardness) coatings. They are a class of coatings that are mostly metastable amorphous materials, but include a micro- or nanocrystalline phase. The coatings are random networks of covalently bonded carbon in hybridized tetragonal (sp^3) and trigonal (sp^2) local coordination, with some of the bonds terminated by hydrogen. These coatings have been deposited successfully by a variety of vacuum deposition techniques on a variety of substrates at or near room temperature. The coatings generally reproduce substrate topography and do not require any postfinishing. However, these coatings mostly adhere best on silicon substrates. Best adhesion is obtained on substrates that form carbides, e.g., Si, Fe, and Ti. On the basis of depth profile analyses using Auger and XPS (x-ray photoelectron spectroscopy) of DLC coatings deposited on silicon substrates, it has been reported that a substantial amount of silicon carbide (on the order of 5–10 nm in thickness) is present at the carbon-silicon interface for the coatings with good adhesion and high hardness (e.g., [33.9]). For good adhesion of DLC coatings to other substrates, in most cases, an interlayer of silicon is required, except for cathodic arc-deposited coatings.

There is significant interest in DLC coatings because of their unique combination of desirable properties. These properties include high hardness and wear resistance, chemical inertness to both acids and alkalis, lack of magnetic response, and an optical band gap ranging from zero to a few eV, depending upon the deposition conditions. These are used in a wide range of applications including tribological, optical, electronic,

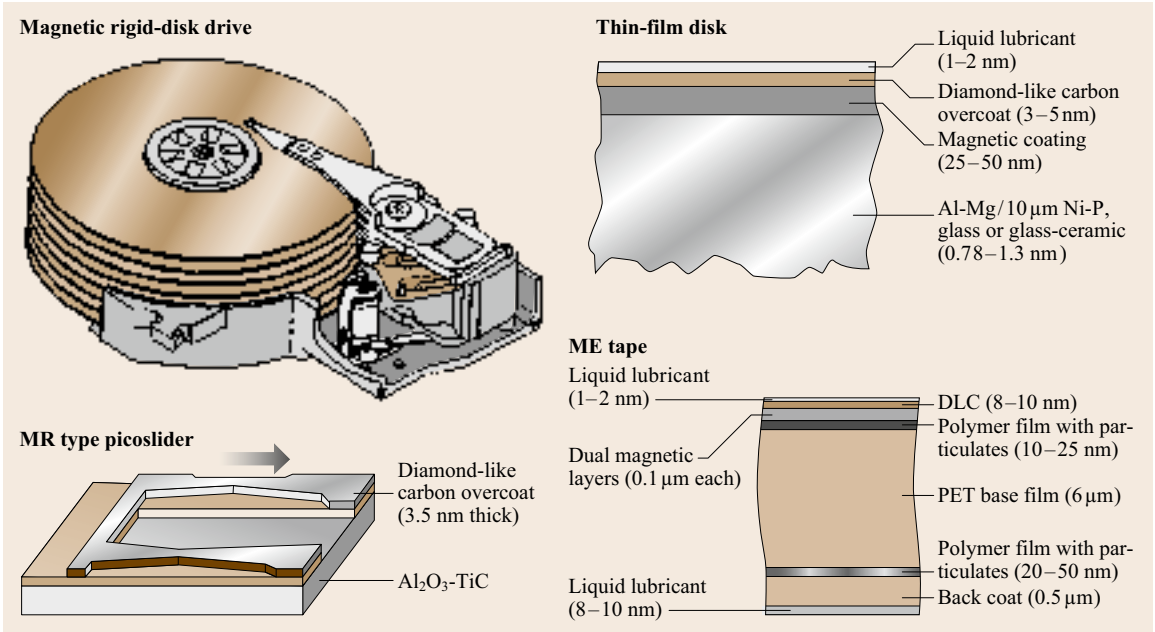

Fig. 33.2 Schematic of a magnetic rigid disk drive and MR-type picoslider and cross-sectional schematics of a magnetic thin-film rigid disk and a metal evaporated (ME) tape

and biomedical applications [33.1, 10, 11]. The high hardness, good friction and wear properties, versatility in deposition and substrates, and no requirements for postfinishing make them very attractive for tribological applications. The largest industrial application of the family of amorphous carbon coatings are typically deposited by DC/RF (direct current/radio frequency) magnetron sputtering (SP), plasma-enhanced chemical vapor deposition, or ion-beam (IB) deposition techniques in magnetic storage devices [33.12–20]. These coatings are employed to protect against wear and corrosion, in magnetic coatings on thin-film rigid disks and metal evaporated (ME) tapes, and in the thin-film head structure of a read/write disk head (Fig. 33.2). To maintain low physical spacing between the magnetic element of a magneto resistive-type (MR) read/write head and the magnetic layer of a media, thicknesses ranging from 3 to 10 nm are employed. Mechanical properties affect friction and wear, and these need to be optimized. In 1998, Gillette introduced Mach 3 razor blades with ultrathin DLC coatings, which is a large industrial application. DLC coatings are also used in other commercial applications such as cutting tools, glass windows of supermarket laser barcode scanners, other optical windows, and sunglasses. These coatings are also being used in micro- and nanoelec-

tromechanical systems (MEMS/NEMS) components (Fig. 33.3) [33.21–25].

In this chapter, an overview of the chemical, mechanical, and tribological characterization of ultrathin amorphous carbon coatings, commonly referred to as diamond-like carbon, is presented. First, an overview of the most commonly used deposition techniques is presented, followed by typical chemical and mechanical characterization data and typical tribological data both from coupon-level testing and functional testing.

33.1 Description of Commonly Used Deposition Techniques

The first hard amorphous carbon coatings were deposited by a beam of carbon ions produced in an argon plasma on room-temperature substrates as reported by *Aisenberg* and *Chabot* [33.26]. Subsequent confirmation by *Spencer* et al. [33.27] led to explosive growth of this field. Following on from the first work, several alternative techniques have been developed. The amorphous carbon coatings have been prepared by a variety of deposition techniques and precursors, including evaporation, DC, RF or ion beam sputtering, RF or DC plasma-enhanced chemical vapor deposition (PECVD), electron cyclotron resonance chemical vapor deposition (ECR-CVD), direct ion beam deposition, pulsed laser vaporization and vacuum arc, from a variety of carbon-bearing solids or gaseous source materials [33.1, 28]. Coatings with both graphitic and diamond-like properties have been produced. Evaporation and ion-plating techniques have been used to produce coatings with graphitic properties (low hardness, high electrical conductivity, very low friction, etc.) and all techniques have been used to produce coatings with diamond-like properties.

Structure and properties of a coating are dependent upon the deposition technique and the deposition parameters. High-energy surface bombardment has been used to produce harder and denser coatings. Decreasing sp^3/sp^2 fractions in order have been reported for cathodic arc deposition, pulsed laser vaporization, direct ion beam deposition, plasma-enhanced chemical vapor deposition, ion beam sputtering, and DC/RF sputtering [33.12, 29, 30]. A common feature to these techniques is that the deposition is energetic, i. e., carbon species arrive with an energy significantly greater than that represented by the substrate temperature. The resultant coatings are amorphous in structure, with hydrogen content up to 50%, and display a high degree of sp^3 character. From the results of previous investigations, it has been proposed that deposition of sp^3-bonded carbon requires the depositing species to have kinetic energies on the order of 100 eV or higher, well above those obtained in thermal processes like evaporation (0–0.1 eV). The species must then be quenched into the metastable configuration via rapid energy removal. Excess energy, such as that provided by substrate heating, is detrimental to the achievement of a high sp^3 fraction. In general, a high fraction of the sp^3-bonded carbon atoms in an amorphous network results in a higher hardness [33.30–37]. The mechanical and tribological properties of a carbon coating depend on the sp^3/sp^2-bonded carbon ratio, the amount of hydrogen in the coating, and adhesion of the coating to the substrate, which are influenced by the precursor material, kinetic energy of the carbon species prior to deposition, deposition rate, substrate temperature, substrate biasing, and the substrate itself [33.30, 34, 36, 38–47]. The kinetic energies and deposition rates involved in selected deposition processes used in the deposition of DLC coatings are compared in Table 33.1 [33.1, 29].

In the studies by *Gupta* and *Bhushan* [33.12, 48], *Li* and *Bhushan* [33.49, 50] and *Sundararajan* and *Bhushan* [33.51], DLC coatings, ranging in thickness typically from 3.5 to 20 nm, were deposited on single-crystal silicon, magnetic Ni-Zn ferrite, and Al_2O_3-TiC substrates (surface roughness $\approx 1-3$ nm RMS) by filtered cathodic arc (FCA) deposition, (direct) ion beam deposition (IBD), electron cyclotron resonance chemical vapor deposition (ECR-CVD), plasma-enhanced chemical vapor deposition (PECVD), and DC/RF planar, magnetron sputtering (SP) deposition techniques [33.52]. Herein, we will limit the presentation of data to coatings deposited by the FCA, IBD, ECR-CVD, and SP deposition techniques.

33.1.1 Filtered Cathodic Arc Deposition Technique

In the filtered cathodic arc deposition of carbon coatings [33.30, 53–60], a vacuum arc plasma source is used to form a carbon film. In the FCA technique used by Bhushan and coworkers (e.g., [33.12]), energetic carbon ions are produced by a vacuum arc discharge between a planar graphite cathode and a grounded anode (Fig. 33.4a). The cathode is a 6 mm diameter high-density graphite disk mounted on a water-cooled copper block. The arc is driven at an arc current of 200 A, arc duration of 5 ms, and arc repetition rate of 1 Hz. The plasma beam is guided by a magnetic field that transports current between the electrodes to form

Table 33.1 Summary of most commonly used deposition techniques and the kinetic energy of depositing species and deposition rates

Deposition technique	Process	Kinetic energy (eV)	Deposition rate (nm/s)
Filtered cathodic arc (FCA)	Energetic carbon ions produced by a vacuum arc discharge between a graphite cathode and a grounded anode	100–2500	0.1–1
Direct ion beam (IB)	Carbon ions produced from methane gas in an ion source and accelerated toward a substrate	50–500	0.1–1
Plasma-enhanced chemical vapor deposition (PECVD)	Hydrocarbon species produced by plasma decomposition of a hydrocarbon gas (such as acetylene) are accelerated toward a DC-biased substrate	1–30	1–10
Electron cyclotron resonance plasma chemical vapor deposition (ECR-CVD)	Hydrocarbon ions produced by the plasma decomposition of ethylene gas in the presence of a plasma at the electron cyclotron resonance condition are accelerated toward a RF-biased substrate	1–50	1–10
DC/RF sputtering	Sputtering of graphite target by argon ion plasma	1–10	1–10

tiny, rapidly moving spots on the cathode surface. The source is coupled to a 90° bent magnetic filter to remove the macroparticles produced concurrently with the plasma in the cathode spots. The ion current density at the substrate is in the range of 10–50 mA/cm^2. The base pressure is less than 10^{-4} Pa. Compared to electron beam evaporation with auxiliary discharge, much higher plasma density is achieved with the aid of powerful arc discharge. In this process, the cathodic material suffers a complicated transition from the solid phase to an expanding, nonequilibrium plasma via liquid and dense, equilibrium nonideal plasma phases [33.59]. The carbon ions in the vacuum arc plasma have a direct kinetic energy of 20–30 eV. The high voltage pulses are applied to the substrate mounted on a water-cooled sample holder; the ions are accelerated through a sheath and arrive at the substrate with an additional energy given by the potential difference between the plasma and the substrate. The substrate holder is pulse biased to a negative voltage up to −2 kV with a pulse duration of 1 μs. The negative biasing of −2 kV corresponds to 2 keV kinetic energy of the carbon ions. The use of a pulse bias instead of a DC bias has the advantages of applying a much higher voltage and building a surface potential on a nonconducting film. The energy of the ions is varied during the deposition. For the first 10% of the deposition the substrates are pulsed biased to −2 keV with a pulse duty cycle of 25%, i. e., for 25% of the time the energy is 2 keV, for the remaining 75% of the time it is 20 eV which is the *natural* energy of carbon ions in a vacuum discharge. For the last 90% of the deposition the pulsed bias voltage is reduced to −200 eV with a pulse bias duty cycle of 25%, i. e., the energy is 200 eV for 25% and 20 eV for 75% of the deposition. The high energy at the beginning leads to a good intermixing and good adhesion of the films whereas the lower energy at the later stage leads to hard films. Under the conditions described, the deposition rate at the substrate is about 0.1 nm/s which is slow. Compared with most gaseous plasmas, the cathodic arc plasma is almost fully ionized and as the ionized carbon atoms have high kinetic energy they help in achieving a high fraction of sp^3-bonded carbon ions which in turn results in a high hardness and higher interfacial adhesion. *Cuomo* et al. [33.43] have reported that based on electron energy loss spectroscopy (EELS) analysis, the sp^3-bonded carbon fraction of cathodic arc coating is 83% as compared with 38% for the ion-beam sputtered carbon. These coatings are reported to be *nonhydrogenated*.

This technique does not require an adhesion underlayer for nonsilicon substrates. However, adhesion of the DLC coatings on the electrically insulating substrate is poor as negative pulse biasing forms an electrical sheath which accelerates depositing ions to the substrate and enhances the adhesion of the coating to the substrate with associated ion implantation. It is difficult to build potential on an insulating substrate and lack of biasing results in poor adhesion.

33.1.2 Ion-Beam Deposition Technique

In direct ion beam deposition of a carbon coating [33.61–65], as used by Bhushan and coworkers (e.g., [33.12]) (deposition carried out by Ion Tech. Inc., Fort Collins, Colorado), the carbon coating is deposited from an accelerated carbon ion beam. The sample is precleaned by ion etching. For the case of nonsilicon substrates, a 2–3 nm thick amorphous silicon adhesion layer is deposited by ion beam sputtering using an ion beam of a mixture of methane and argon at 200 V. For the carbon deposition, the chamber is pumped to about 10^{-4} Pa and methane gas is fed through the cylindrical ion source and is ionized by energetic electrons produced by a hot-wire filament (Fig. 33.4b). Ionized species then pass through a grid with a bias voltage of

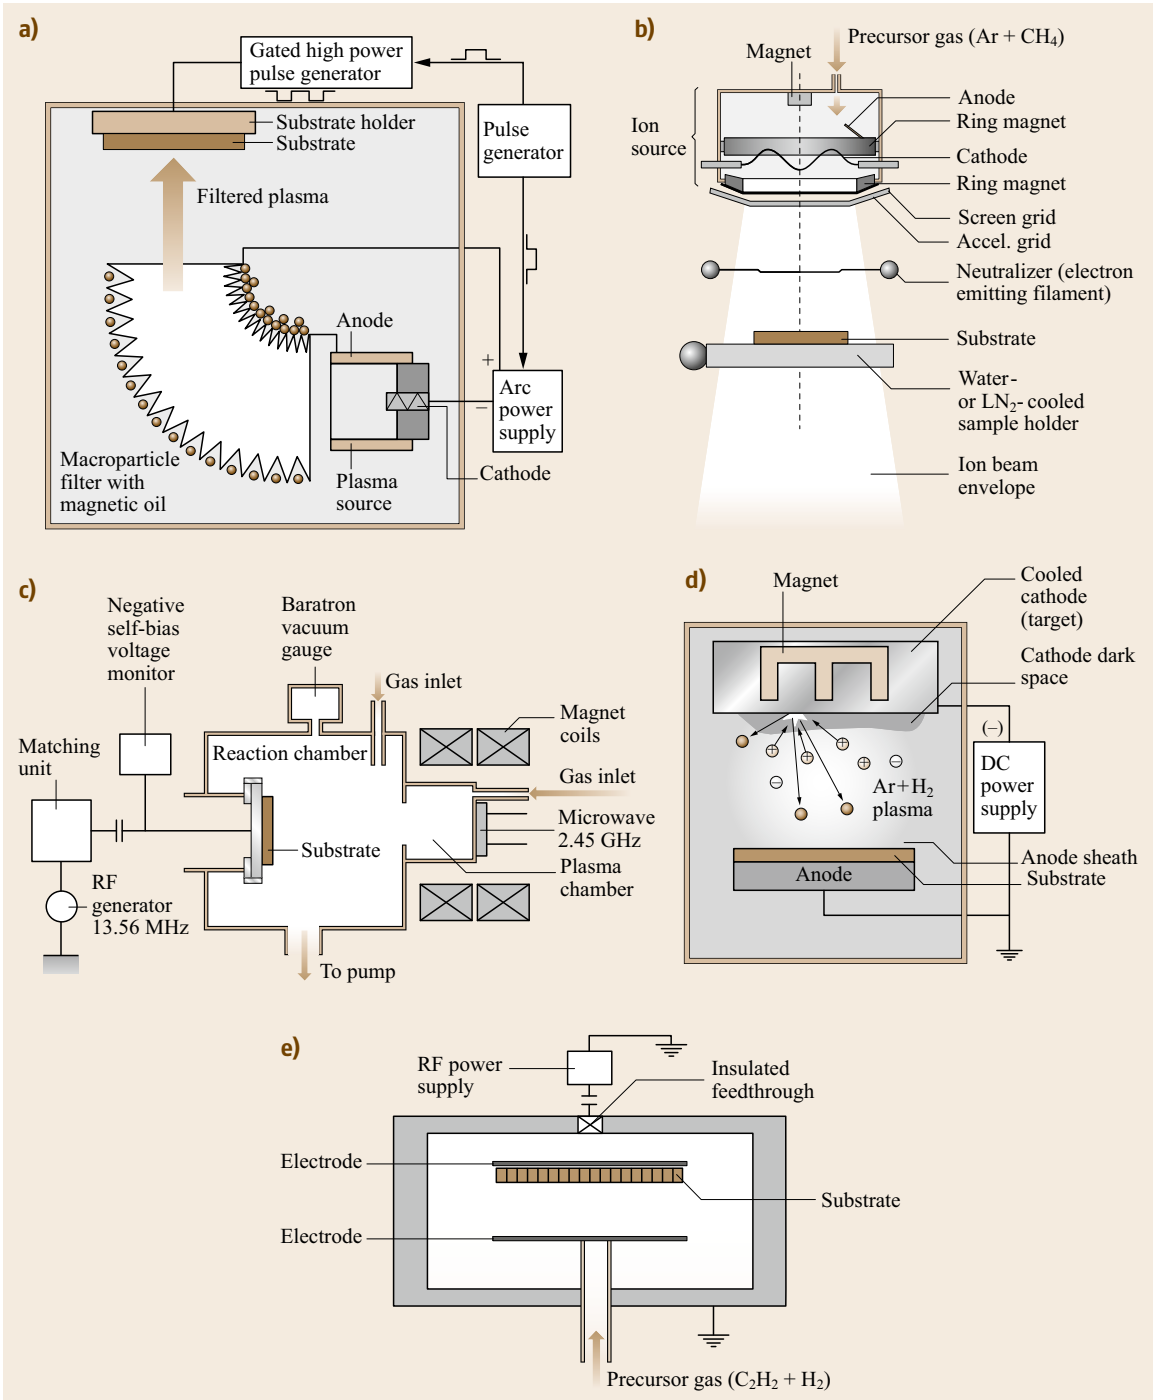

Fig. 33.4a–e Schematic diagrams of deposition by **(a)** filtered cathodic arc deposition, **(b)** ion beam deposition, **(c)** electron cyclotron resonance chemical vapor deposition (ECR-CVD), **(d)** DC planar magnetron sputtering, and **(e)** plasma-enhanced chemical vapor deposition (PECVD)

about 50 eV where they gain a high acceleration energy and reach a hot-wire filament, emitting thermionic electrons that neutralize the incoming ions. Discharging of ions is important when insulating ceramics are used as substrates. The species are then deposited on a water-cooled substrate. Operating conditions are adjusted to give an ion beam with an acceleration energy of about 200 eV and a current density of about 1 mA/cm^2. Under this operating condition, the deposition rate is about 0.1 nm/s which is slow. Incidentally, for deposition of tough and soft coatings, these are deposited at high acceleration energy of about 400 eV at a deposition rate of about 1 nm/s. The ion-beam deposited carbon coatings are reported to be hydrogenated (30–40 at.% hydrogen).

33.1.3 Electron Cyclotron Resonance Chemical Vapor Deposition Technique

The lack of electrodes and its ability to create high densities of charged and excited species at low pressures ($\leq 10^{-4}$ Torr) in ECR (electron cyclotron resonance) plasma, make it an attractive processing discharge for coating depositions [33.66]. In the ECR-CVD carbon-coating deposition process described by *Suzuki* and *Okada* [33.67] and used by *Li* and *Bhushan* [33.49, 50] and *Sundararajan* and *Bhushan* [33.51], microwave power is generated by a magnetron operating in continuous mode at a frequency of 2.45 GHz (Fig. 33.4c). The plasma chamber functions as a microwave cavity resonator. The magnetic coils arranged around the plasma chamber generate a magnetic field of 875 G necessary for electron cyclotron resonance conditions. The substrate is placed on a stage which is capacitively connected to a 13.56 MHz RF generator. The process gas is introduced into the plasma chamber and the hydrocarbon ions produced are accelerated by a negative self-bias voltage, which is generated by applying RF power to the substrate. Both the substrate stage and plasma chamber are water-cooled. The process gas used is 100% ethylene and its flow rate is held constant at 100 sccm; the microwave power is 100–900 W while the RF power is 30–120 W. The pressure during deposition is kept close to the optimum value of 5.5×10^{-3} Torr. Before the deposition, the substrates are cleaned using Ar ions generated in the ECR plasma chamber.

33.1.4 Sputtering Deposition Technique

In the DC planar magnetron sputtered carbon coating technique [33.13, 34, 38, 41, 68–72], a carbon coating is deposited by the sputtering of a graphite target with Ar ion plasma. In the glow discharge, positive ions from the plasma strike the target with sufficient energy to dislodge atoms by momentum transfer, which are intercepted by the substrate. First, a circa 5 nm thick amorphous silicon adhesion layer is deposited by sputtering if the deposition process is to be carried out on a nonsilicon surface. In the process used by *Bhushan* and coworkers (e.g., [33.12]), the coating is deposited by sputtering of the graphite target with Ar ion plasma, at 300 W power for a 200 mm diameter target and a pressure of about 0.5 Pa (6 mTorr) (Fig. 33.4d). Plasma is generated by applying a DC potential between the substrate and the target. *Bhushan* et al. [33.36] reported that the sputtered carbon coating contains about 35 at.% hydrogen. The hydrogen is derived from hydrocarbon contaminants present in the deposition chamber. To produce a hydrogenated carbon coating with a larger concentration of hydrogen, deposition is carried out in Ar and hydrogen plasma.

33.1.5 Plasma-Enhanced Chemical Vapor Deposition Technique

In the RF-PECVD carbon coating deposition process as used by Bhushan and coworkers (e.g., [33.12]), the carbon coating is deposited by adsorption of most free radicals of hydrocarbon to the substrate and chemical bonding to other atoms on the surface. The hydrocarbon species are produced by the RF plasma decomposition of hydrocarbon precursors such as acetylene (C_2H_2) (Fig. 33.4e) [33.28, 70, 73–76]. Instead of requiring thermal energy, as in thermal CVD, the energetic electrons in the plasma (at pressures ranging from 1 to 5×10^2 Pa, typically less than 10 Pa) can activate almost any reaction among the gases in the glow discharge at relatively low substrate temperatures ranging from 100 to 600 °C (typically less than 300 °C). To deposit the coating on nonsilicon substrates, a circa 4 nm thick amorphous silicon adhesion layer, used to improve adhesion, is first deposited under similar conditions from a gas mixture of 1% silane in argon [33.77]. In the process used by *Bhushan* and coworkers [33.12], the plasma is sustained in a parallel-plate geometry by a capacitive discharge at 13.56 MHz, at a surface power density on the order of 100 mW/cm^2. The deposition is carried out at a flow rate on the order of 6 sccm and at a pressure on the order of 4 Pa (30 mTorr) on a cathode-mounted substrate maintained at a substrate temperature of 180 °C. The cathode bias is fixed at the order of −120 V with an external DC power supply attached to the substrate (powered electrode). The carbon coatings deposited by PECVD usually contain hydrogen up to 50% [33.36, 78].

33.2 Chemical Characterization and Effect of Deposition Conditions on Chemical Characteristics and Physical Properties

The chemical structure and properties of amorphous carbon coatings are a function of the conditions of deposition. It is important to understand the relationship between the chemical structure of amorphous carbon coatings and their properties in order to define useful deposition parameters. Amorphous carbon films are metastable phases formed when carbon particles are condensed on a substrate. The prevailing atomic arrangement in the DLC coatings is amorphous or quasiamorphous with small diamond (sp^3), graphite (sp^2), and other unidentifiable micro- or nanocrystallites. The coatings in dependence on the deposition process and its conditions contain varying amounts of sp^3/sp^2 ratio and hydrogen. The sp^3/sp^2 ratio of DLC coatings ranges typically from 50% to close to 100% with an increase in hardness with sp^3/sp^2 ratio. Most DLC coatings except those produced by a filtered cathodic arc contain from a few to about 50 at.% hydrogen. Sometimes hydrogen and nitrogen are deliberately added to produce hydrogenated (a-C:H) and nitrogenated amorphous carbon (a-C:N) coatings, respectively. Hydrogen helps to stabilize sp^3 sites (most of the carbon atoms attached to hydrogen have a tetrahedral structure). Therefore, the sp^3/sp^2 ratio for hydrogenated carbon is higher [33.31]. The optimal sp^3/sp^2 ratio in a random covalent network composed of sp^3 and sp^2 carbon sites (N_{sp^2} and N_{sp^3}) and hydrogen is [33.31],

$$\frac{N_{sp^3}}{N_{sp^2}} = \frac{6X_H - 1}{8 - 13X_H} , \qquad (33.1)$$

where X_H is the hydrogen atom fraction. The hydrogenated carbon has a larger optical band gap, higher electrical resistivity (semiconductor), and has a lower optical absorption or high optical transmission. The hydrogenated coatings have a lower density probably because of reduction of cross-linking due to hydrogen incorporation. However, hardness decreases with an increase in hydrogen even though the proportion of sp^3 sites increases (that is, as the local bonding environment becomes more diamond-like) [33.79, 80]. It has been speculated that the high hydrogen content introduces frequent terminations in the otherwise strong three-dimensional network and that hydrogen increases the soft polymeric component of the structure more than it enhances the cross-linking sp^3 fraction.

A number of investigations have been performed to identify the microstructure of amorphous carbon films using a variety of techniques such as Raman spectroscopy, EELS, nuclear magnetic resonance, optical measurements, transmission electron microscopy, and x-ray photoelectron spectroscopy [33.34]. The structure of diamond-like amorphous carbon is amorphous or quasiamorphous with small graphitic (sp^2), tetrahedrally coordinated (sp^3), and other unidentifiable nanocrystallites (typically on the order of a couple of nm, randomly oriented) [33.34, 81, 82]. These studies indicate that the chemical structure and physical properties of the coatings are quite variable, depending on deposition techniques and film growth conditions. It is clear that both sp^2 and sp^3-bonded atomic sites are incorporated in diamond-like amorphous carbon coatings and that the physical and chemical properties of the coatings depend strongly on their chemical bonding and microstructure. Systematic studies have been conducted for chemical characterization and to investigate how the physical and chemical properties of amorphous carbon coatings vary as a function of deposition parameters (e.g., [33.34, 36, 41]). EELS and Raman spectroscopy are commonly used to characterize the chemical bonding and microstructure. Hydrogen concentration of the coatings is obtained by means of forward recoil spectrometry (FRS). A variety of physical properties of the coatings relevant to tribological performance are also measured.

To show conventional data obtained from characterization of typical amorphous carbon coatings and their relationships to physical properties, we present data in the following sections on several sputtered, one RF-PECVD amorphous carbon and one microwave-PECVD (MPECVD) diamond coating [33.34, 36, 41]. The sputtered coatings were DC magnetron sputtered at a chamber pressure of 10 mTorr, under sputtering power densities of 0.1 and 2.1 W/cm^2 in a pure Ar plasma, labeled W1 and W2, respectively. They were prepared at a power density of 2.1 W/cm^2 with various hydrogen fractions of 0.5, 1, 3, 5, 7, and 10% in Ar/H gas mixtures; these are labeled H1, H2, H3, H4, H5, and H6, respectively.

33.2.1 EELS and Raman Spectroscopy

EELS and Raman spectra were obtained of four sputtered (W1, W2, H1, and H3) and one PECVD carbon sample. Figure 33.5 shows the EELS spectra of these carbon coatings. EELS spectra for bulk diamond and polycrystalline graphite in an energy range up to 50 eV are also shown in Fig. 33.5. One prominent peak is seen at 35 eV in diamond, while two peaks are seen at 27 and 6.5 eV in graphite, which are called $(\pi + \sigma)$

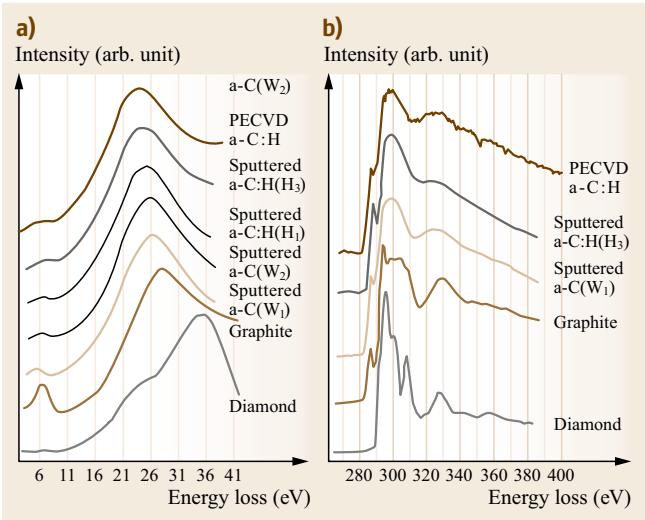

Fig. 33.5 **(a)** Low-energy and **(b)** high-energy EELS of DLC coatings produced by DC magnetron sputtering and RF-PECVD techniques. Data for bulk diamond and polycrystalline graphite are included for comparisons (after [33.36])

and (π) peaks, respectively. These peaks are produced by the energy loss of transmitted electrons to the plasmon oscillation of the valence electrons. The $\pi + \sigma$ peak in each coating is positioned at a lower energy region than that of graphite. The π peaks in the W series and PECVD samples are also seen at a lower energy region than that of the graphite. However, the π peaks in the H-series are comparable to or higher than that of graphite (Table 33.2). The plasmon oscillation frequency is proportional to the square root of the corresponding electron density to a first approximation. Therefore, the samples in the H-series most likely have a higher density of π electrons than the other samples.

Amorphous carbon coatings mainly contain a mixture of sp^2- and sp^3-bonds even though there is some evidence for the presence of sp-bonds as well [33.83]. The PECVD coatings and the H-series coatings in this study have nearly the same mass density as seen in Table 33.4, to be presented later, but the former have a lower concentration of hydrogen (18.1%) than the H-series (35–39%), as seen in Table 33.3, to be presented later. The relatively low energy position of the π peaks of PECVD coatings, compared to those of the H-series, indicates that the PECVD coatings contain a higher fraction of sp^3-bonds than the sputtered hydrogenated carbon coatings (H-series).

Figure 33.5b shows the EELS spectra associated with inner-shell (*K*-shell) ionization. Again, the spectra for diamond and polycrystalline graphite are included for comparison. Sharp peaks are observed at 285.5 and 292.5 eV in graphite, while no peak is seen at 285.5 eV in diamond. The general features of the *K*-shell EELS spectra for the sputtered and PECVD carbon samples resemble the features of graphite, but with the higher energy features smeared. The observation of the peak at 285.5 eV in the sputtered and PECVD coatings also indicates the presence of sp^2-bonded atomic sites in the coatings. All these spectra peak at 292.5 eV, similar to the spectra of graphite, but the peak in graphite is sharper.

Raman spectra from samples W1, W2, H1, and PECVD are shown in Fig. 33.6. Raman spectra could not be observed in specimens H2 and H3 due to high fluorescence signals. The Raman spectra of single-crystal diamond and polycrystalline graphite are also shown for comparison in Fig. 33.6. The results of the spectral fits are summarized in Table 33.2. We will focus on the G-band position, which has been shown to be related to the fraction of sp^3-bonded sites. Increasing the power density in the amorphous carbon coatings (W1 and W2) results in a higher G-band frequency, implying a smaller fraction of sp^3-bonding in W2 than in W1. This is consistent with the higher density of W1. H1 and PECVD still have lower G-band positions than W1, implying an even higher fraction of sp^3-bonding, which is presumably caused by the incorporation of H atoms into the lattice. The high hardness of H3 might be attributed to efficient sp^3 cross-linking of small, sp^2-ordered domains.

The Raman spectrum of a MPECVD diamond coating is shown in Fig. 33.6. The diamond Raman peak is at 1333 cm^{-1} with a line width of 7.9 cm^{-1}. There is a small broad peak around 1525 cm^{-1}, which is attributed to a small amount of a-C:H. This impurity peak is not intense enough to fit to separate G- and D-bands. The diamond peak frequency is very close to that of natural diamond (1332.5 cm^{-1}; Fig. 33.6), indicating that the coating is not under stress [33.84]. The large line width compared to that of natural diamond (2 cm^{-1}) indicates that the microcrystallites likely have a high concentration of defects [33.85].

33.2.2 Hydrogen Concentrations

FRS analysis of six sputtered (W2, H2, H3, H4, H5, and H6) coatings, one PECVD coating, and one diamond coating was performed. Figure 33.7 shows an overlay of the spectra from the six sputtered samples. Similar spectra were obtained from the PECVD and the diamond films. Table 33.3 shows the H and C fractions as well as the amount of impurities (Ar and O) in the films in atomic %. Most apparent is the large fraction of H in the sputtered films. Regardless of how much H_2 is in the Ar sputtering gas, the H content of the coatings is about the same, $\approx$ 35 at.%. Interestingly, there is still $\approx$ 10% H present in the coating sputtered in pure Ar

(W2). It is also interesting to note that Ar is present only in coatings grown under low (< 1%) H content in the Ar carrier gas. The presence of O in the coatings, combined with the fact that the coatings were prepared approximately 9 months before the FRS analysis, caused suspicion that they had absorbed water vapor, and that this may be the cause for the H peak in specimen W2.

All samples were annealed for 24 h at 250 °C in a flowing He furnace and then reanalyzed. Surprisingly, the H content of all coatings measured increased slightly, even though the O content decreased, and W2 still had a substantial amount of H_2. This slight increase in H concentration is not understood. However, since the H concentration did not decrease with the oxygen

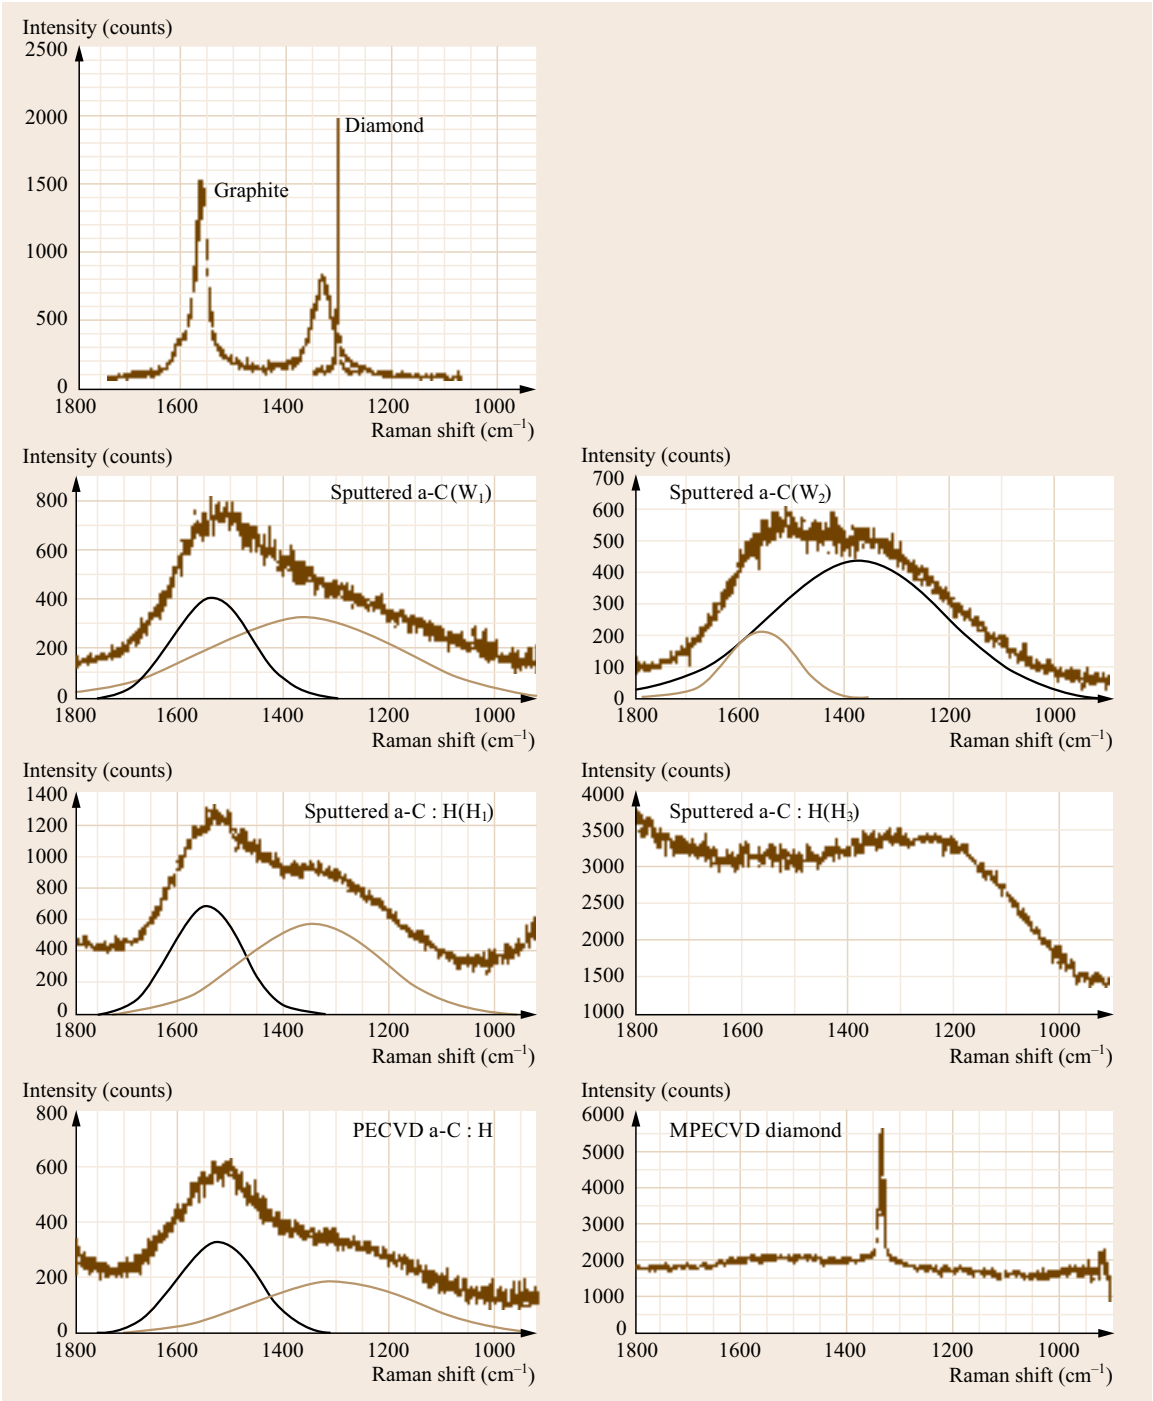

Fig. 33.6 Raman spectra of DLC coatings produced by DC magnetron sputtering and RF-PECVD techniques and a diamond film produced by the MPECVD technique. Data for bulk diamond and microcrystalline graphite are included for comparison (after [33.36])

as a result of annealing, it suggests that the high H concentration is not due to adsorbed water vapor. The PECVD film has more H ($\approx 18\%$) than the sputtered films initially, but after annealing it has the same fraction as specimen W2, the film sputtered in pure Ar. The diamond film has the smallest amounts of hydrogen, as seen in Table 33.3.

33.2.3 Physical Properties

Physical properties of the four sputtered (W1, W2, H1, and H3) coatings, one PECVD coating, one diamond coating, and bulk diamond and graphite are presented in Table 33.4. The hydrogenated carbon and the diamond coatings have very high resistivity compared to unhydrogenated carbon coatings. It appears that unhydrogenated carbon coatings have a higher density than the hydrogenated carbon coatings, although both groups are less dense than graphite. The density depends on deposition technique and parameters. It appears that unhydrogenated sputtered coatings deposited at low power exhibit the highest density. Nanohardness of hydrogenated carbon is somewhat lower than that of the unhydrogenated carbon coatings. PECVD coatings are significantly harder than sputtered coatings. The nanohardness and modulus of elasticity of the diamond coatings are very high compared to that of DLC coatings even though the hydrogen content is similar. The compressive residual stresses of the PECVD coatings are substantially higher than those of sputtered coatings, which is consistent with the hardness results.

Figure 33.8a shows the effect of hydrogen in the plasma on the residual stresses and the nanohardness for sputtered coatings W2 and H1 to H6. The coatings

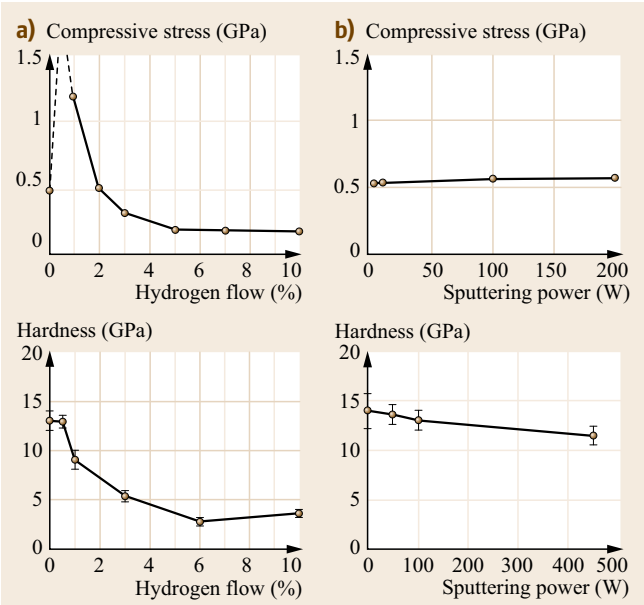

Fig. 33.8a,b Residual compressive stresses and nanohardness **(a)** as a function of hydrogen flow rate; sputtering power is 100 W and target diameter is 75 mm (power density $= 2.1\,\mathrm{W/cm^2}$), and **(b)** as a function of sputtering power over a 75 mm diameter target with no hydrogen added in the plasma (after [33.41])

made with H_2 flow between 0.5 and 1.0% delaminate very quickly, even when only a few tens of nm thick. In pure Ar and at H_2 flows greater than 1%, the coatings appear to be more adhesive. The tendency of some coatings to delaminate can be caused by intrinsic stress in the coating, which is measured by substrate bending. All of the coatings in the figure are in compressive stress. The maximum stress occurs between 0 and 1% H_2 flow, but the stress cannot be quantified in this range because the coatings instantly delaminate upon exposure to air. At higher hydrogen concentrations the stress gradually diminishes. A generally decreasing trend is observed in the hardness of the coatings as hydrogen content increased. The hardness decreases slightly, going from 0% H_2 to 0.5% H_2, and then decreases sharply. These results are probably lower than the true values because of local delamination around the indentation point. This is especially likely for the 0.5% and 1.0% coatings where delamination is visually apparent, but may also be true to a lesser extent for the other coatings. Such an adjustment would bring the hardness profile into closer correlation with the stress profile. *Weissmantel* et al. [33.69] and *Scharff* et al. [33.86] observed a downturn in hardness for high bias and low pressure of hydrocarbon gas in ion-plated carbon coating and therefore presumably low hydrogen content in support of the above contention.

Figure 33.8b shows the effect of sputtering power (with no hydrogen added in the plasma) on the residual stresses and nanohardness for various sputtered coatings. As the power decreases, compressive stress does not seem to change while nanohardness slowly increases. The rate of change becomes more rapid at very low power levels.

Addition of H_2 during sputtering of carbon coatings increases H concentration in the coating. Hydrogen causes the character of the C-C bonds to shift from sp^2 to sp^3, and the rising number of C-H bonds which ultimately relieves stress and produces a softer *polymer-like* material. Low-power deposition, like the presence of hydrogen, appears to stabilize the formation of sp^3 C-C bonds, increasing hardness. These coatings have lower stress and better adhesion. An increase in temperature during deposition at high power density results in graphitization of the coating material, responsible for a decrease in hardness with an increase in power density. Unfortunately, low power also means impractically low deposition rates.

33.2.4 Summary

On the basis of EELS and Raman data, all DLC coatings have both sp^2- and sp^3-bonding. The sp^2/sp^3 bonding ratio depends on deposition techniques and parameters. The DLC coatings deposited by sputtering and PECVD, contain significant concentrations of hydrogen while the diamond coating contains only small amounts of hydrogen impurity. Sputtered coatings with no deliberate addition of hydrogen in the plasma contain a significant amount of hydrogen. Regardless of how much hydrogen is in the Ar sputtering gas, the hydrogen content of the coatings increases initially with no further increase thereafter.

Hydrogen flow and sputtering power density affect the mechanical properties of these coatings. Maximum compressive residual stress and hardness occur between 0% and 1% hydrogen flow, resulting in rapid delamination. Low sputtering power moderately increases hardness while relieving residual stress.

33.3 Micromechanical and Tribological Characterizations of Coatings Deposited by Various Techniques

33.3.1 Micromechanical Characterization

Common mechanical characterizations include measurement of hardness and elastic modulus, fracture toughness, fatigue life, and scratch and wear testing. Nanoindentation and atomic force microscopy (AFM) are used for mechanical characterization of ultrathin films.

Hardness and elastic modulus are calculated from the load displacement data obtained by nanoindentation at loads ranging typically from 0.2 to 10 mN using a commercially available nanoindenter [33.23, 87]. This instrument monitors and records the dynamic load and displacement of the three-sided pyramidal diamond (Berkovich) indenter during indentation. For fracture toughness measurement of ultrathin films ranging from 100 nm to a few μm, a nanoindentation-based technique is used in which through-thickness cracking in the coating is detected from a discontinuity observed in the load-displacement curve and energy released during the cracking is obtained from the curve [33.88–90]. On the basis of energy released, fracture mechanics analysis is then used to calculate fracture toughness. An indenter with a cube-corner tip geometry is preferred because the through-thickness cracking of hard films can be accomplished at lower loads. In fatigue measurement, a conical diamond indenter having a tip radius of about one micron is used and load cycles of a sinusoidal shape are applied [33.91, 92]. The fatigue behavior of coatings is studied by monitoring the change in contact stiffness which is sensitive to the damage formation.

Hardness and Elastic Modulus

For materials that undergo plastic deformation, high hardness and elastic modulus are generally needed for low friction and wear, whereas for brittle materials, high fracture toughness is needed [33.1–3, 21]. DLC coatings used for many applications are hard and brittle and values of hardness and fracture toughness need to be optimized.

Representative load-displacement plots of indentations made at 0.2 mN peak indentation load on 100 nm thick DLC coatings deposited by the four deposition techniques on single-crystal silicon substrate are compared in Fig. 33.9. Indentation depths at peak load range from about 18−26 nm, smaller than that of the coating thickness. Many of the coatings exhibit discontinuity or pop-in marks in the loading curve, which indicate a sudden penetration of the tip into the sample. A nonuniform penetration of the tip into a thin coating possibly results due to either formation of cracks in the coating, formation of cracks at the coating-substrate interface, or

debonding or delamination of the coating from the substrate.

The hardness and elastic modulus values at a peak load of 0.2 mN on the various coatings and single-crystal silicon substrate are summarized in Table 33.5 and Fig. 33.10 [33.48, 50, 90, 91]. Typical values for the peak and residual indentation depths ranged from 18 to 26 nm and 6 to 12 nm, respectively. The FCA coatings exhibit the highest hardness of 24 GPa and elastic modulus of 280 GPa of the various coatings, followed by the ECR-CVD, IB, and SP coatings. Hardness and elastic modulus have been known to vary over a wide range with sp^3-to-sp^2 bonding ratio, which depends on the kinetic energy of the carbon species and amount of hydrogen [33.6, 31, 48, 93, 94]. The high hardness and elastic modulus of the FCA coatings are attributed to the high kinetic energy of carbon species involved in the FCA deposition [33.12, 48]. *Anders* et al. [33.58] also reported a high hardness, measured by nanoindentation, of about 45 GPa for cathodic arc carbon coatings. They observed a change in hardness from 25 to 45 GPa with pulsed bias voltage and bias duty cycle. The high hardness of cathodic arc carbon was attributed to the high percentage (more than 50%) of sp^3 bonding. *Savvides* and *Bell* [33.95] reported an increase in hardness from 12 to 30 GPa and in elastic modulus from 62 to 213 GPa with an increase of sp^3-to-sp^2 bonding ratio, from 3 to 6, for a-C:H coating deposited by low-energy ion-assisted unbalanced magnetron sputtering of a graphite target in an Ar-H_2 mixture.

Bhushan et al. [33.36] reported hardnesses of about 15 and 35 GPa and elastic moduli of about 140 and

200 GPa, measured by nanoindentation, for a-C:H coatings deposited by DC magnetron sputtering and RF-plasma-enhanced chemical vapor deposition techniques, respectively. The high hardness of RF-PECVD a-C:H coatings is attributed to a higher concentration of sp^3 bonding than in a sputtered hydrogenated a-C:H coating. Hydrogen is believed to play a crucial role in the bonding configuration of carbon atoms by helping to stabilize tetrahedra coordination (sp^3 bonding) of carbon species. *Jansen* et al. [33.79] suggested that the incorporation of hydrogen efficiently passivates the dangling bonds and saturates the graphitic bonding to some extent. However, a large concentration of hydrogen in the plasma in sputter deposition is undesirable. *Cho* et al. [33.34] and *Rubin* et al. [33.41] observed that hardness decreased from 15 to 3 GPa with increased hydrogen content. *Bhushan* and *Doerner* [33.96] reported a hardness of about 10–20 GPa and an elastic modulus of about 170 GPa, measured by nanoindentation, for 100 nm thick DC-magnetron sputtered a-C:H on the silicon substrate.

Residual stresses measured using a well-known curvature measurement technique are also presented in Table 33.5. The DLC coatings are under significant compressive internal stresses. Very high compressive stresses in FCA coatings are believed to be partly responsible for their high hardness. However, high stresses result in coating delamination and buckling. For this reason, the coatings thicker than about 1 μm have a tendency to delaminate from the substrates.

Fracture Toughness

Representative load-displacement curves of indentations on the 400 nm thick cathodic arc carbon coating on silicon at various peak loads are shown in Fig. 33.11. Steps are found in all curves as shown by the arrows in Fig. 33.11a. In the 30 mN SEM (scanning electron microscope) micrograph, in addition to several radial cracks, ring-like through-thickness cracking is observed with small lips of material overhanging the edge of indentation. The step at about 23 mN in the loading curves of indentations made at 30 and 100 mN peak indentation loads results from the ring-like through-thickness cracking. The step at 175 mN in the loading curve of the indentation made at 200 mN peak indentation load is caused by spalling and second ring-like through-thickness cracking.

On the basis of work by *Li* et al. [33.88], the fracture process progresses in three stages: (1) first ring-like through-thickness cracks form around the indenter by high stresses in the contact area, (2) delamination and buckling occur around contact area at the coating-substrate interface by high lateral pressure, (3) second ring-like through-thickness cracks and spalling are generated by high bending stresses at the edges of the buckled coating (Fig. 33.12a). In the first stage, if the coating under the indenter is separated from the bulk coating via the first ring-like through-thickness cracking, a corresponding step will be present in the loading curve. If discontinuous cracks form and the coating under the indenter is not separated from the remaining coating, no step appears in the loading curve because the coating still supports the indenter and the indenter cannot suddenly advance into the material. In the second stage, for the coating used in the present study, the advances of the indenter during the radial cracking, delamination, and buckling are not big enough to form steps in the loading curve because the coating around the indenter still supports the indenter, but generate discontinuities which change the slope of the loading curve with increasing indentation loads. In the third stage, the stress concentration at the end of the interfacial crack cannot be relaxed by the propagation of the interfacial crack. With an increase in indentation depth, the height of the bulged coating increases. When the height

reaches a critical value, the bending stresses caused by the bulged coating around the indenter will result in the second ring-like through-thickness crack formation and spalling at the edge of the buckled coating as shown in Fig. 33.12a, which leads to a step in the loading curve. This is a single event and results in the separation of the part of the coating around the indenter from the bulk coating via cracking through coatings. The step in the loading curve is only from coating cracks and not from interfacial or substrate cracks.

The area under the load-displacement curve is the work performed by the indenter during elastic-plastic deformation of the coating-substrate system. The strain energy release in the first/second ring-like cracking and spalling can be calculated from the corresponding steps in the loading curve. Figure 33.12b shows a modeled load-displacement curve. In the figure, OACD is the loading curve and DE is the unloading curve. The first ring-like through-thickness crack should be considered. It should be emphasized that the edge of the buckled coating is far from the indenter, therefore, it does not matter if the indentation depth exceeds the coating thickness or if deformation of the substrate occurs around the indenter when we measure fracture toughness of the coating from the released energy during the second ring-like through-thickness cracking (spalling). Suppose that the second ring-like through-thickness cracking occurs at AC. Now, let us consider the loading curve OAC. If the second ring-like through-thickness crack does not occur, it can be understood that OA will be extended to OB to reach the same displacement as OC. This means that the crack formation changes the loading curve OAB into OAC. For point B, the elastic-plastic energy stored in the coating-substrate system should be OBF. For point C, the elastic-plastic energy stored in the coating-substrate system should be OACF. Therefore, the energy difference before and after the crack generation is the area of ABC, i. e., this energy stored in ABC will be released as strain energy to create the ring-like through-thickness crack. According to the theoretical analysis by *Li* et al. [33.88], the fracture toughness of thin films can be written as

$$K_{\mathrm{Ic}} = \left[\left(\frac{E}{(1-\nu^2)\,2\pi C_{\mathrm{R}}}\right)\left(\frac{U}{t}\right)\right]^{1/2}, \qquad (33.2)$$

where E is the elastic modulus, ν is the Poisson's ratio, $2\pi C_{\mathrm{R}}$ is the crack length in the coating plane, t is the coating thickness, and U is the strain energy difference before andafter cracking.

Using (33.2), the fracture toughness of the coatings are calculated. The loading curve is extrapolated along the tangential direction of the loading curve from the starting point of the step-up to reach the same displacement as the step. The area between the extrapolated line and the step is the estimated strain energy difference before and after cracking. C_{R} is measured from SEM micrographs or AFM images of indentations. The second ring-like crack is where the spalling occurs. For example, for the 400 nm thick cathodic arc carbon coating data presented in Fig. 33.11, U of 7.1 nNm is assessed from the steps in Fig. 33.11a at the peak indentation loads of 200 mN. For C_{R} of 7.0 µm from Fig. 33.11b, $E = 300$ GPa measured using the nanoindenter and an assumed value of 0.25 for ν, the fracture toughness value is calculated as 10.9 MPa $\sqrt{m}$ [33.88, 89]. The fracture toughness and related data for various 100 nm thick DLC coatings are presented in Fig. 33.10 and Table 33.5.

Nanofatigue

A delayed fracture resulting from extended service is called fatigue [33.97]. Fatigue fracturing progresses through a material via changes within the material at the tip of a crack, where there is a high stress intensity. There are several situations: cyclic fatigue, stress corrosion, and static fatigue. Cyclic fatigue results from cyclic loading of machine components. In a low-flying slider in a magnetic head-disk interface, isolated asperity contacts occur during use and the fatigue failure occurs in the multilayered thin-film structure of the magnetic disk [33.13]. In many MEMS components, impact occurs and the failure mode is cyclic fatigue. Asperity contacts can be simulated using a sharp diamond tip in an oscillating contact with the component.

Figure 33.13 shows the schematic of a fatigue test on a coating-substrate system using a continuous stiffness measurement (CSM) technique. Load cycles are applied to the coating, resulting in a cyclic stress; P is the cyclic load, P_{mean} is the mean load, P_o is the oscillation load amplitude, and ω is the oscillation frequency. The following results can be obtained: (1) endurance limit; i. e., the maximum load below which there is no coating failure for a preset number of cycles; (2) number of cycles at which the coating failure occurs; and (3) changes in contact stiffness measured by using the unloading slope of each cycle which can be used to monitor the propagation of interfacial cracks during the cyclic fatigue process.

Figure 33.14a shows the contact stiffness as a function of the number of cycles for 20 nm thick FCA coatings cyclically deformed by various oscillation load amplitudes with a mean load of 10 μN at a frequency of 45 Hz. At 4 μN load amplitude, no change in contact stiffness was found for all coatings. This indicates that 4 μN load amplitude is not high enough to damage the coatings. At 6 μN load amplitude, an abrupt decrease in contact stiffness was found at a certain number of cycles for each coating, indicating that fatigue damage has occurred. With increasing load amplitude, the number of cycles to failure, N_f, decreases for all coatings. Load amplitude versus N_f, a so-called S–N curve, is plotted in Fig. 33.14b. The critical load amplitude, below which no fatigue damage occurs (an endurance limit), was identified for each coating. This critical load amplitude together with mean load is of critical importance to the design of head-disk interfaces or MEMS/NEMS device interfaces.

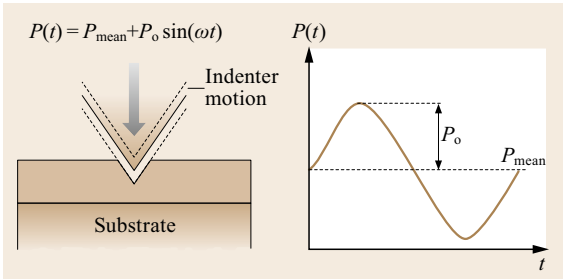

Fig. 33.13 Schematic of a fatigue test on a coating-substrate system using the continuous stiffness measurement technique

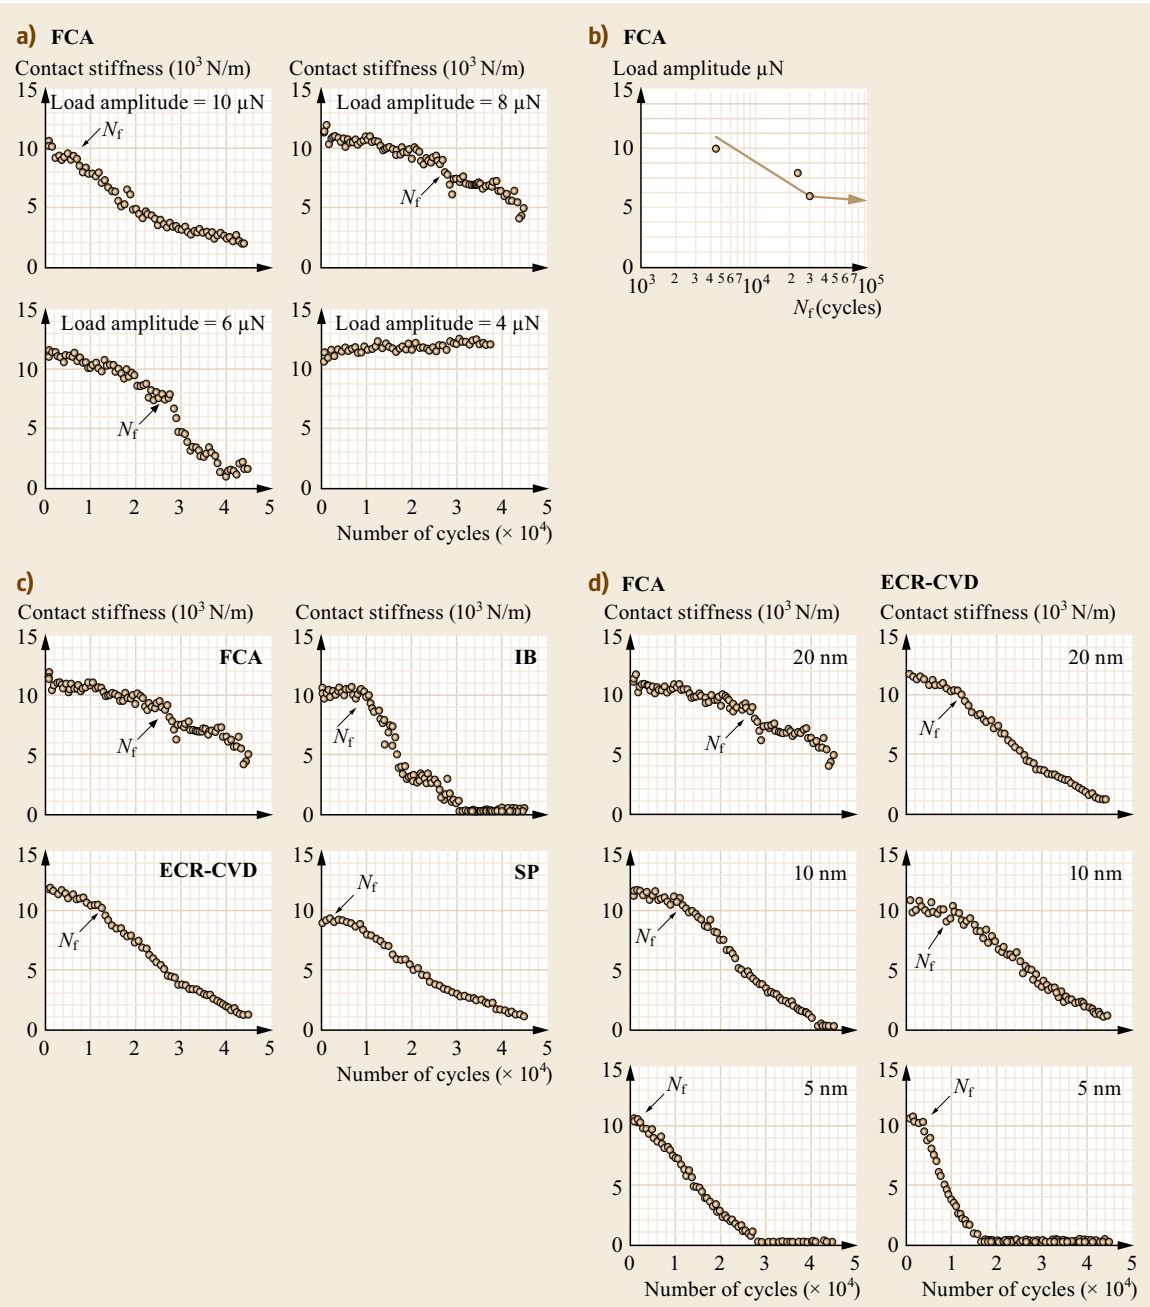

Fig. 33.14 **(a)** Contact stiffness as a function of the number of cycles for 20 nm thick FCA coatings cyclically deformed by various oscillation load amplitudes with a mean load of 10 μN at a frequency of 45 Hz; **(b)** plot of load amplitude versus N_f; **(c)** contact stiffness as a function of the number of cycles for four different 20 nm thick coatings; and **(d)** contact stiffness as a function of the number of cycles for two coatings of different thicknesses

To compare the fatigue lives of the different coatings studied, the contact stiffness as a function of the number of cycles for 20 nm thick FCA, IB, ECR-CVD, and SP coatings cyclically deformed by an oscillation load amplitude of 8 μN with a mean load of 10 μN at a frequency of 45 Hz is shown in Fig. 33.14c. The FCA coating has the longest N_f, followed by ECR-CVD, IB, and SP coatings. In addition, after N_f, the contact

stiffness of the FCA coating shows a slower decrease than the other coatings. This indicates that after N_f, the FCA coating had less damage than others. The fatigue behavior of FCA and ECR-CVD coatings of different thicknesses is compared in Fig. 33.14d. For both coatings, N_f decreases with decreasing coating thickness. At 10 nm, FCA and ECR-CVD have almost the same fatigue life. At 5 nm, the ECR-CVD coating shows a slightly longer fatigue life than the FCA coating. This indicates that even for nanometer thick DLC coatings their microstructure and residual stresses are not uniform across the thickness direction. Thinner coatings are more influenced by interfacial stresses than thicker coatings.

Figure 33.15a shows the high magnification SEM images of 20 nm thick FCA coatings before, at, and after N_f. In the SEM images, the net-like structure is the gold film coated on the DLC coating, which should be ignored in analyzing the indentation fatigue damage. Before N_f, no delamination or buckling was found except the residual indentation mark at magnifications up to 1 200 000 × using SEM. This suggests that only plastic deformation occurred before N_f. At N_f, the coating around the indenter bulged upwards, indicating delamination and buckling. Therefore, it is believed that the decrease in contact stiffness at N_f results from the delamination and buckling of the coating from the substrate. After N_f, the buckled coating was broken down around the edge of the buckled area, forming a ring-like crack. The remaining coating overhung at the edge of the buckled area. It is noted that the indentation size increases with increasing number of cycles. This indicates that deformation, delamination and buckling, and ring-like crack formation occurred over a period of time.

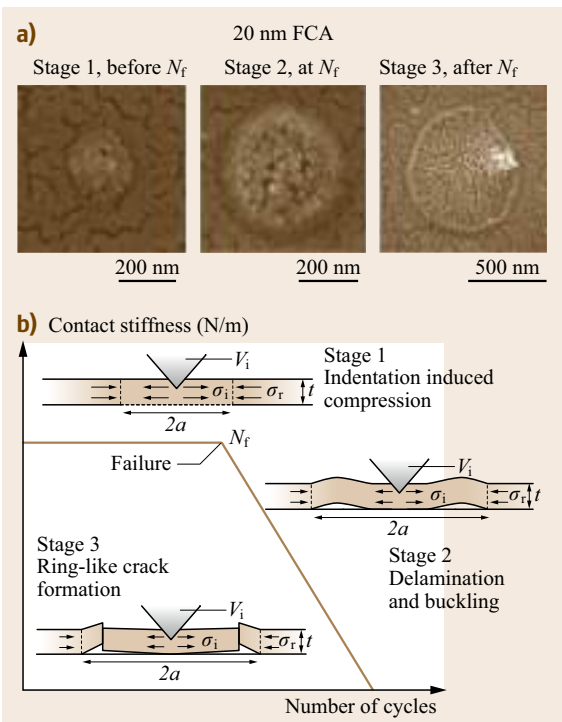

Fig. 33.15 **(a)** High magnification SEM images of a coating before, at, and after N_f, and **(b)** schematic of various stages in the indentation fatigue damage for a coating-substrate system (after [33.91])

The schematic in Fig. 33.15b shows various stages in the indentation fatigue damage for a coating-substrate system. On the basis of this study, three stages appear to exist in the indentation fatigue damage: (1) indentation-induced compression; (2) delamination and buckling; (3) ring-like crack formation at the edge of the buckled coating. Residual stresses are often induced in coatings by the deposition process. The model shown in Fig. 33.15b considers a coating with a uniform biaxial residual compression σ_r. In the first stage, indentation induces elastic/plastic deformation, exerting an outward acting pressure on the coating around the indenter. Interfacial defects like voids and impurities act as original cracks. These cracks propagate and link up as the indentation compressive stress increases. At this stage, the coating, which is under the indenter and above the interfacial crack (with a crack length of $2a$), still maintains a solid contact with the substrate; the substrate still fully supports the coating. Therefore, this interfacial crack does not lead to an abrupt decrease in contact stiffness, but gives rise to a slight decrease in contact stiffness as shown in Fig. 33.14. The coating above the interfacial crack is treated as a rigidly clamped disk. We assume that the crack radius, a, is large compared with the coating thickness t. Since the coating thickness ranges from 20 to 5 nm, this assumption is easily satisfied in this study (radius of the delaminated and buckled area, shown in Fig. 33.15a, is on the order of 100 nm). The compressive stress caused by indentation is given as [33.98]

$$\sigma_i = \frac{EV_i}{2\pi t a^2 (1-\nu)} , \qquad (33.3)$$

where ν and E are the Poisson's ratio and elastic modulus of the coating, V_i is the indentation volume, t is the coating thickness, and a is the crack radius. With increasing number of cycles, the indentation volume V_i increases. Therefore, the indentation compressive stress σ_i increases accordingly. In the second stage, buckling occurs during the unloading segment of the fatigue testing cycle when the sum of indentation compressive stress σ_i and the residual stress σ_r exceed the critical buckling stress σ_b for the delaminated circular section

as given by [33.99]

$$\sigma_b = \frac{\mu^2 E}{12\,(1-\nu^2)}\left(\frac{t}{a}\right)^2 , \qquad (33.4)$$

where the constant μ equals 42.67 for a circular clamped plate with a constrained center point and 14.68 when the center is unconstrained. The buckled coating acts as a cantilever. In this case, the indenter indents a cantilever rather than a coating-substrate system. This ultrathin coating cantilever has much less contact stiffness than the coating-substrate system. Therefore, the contact stiffness shows an abrupt decrease at N_f. In the third stage, with increasing number of cycles, the delaminated and buckled size increases, resulting in a further decrease in contact stiffness since the cantilever beam length increases. Conversely, a high bending stress acts at the edge of the buckled coating. The larger the buckled size, the higher is the bending stress. The cyclically bending stress causes fatigue damage at the end of the buckled coating, forming a ring-like crack. The coating under the indenter is separated from the bulk coating (caused by the ring-like crack at the edge of the buckled coating) and the substrate (caused by the delamination and buckling in the second stage). Therefore, the coating under the indenter is not constrained but is free to move with the indenter during fatigue testing. At this point, the sharp nature of the indenter is lost because the coating under the indenter gets stuck on the indenter. The indentation fatigue experiment results in the contact of a relatively huge blunt tip with the substrate. This results in a low contact stiffness value.

Compressive residual stresses result in delamination and buckling. A coating with higher adhesion strength and a less compressive residual stress is required for a higher fatigue life. Interfacial defects should be avoided in the coating deposition process. We know that the ring-like crack formation occurs in the coating. Formation of fatigue cracks in the coating depends upon the hardness and fracture toughness. Cracks are more difficult to form and propagate in the coating with higher strength and fracture toughness.

It is now accepted that long fatigue life in a coating-substrate almost always involves *living with cracks*, that the threshold or limit condition is associated with the nonpropagation of existing cracks or defects, even though these cracks may be undetectable [33.97]. For all coatings studied, at 4 μN, contact stiffness does not change much. This indicates that delamination and buckling did not occur within the number of cycles tested in this study. This is probably because the indentation-induced compressive stress was not high enough to allow the cracks to propagate and link up under the indenter or the sum of indentation compressive stress σ_i and the residual stress σ_r did not exceed the critical buckling stress σ_b.

Figure 33.10 and Table 33.5 summarize the hardness, elastic modulus, fracture toughness, and fatigue life of all coatings studied. A good correlation exists between fatigue life and other mechanical properties. Higher mechanical properties result in a longer fatigue life. The mechanical properties of DLC coatings are controlled by the sp^3-to-sp^2 ratio. The sp^3-bonded carbon exhibits the outstanding properties of diamond [33.52]. A higher deposition kinetic energy will result in a larger fraction of sp^3-bonded carbon in an amorphous network. Thus, the higher kinetic energy for the FCA could be responsible for its better carbon structure and higher mechanical properties [33.49–51, 100]. Higher adhesion strength between the FCA coating and substrate makes the FCA coating more difficult to delaminate from the substrate.

33.3.2 Microscratch and Microwear Studies

For microscratch studies, a conical diamond indenter (e.g., having a tip radius of about one micron and included angle of 60°) is drawn over the sample surface, and the load is increased steadily (typically 2–25 mN), until substantial damage occurs. The coefficient of friction is monitored during scratching. Scratch-induced damage of a coating, specifically fracture or delamination, can be monitored by in situ friction force measurements and by optical and SEM imaging of the scratches after tests. A gradual increase in friction is associated with plowing and an abrupt increase in friction is associated with fracture or catastrophic failure [33.101]. The load, corresponding to the abrupt increase in friction or an increase in friction above a certain value (typically 2× the initial value), provides a measure of scratch resistance or adhesive strength of a coating and is called *critical load*. Depth of scratches with increasing scratch length or normal load is measured using an AFM, typically with an area of 10 × 10 μm [33.2, 3, 49, 102].

Microscratch and microwear studies are also conducted using an AFM [33.23, 51, 100, 103, 104]. A square-pyramidal diamond tip (tip radius ≈ 100 nm) or a three-sided pyramidal diamond (Berkovich) tip, with an apex angle of 60° and a tip radius of about 100 nm, mounted on a platinum-coated, rectangular stainless steel cantilever of stiffness of about 40 N/m, is scanned orthogonal to the long axis of the cantilever to generate scratch and wear marks. During the scratch test, the normal load is either kept constant or is increased (typically from 0 to 100 μN), until damage occurs. Topography images of the scratch are obtained in situ with the AFM at a low load. By scanning the

sample during scratching, wear experiments can be conducted. Wear at a constant load is monitored as a function of number of cycles. Normal loads ranging from 10–80 μN are typically used.

Microscratch

Scratch tests conducted with a sharp diamond tip simulate a sharp asperity contact. In a scratch test, the cracking or delamination of a hard coating is signaled by a sudden increase in the coefficient of friction [33.23]. The load associated with this event is called the *critical load*.

Wu [33.105], *Bhushan* et al. [33.71], *Gupta* and *Bhushan* [33.12, 48], and *Li* and *Bhushan* [33.49, 50, 102] have used a nanoindenter to perform microscratch studies (mechanical durability) of various carbon coatings. The coefficient of friction profiles as a function of increasing normal load and AFM surface height maps of regions over scratches at the respective critical loads (indicated by the arrows in the friction profiles and AFM images), made on the various coatings of different thicknesses and the single-crystal silicon substrate using a conical tip are compared in Figs. 33.16 and 33.17. *Bhushan* and *Koinkar* [33.103], *Koinkar* and *Bhushan* [33.104], *Bhushan* [33.23], and *Sundararajan* and *Bhushan* [33.51, 100] have used an AFM to perform microscratch studies. Data for various coatings of different thicknesses and the silicon substrate using a Berkovich tip are compared in Figs. 33.18 and 33.19. Critical loads for various coatings tested using the nanoindenter and AFM are summarized in Fig. 33.20. The selected data for 20 nm thick coatings obtained using the nanoindenter, are also presented in Fig. 33.10 and Table 33.5.

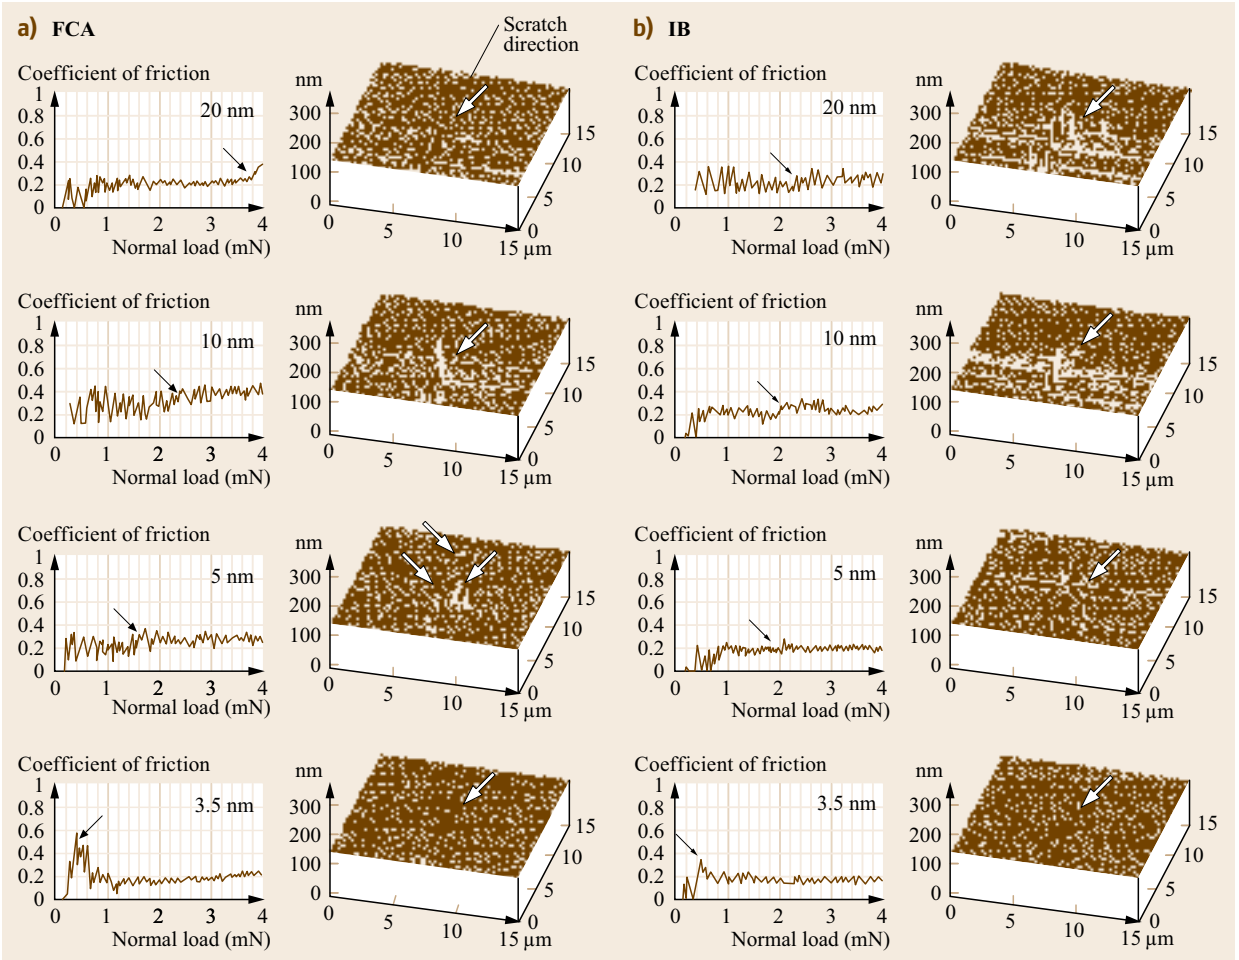

Fig. 33.16a–d Coefficient of friction profiles as a function of normal load and corresponding AFM surface height maps of regions over scratches at the respective critical loads (indicated by the *arrows* in the friction profiles and AFM images) for coatings of different thicknesses deposited by various deposition techniques: **(a)** FCA, **(b)** IB, **(c)** ECR-CVD, **(d)** SP

It can be seen that there exists a well-defined critical load for each coating. The AFM images clearly show that below the critical loads the coatings were plowed by the scratch tip, associated with the plastic flow of materials. At and after the critical loads, debris (chips) or buckling were observed on the sides of scratches. Delamination or buckling can be observed around or after the critical loads which suggests that the damage starts from delamination and buckling. For the 3.5 and 5 nm thick FCA coatings, before the critical loads small debris are observed on the sides of scratches. This suggests that the thinner FCA coatings are not so durable. It is obvious that for a given deposition method, the critical loads increase with increasing coating thickness. This indicates that the critical load is determined not only by the adhesion strength to the substrate but also by the coating thickness. We note that the debris generated on the thicker coatings are larger than that generated on the thinner coatings. For a thicker coating, which is more difficult to be broken, the broken coating chips (debris) are larger than those of the thinner coatings. The difference in the residual stresses of the coatings of different thicknesses could also affect debris size. The AFM image shows that the silicon substrate was damaged by plowing, associated with the plastic flow of materials. At and after the critical load, small and uniform debris are observed and the amount of debris increases with increasing normal load.

Since, at the critical load, the damage mechanism appears to be the onset of plowing, higher hardness and fracture toughness of a coating will therefore result in higher load required for deformation and hence higher critical load. Figure 33.21 shows critical loads of the various coatings, obtained with AFM tests, as a function of the coating hardness and fracture toughness (from Table 33.5). It can be seen that, in general, higher coating hardness and fracture toughness result

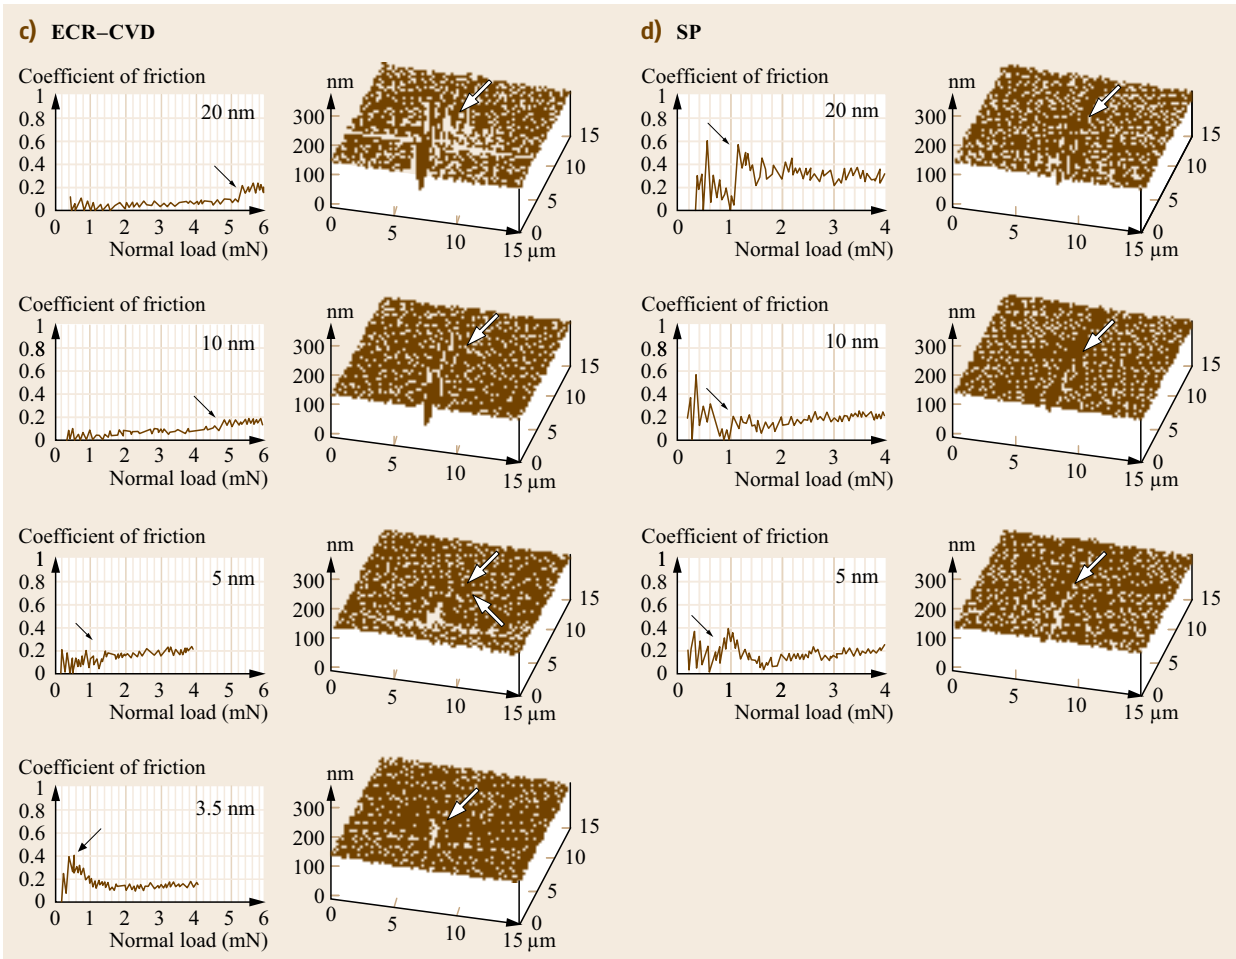

Fig. 33.16 (continued)

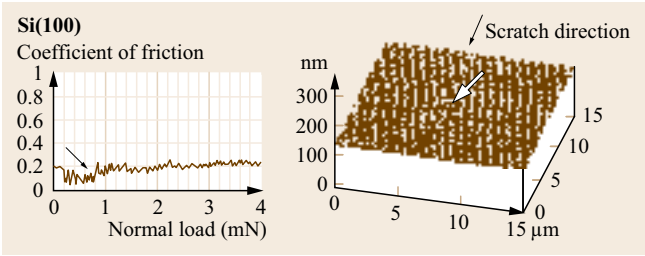

Fig. 33.17 Coefficient of friction profiles as a function of normal load and corresponding AFM surface height maps of regions over scratches at the respective critical loads (indicated by the *arrows* in the friction profiles and AFM images) for Si(100)

in higher critical load. The only exceptions are the FCA coatings at 5 and 3.5 nm coating thickness, which show the lowest critical loads despite their high hardness and fracture toughness. The brittleness of the thinner FCA coatings may be one reason for their low critical loads. The mechanical properties of coatings that are less than 10 nm thick are unknown. The FCA process may result in coatings with low hardness at such low thickness due to differences in coating stoichiometry and structure as compared to the coatings of higher thickness. Also, at these thicknesses stresses at the coating-substrate interface may affect adhesion and load-carrying capacity of the coatings.

On the basis of experimental results, a schematic of scratch damage mechanisms of the DLC coatings used in this study is shown in Fig. 33.22. Below the critical load, if a coating has a good combination of strength and fracture toughness, plowing associated with the plastic flow of materials is responsible for the damage of the coating (Fig. 33.22a). Whereas, if a coating has a lower fracture toughness, cracking could occur during plowing, associated with the formation of small debris (Fig. 33.22b). When normal load increases up to the critical load, delamination or buckling will occur at the coating-substrate interface (Fig. 33.22c). Further increase in normal load will result in breakdown of a coating via through-coating thickness cracking, as shown in Fig. 33.22d. Therefore, adhesion strength plays a crucial role in the determination of critical load. If a coating has stronger adhesive strength with the substrate, the coating is more difficult to be delaminated, which will result in a higher critical load. The interfacial and residual stresses of a coating could greatly affect the delamination and buckling [33.1]. The coating with higher interfacial and residual stresses is more easily delaminated and buckled, which will result in

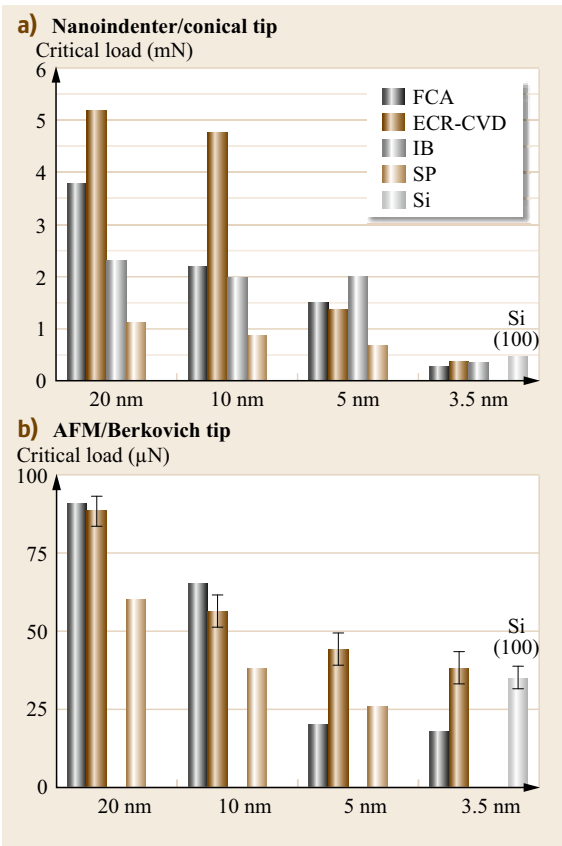

Fig. 33.20a,b Critical loads estimated from the coefficient of friction profiles from **(a)** nanoindenter and **(b)** AFM tests for various coatings of different thicknesses and the Si(100) substrate

a low critical load. It has been reported earlier that the FCA coatings have higher residual stresses than the other coatings [33.48]. Interfacial stresses play a more important role when a coating gets thinner. A large mismatch in elastic modulus between the FCA coatings and the silicon substrate may cause large interfacial stresses. This may be why the thinner FCA coatings show relatively low critical loads compared with the thicker FCA coatings, even though the FCA coatings have higher hardness and elastic modulus. The brittleness of the thinner FCA coatings may be another reason for the lower critical loads. The strength and fracture toughness of a coating also affect the critical load. Higher strength and fracture toughness will make the coating more difficult to be broken after delamination and buckling. The high scratch resistance/adhesion of FCA coatings is attributed to an atomic intermixing at the coating-substrate interface because of high kinetic energy (2 keV) plasma formed during the cathodic arc deposition process [33.58]. The atomic intermixing at the interface provides a graded compositional transi-

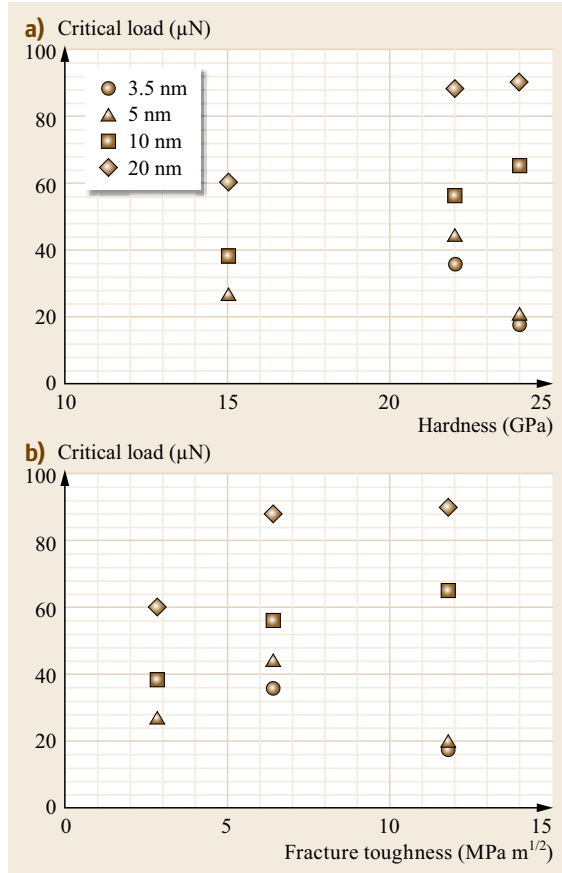

Fig. 33.21a,b Measured critical loads estimated from the coefficient of friction profiles from AFM tests as a function of **(a)** coating hardness and **(b)** fracture toughness. Coating hardness and fracture toughness values were obtained using a nanoindenter on 100 nm thick coatings (Table 33.5)

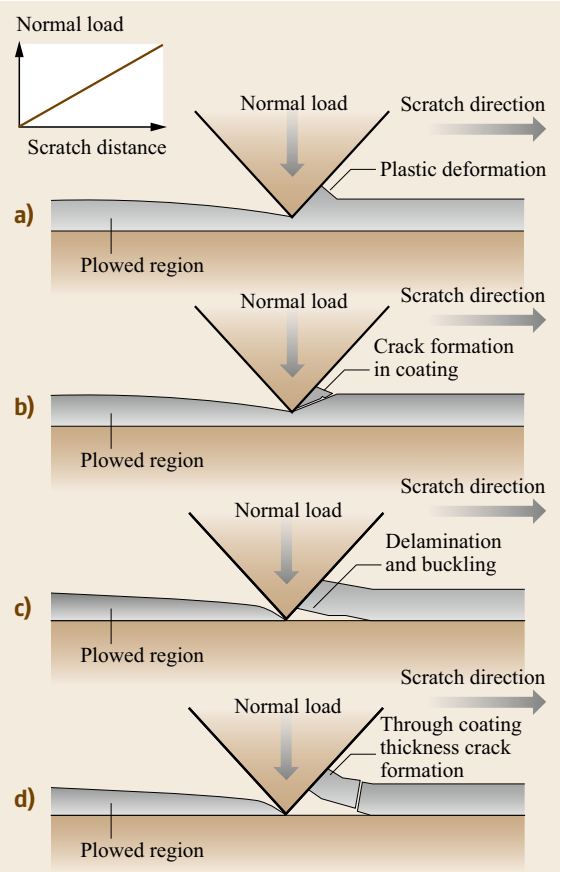

Fig. 33.22a–d Schematic of scratch damage mechanisms of the DLC coatings, **(a)** plowing associated with the plastic flow of materials, **(b)** plowing associated with the formation of small debris, **(c)** delamination and buckling at the critical load, and **(d)** breakdown via through-coating thickness cracking at and after the critical load (after [33.49])

tion between the coating and the substrate materials. In all other coatings used in this study, the kinetic energy of the plasma was insufficient for atomic intermixing.

Gupta and *Bhushan* [33.12, 48] and *Li* and *Bhushan* [33.49, 50] measured scratch resistance of DLC coatings deposited on Al_2O_3-TiC, Ni-Zn ferrite, and single-crystal silicon substrates. For good adhesion of a DLC coating to other substrates, in most cases, an interlayer of silicon is required except for cathodic arc deposited coatings. The best adhesion with cathodic arc carbon coating is obtained on electrically conducting substrates such as Al_2O_3-TiC and silicon as compared to Ni-Zn ferrite.

Microwear

Microwear studies can be conducted using an AFM [33.23]. For microwear studies, a three-sided pyramidal single-crystal natural diamond tip with an apex angle of about 80° and a tip radius of about 100 nm is used at relatively high loads of 1–150 μN. The diamond tip is mounted on a stainless steel cantilever beam with a normal stiffness of about 30 N/m. The sample is generally scanned in a direction orthogonal to the long axis of the cantilever beam (typically at a rate of 0.5 Hz). The tip is mounted on the beam such that one of its edges is orthogonal to the beam axis. For wear studies, typically an area of 2 μm × 2 μm is scanned for a selected number of cycles.

Microwear studies of various types of DLC coatings have been conducted [33.51, 103, 104]. Figure 33.23a shows a wear mark on uncoated Si(100). Wear occurs uniformly and material is removed layer by layer via plowing from the first cycle, resulting in the constant friction force seen during the wear (Fig. 33.24a). Figure 33.23b shows AFM images of the wear marks on all 10 nm coatings. It is seen that coatings wear nonuniformly. Coating failure is sudden and accompanied by a sudden rise in the friction force (Fig. 33.24b). Figure 33.24 shows the wear depth of the Si(100) substrate and various DLC coatings at two different loads. FCA and ECR-CVD, 20 nm thick coatings show excellent wear resistance up to 80 μN, the load that is required for the IB 20 nm coating to fail. In these tests, *failure* of a coating results when the wear depth exceeds the quoted coating thickness. The SP 20 nm coating fails at the much lower load of 35 μN. At 60 μN, the coating hardly provides any protection. Moving onto the 10 nm coatings, ECR-CVD coating requires about 45 cycles at 60 μN to fail as compared to IB and FCA which fail at 45 μN. The FCA coating exhibits slight roughening in the wear track after the first few cycles, which leads to an increase in the friction force. The SP coating continues to exhibit poor resistance, failing at 20 μN. For the 5 nm coatings, the load required for the coatings to fail continue to decrease. But IB and ECR-CVD still provide adequate protection as compared to bare Si(100) in that order, failing at 35 μN compared to FCA at 25 μN and SP at 20 μN. Almost all the 20, 10, and 5 nm coatings provide better wear resistance than bare silicon. At 3.5 nm, the FCA coating provides no wear resistance, failing almost instantly at 20 μN. The IB and ECR-CVD coating show good wear resistance at 20 μN compared to bare Si(100). But IB lasts only about 10 cycles and ECR-CVD about 3 cycles at 25 μN.

The wear tests highlight the differences in the coatings more vividly than the scratch tests. At higher thicknesses (20 and 10 nm), the ECR-CVD and FCA coating appear to show the best wear resistance. This is probably due to higher hardness of the coatings (see Table 33.5). At 5 nm, the IB coating appears to be the

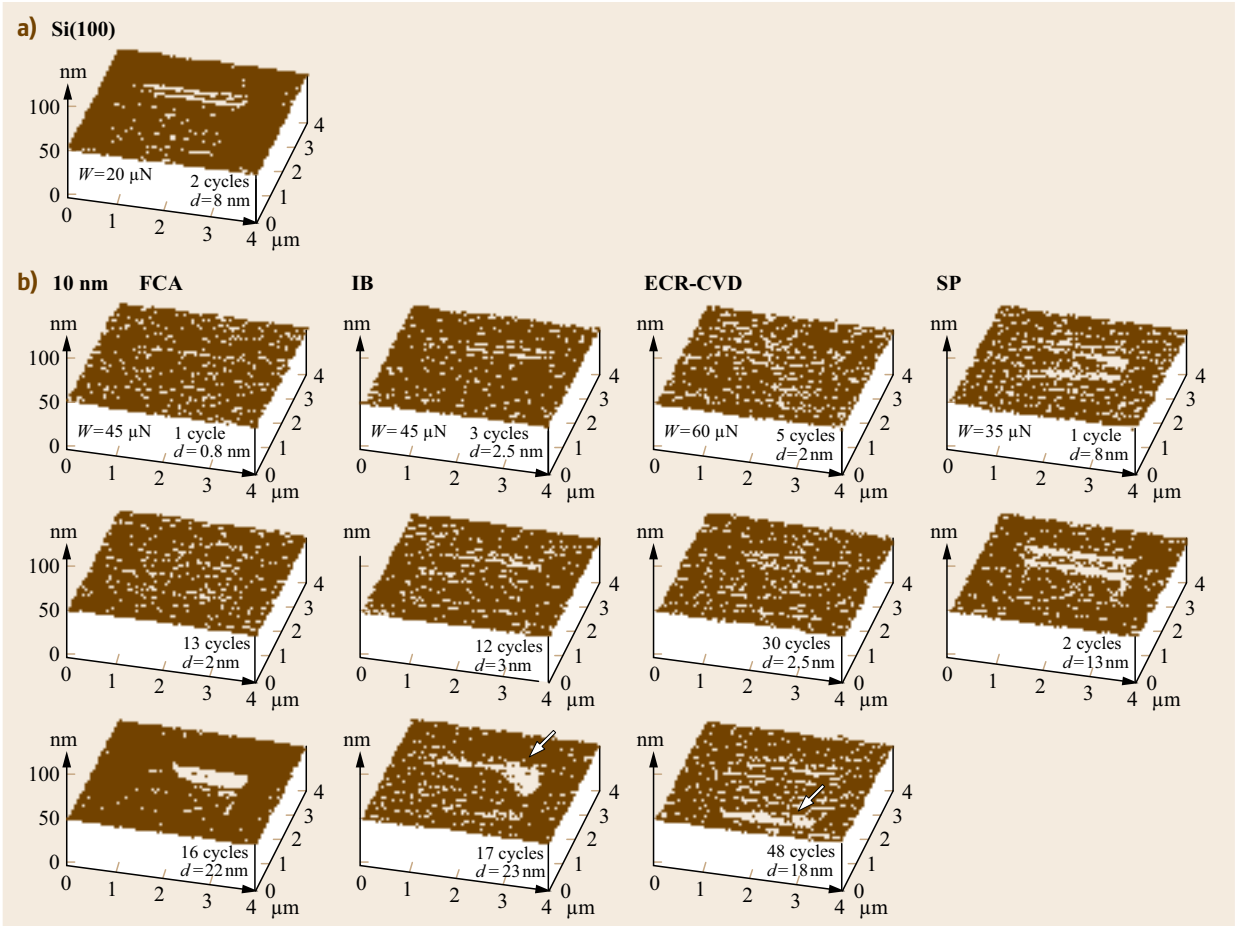

Fig. 33.23a,b AFM images of wear marks on **(a)** bare Si(100), and **(b)** all 10 nm thick DLC coatings (after [33.51])

best. FCA coatings show poorer wear resistance with decreasing coating thickness. This suggests that the trends in hardness seen in Table 33.5 no longer hold at low thicknesses. SP coatings showed consistently poor wear resistance at all thicknesses. The IB 3.5 nm coating does provide reasonable wear protection at low loads.

33.3.3 Macroscale Tribological Characterization

So far data on mechanical characterization and microscratch and microwear studies using a nanoindenter and an AFM have been presented. Mechanical properties affect tribological performance of the coatings and microwear studies simulate a single asperity contact which helps in the development of fundamental understanding of the wear process. These studies are useful in screening various candidates as well as to understand the relationships between deposition conditions and properties of various samples. As a next step, macroscale friction and wear tests need to be conducted to measure tribological performance of the coatings.

Macroscale accelerated friction and wear tests to screen a large number of candidates and functional tests on selected candidates have been conducted. An accelerated test is designed to accelerate the wear process such that it does not change the failure mechanism. The accelerated friction and wear tests are generally conducted using a ball-on-flat tribometer under reciprocating motion [33.71]. Typically, a diamond tip with 20 μm tip radius or a sapphire ball with 3 mm diameter and surface finish of about 2 nm RMS is slid against the coated substrates at selected loads. Coefficient of friction is monitored during the tests.

Functional tests are conducted using an actual machine under close to actual operating conditions for which coatings are developed. Generally, the tests are accelerated somewhat to fail the interface in a short time.

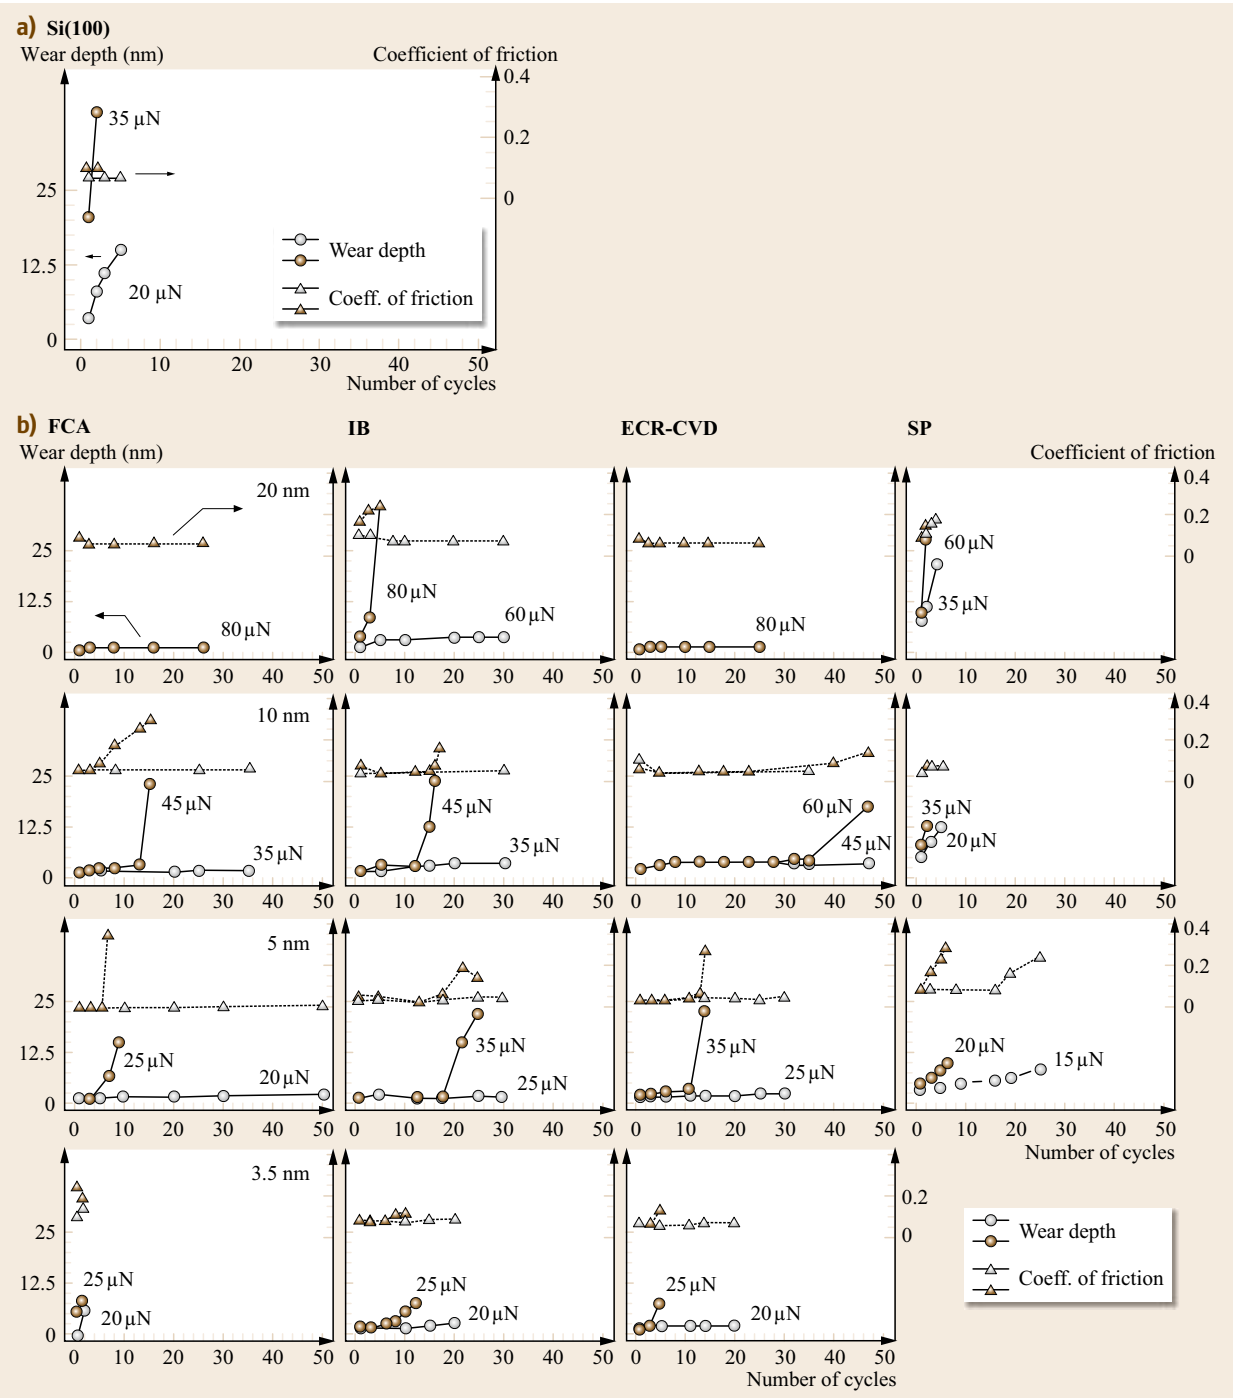

Fig. 33.24a,b Wear data of **(a)** bare Si(100) and **(b)** all DLC coatings. Coating thickness is constant along each row in **(b)**. Both wear depth and coefficient of friction during wear for a given cycle are plotted (after [33.51])

Accelerated Friction and Wear Tests

Li and *Bhushan* [33.49] conducted accelerated friction and wear tests on DLC coatings deposited by various deposition techniques, using a ball-on-flat tribometer. Average values of coefficient of friction are presented in Table 33.5. The optical micrographs of wear tracks and

debris formed on all samples when slid against a sapphire ball after sliding distance of 5 m are presented in Fig. 33.25. The normal load used for the 20 and 10 nm thick coatings is 200 mN and the normal load used for the 5 and 3.5 nm thick coatings and silicon substrate is 150 mN.

Among the 20 nm thick coatings, the SP coating exhibits a higher coefficient of friction of about 0.3 than the other coatings which have comparable values of coefficient of friction of about 0.2. The optical micrographs show that the SP coating has a larger wear track and more debris than the IB coatings. No wear track and debris were found on the 20 nm thick FCA and ECR-CVD coatings. The optical micrographs of 10 nm thick coatings show that the SP coating was severely damaged showing a large wear track with scratches and lots of debris. The FCA and ECR-CVD coatings show smaller wear tracks and less debris than the IB coatings.

For the 5 nm thick coatings, the wear tracks and debris of the IB and ECR-CVD coatings are comparable. The bad wear resistance of the 5 nm thick FCA coating is in good agreement with the low scratch critical load, which may be due to the higher interfacial and residual stresses as well as brittleness of the coating.

At 3.5 nm, all coatings exhibit wear. The FCA coating provides no wear resistance, failing instantly like the silicon substrate. Large block-like debris is observed on the sides of the wear track of the FCA coating. This indicates that large region delamination and buckling occurred during sliding, resulting in large block-like debris. These block-like debris, in turn, scratched the coating, making the coating damage even more severe. The IB and ECR-CVD coatings are able to provide some protection against wear at 3.5 nm.

In order to better evaluate the wear resistance of various coatings, based on the optical examination of the wear tracks and debris after tests, the wear damage index bar chart of the various coatings of different thicknesses and an uncoated silicon substrate is presented in Fig. 33.26. Among the 20 and 10 nm thick coatings, the SP coatings show the worst damage, followed by IB and FCA/ECR-CVD. At 5 nm, the FCA and SP coatings show the worst damage, followed by IB, and ECR-CVD coatings. All 3.5 nm thick coatings show the same heavy damage as the uncoated silicon substrate.

The wear damage mechanisms of thick and thin DLC coatings studied are believed to be as illustrated in Fig. 33.27. The deformation zone and Herztian and wear fatigue cracks formed beneath the surface during the early stages of sliding extend within the coating upon subsequent sliding [33.1]. Formation of fatigue cracks depend upon the hardness and subsequent cycles. These are controlled by the sp^3-to-sp^2 ratio. For thicker coatings, the cracks generally do not penetrate the coating. While for a thinner coating, the cracks easily propagate down to the interface with the aid of the interfacial stresses, and they get diverted along the interface just enough to cause local delamination of the coating. When this happens, the coating experiences excessive plowing. At this point, the coating fails catastrophically, resulting in a sudden rise in the coeffi-

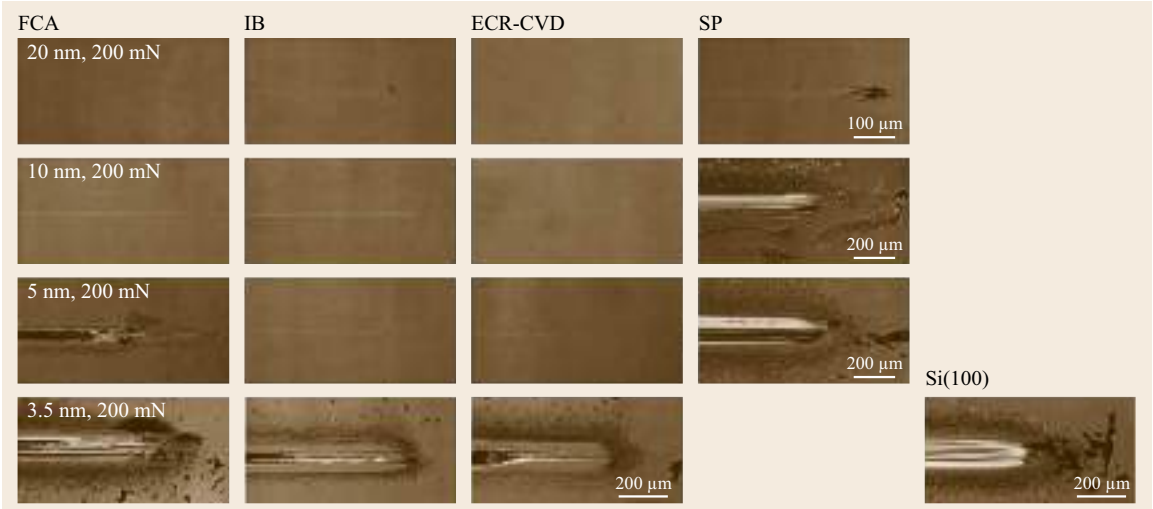

Fig. 33.25 Optical micrographs of wear tracks and debris formed on the various coatings of different thicknesses and silicon substrate when slid against a sapphire ball after sliding distance of 5 m. The end of the wear track is on the right hand side of the image

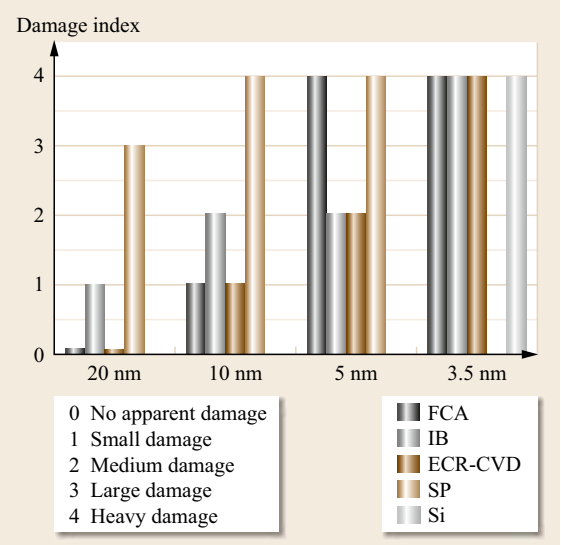

Fig. 33.26 Wear damage index bar chart of the various coatings of different thicknesses and Si(100) substrate based on optical examination of the wear tracks and debris

cient of friction. All 3.5 nm thick coatings failed much quicker as compared to the thicker coatings. It appears that these thin coatings have very low load-carrying capacity and therefore the substrate undergoes deformation almost immediately. This generates stresses at the interface that weaken coating adhesion and lead to delamination of the coating. Another reason may be that the thickness is insufficient to produce a coating comprised of the DLC structure. Instead the bulk may be made up of a matrix characteristic of the interface region where atomic mixing occurs with the substrate and/or any interlayer used. This would also result in poor wear resistance and silicon-like behavior of the coating, especially in the case of FCA coatings, which show the worst performance at 3.5 nm. In contrast to the other coatings, all SP coatings show the worst wear performance at any thickness (Fig. 33.25). This may be due to their poor mechanical properties, such as lower hardness and scratch resistance compared to the other coatings.

Comparison of Figs. 33.20 and 33.26 shows a very good correlation between wear damage and scratch critical loads. Less wear damage corresponds to higher scratch critical load. Based on the data, thicker coatings do show better scratch and wear resistance than thinner coatings. This is probably due to better load-carrying capacity of the thick coatings as compared to the thinner ones. For a given coating thickness, higher hardness and fracture toughness and better adhesion strength are believed to be responsible for the superior wear performance.

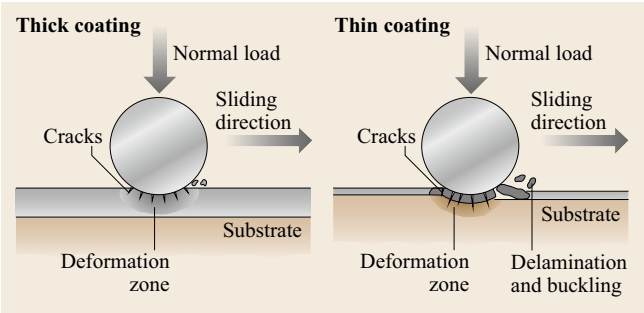

Fig. 33.27 Schematic of wear damage mechanisms of thick and thin DLC coatings (after [33.49])

Effect of Environment

Friction and wear performance of amorphous carbon coatings are found to be strongly dependent on the water vapor content and partial gas pressure in the test environment. Friction data for an amorphous carbon film on a silicon substrate sliding against steel are presented as a function of the partial pressure of water vapor in Fig. 33.28 [33.1, 13, 70, 106, 107]. Friction increases dramatically above a relative humidity of about 40%. At high relative humidity, condensed water vapor forms meniscus bridges at the contacting asperities and the menisci result in an intrinsic attractive force

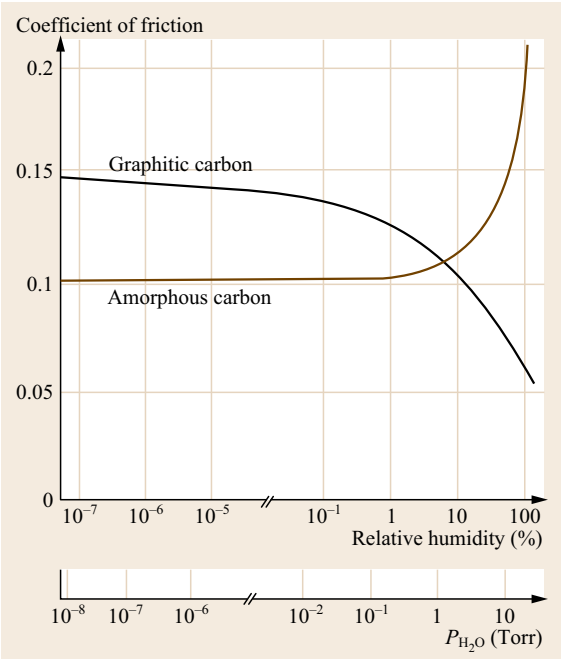

Fig. 33.28 Coefficient of friction as a function of relative humidity and water vapor partial pressure of a RF-plasma-deposited amorphous carbon coating and a bulk graphitic carbon coating sliding against a steel ball

which is responsible for an increase in friction. For completeness, the data for the coefficient of friction of bulk graphitic carbon are also presented in Fig. 33.28. Note that friction decreases with an increase in relative humidity [33.108]. Graphitic carbon has a layered lattice crystal structure. Graphite absorbs polar gases (H_2O, O_2, CO_2, NH_3, etc.) at the edges of the crystallites, which weakens the interlayer bonding forces facilitating interlayer slip and results in lower friction [33.1].

To better study the effect of environment for carbon-coated magnetic disks, a number of tests have been conducted in controlled environments. *Marchon* et al. [33.109] conducted tests in alternating environments of oxygen and nitrogen gases (Fig. 33.29). The coefficient of friction increases as soon as oxygen is added to the test environment whereas in a nitrogen environment the coefficient of friction decreases slightly. Tribochemical oxidation of the DLC coating in the oxidizing environment is responsible for an increase in the coefficient of friction implying wear. *Dugger* et al. [33.110], *Strom* et al. [33.111], *Bhushan* and *Ruan* [33.112], and *Bhushan* et al. [33.72] conducted tests with DLC-coated magnetic disks (with a circa 2 nm thick perfluoropolyether lubricant film) in contact with Al_2O_3-TiC sliders, in different gaseous environments including a high vacuum of 2×10^{-7} Torr (Fig. 33.30). The wear lives are shortest in a high vacuum and the longest in most atmospheres of nitrogen and argon with the following order (from best to worst): argon or nitrogen, Ar + H_2O, ambient air, Ar + O_2, and Ar + H_2O, vacuum. From this sequence of wear performance, we can see that having oxygen and water in an operating environment worsen the wear performance of the coatings, but having nothing in it (i. e., a vacuum) is the worst of all. Indeed, failure mechanisms differ in various environments. In high vacuum, intimate contact between disk and slider surfaces results in significant wear. In ambient air, Ar + O_2, and Ar + H_2O, tribochemical oxidation of the carbon overcoat is responsible for interface failure. For experiments performed in pure argon and nitrogen, mechanical shearing of the asperities cause the formation of debris which is responsible for the formation of scratch marks on the carbon surface as could be observed with an optical microscope [33.72].

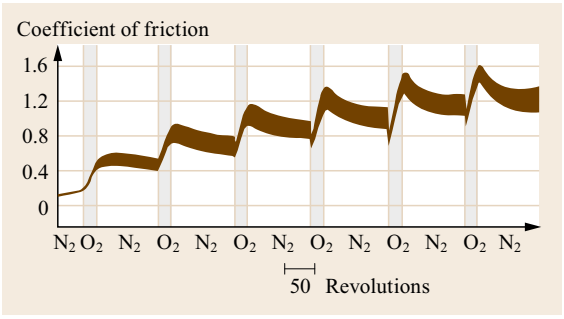

Fig. 33.29 Coefficient of friction as a function of sliding distance for a ceramic slider against a magnetic disk coated with 20 nm thick DC magnetron sputtered DLC coating, measured at a speed of 0.06 m/s and 10 g load. The environment is alternated between oxygen and nitrogen gases (after [33.109])

Functional Tests

Magnetic thin-film heads made with Al_2O_3-TiC substrate are used in magnetic storage applications [33.13]. The multilayered thin-film pole-tip structure present on the head surface wears more rapidly than the Al_2O_3-TiC substrate which is much harder. Pole-tip recession (PTR) is a serious concern in magnetic storage [33.16–20, 113]. Two of the diamond-like carbon coatings superior in mechanical properties – ion beam and cathodic arc carbon – were deposited on the air bearing surfaces of Al_2O_3-TiC head sliders [33.16]. The functional tests were conducted by running a metal-particle MP tape in a computer tape drive. Average PTR as a function of sliding distance data are presented in Fig. 33.31. We note that PTR increases for the uncoated head, whereas for the coated heads there is a slight increase in PTR in early sliding followed by little change. Thus, coatings provide protection.

The micromechanical and accelerated and functional tribological data presented here clearly suggest

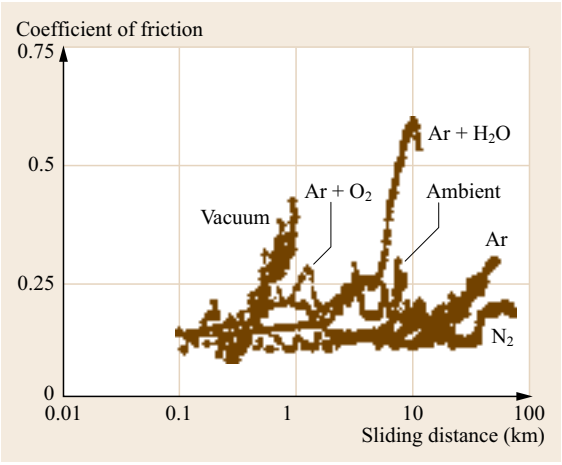

Fig. 33.30 Durability measured by sliding an Al_2O_3-TiC magnetic slider against a magnetic disk coated with a 20 nm thick DC sputtered amorphous carbon coating and a 2 nm thick perfluoropolyether film, measured at a speed of 0.75 m/s and 10 g load. Vacuum refers to 2×10^{-7} Torr (after [33.72])

that there is a good correlation between the scratch resistance and wear resistance measured using accelerated tests and functional tests. Thus, scratch tests can be successfully used to screen coatings for wear applications.

33.3.4 Coating Continuity Analysis

Ultrathin coatings less than 10 nm thick, may not uniformly coat the sample surface. In other words, the coating may be discontinuous and deposited in the form of islands on the microscale. A possible reason for poor wear protection and the nonuniform failure of the coatings may be due to poor coverage of the thin coatings on the substrate. Coating continuity can be studied by using surface analytical techniques such as Auger and/or XPS analyses. Any discontinuity with coating thickness less than sampling depth of the instrument will detect locally the substrate species [33.50, 51, 103].

The results of XPS analysis on various coatings, deposited on Si(100) substrates, over a 1.3 mm^2 region (single point measurement with spot diameter 1300 μm) are shown in Fig. 33.32. The sampling depth is about 2–3 nm. The poor SP coatings show much less carbon content (< 75% atomic concentration) as do the poor 5 nm and 3.5 nm FCA coatings (< 60%) as compared to the IB and ECR-CVD coatings. Silicon is detected in all 5 nm coatings. From the data it is hard to say if the Si is from the substrate or from exposed regions due to coating discontinuity. Based on the sampling depth any Si detected in 3.5 nm coatings would likely be from the substrate. The other interesting observation is that all poor coatings (all SP and FCA 5 and 3.5 nm) show almost twice the oxygen content compared to the other coatings. Any oxygen present may be due to leaks in the deposition chamber and is present in the form of silicon oxides.

AES (Auger electron spectroscopy) measurements, averaged over a scan area of 900 μm^2, were conducted

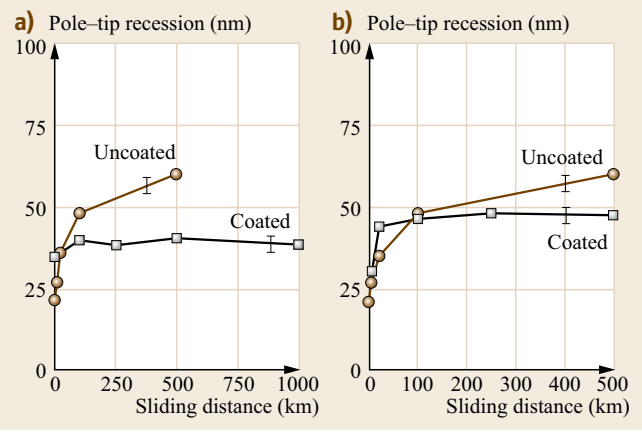

Fig. 33.31a,b Pole-tip recession as a function of sliding distance as measured with an AFM for **(a)** uncoated and 20 nm thick ion-beam carbon-coated, and **(b)** uncoated and 20 nm thick cathodic arc carbon-coated Al_2O_3-TiC heads run against MP tapes (after [33.16])

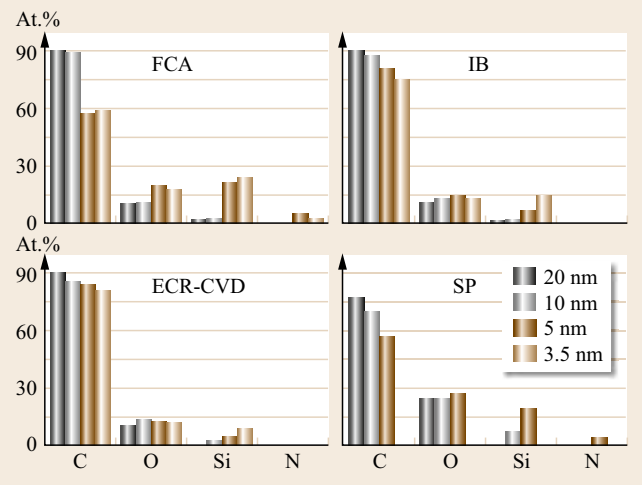

Fig. 33.32 Quantified XPS data for various DLC coatings on Si(100) substrate (after [33.51]). Atomic concentrations are shown

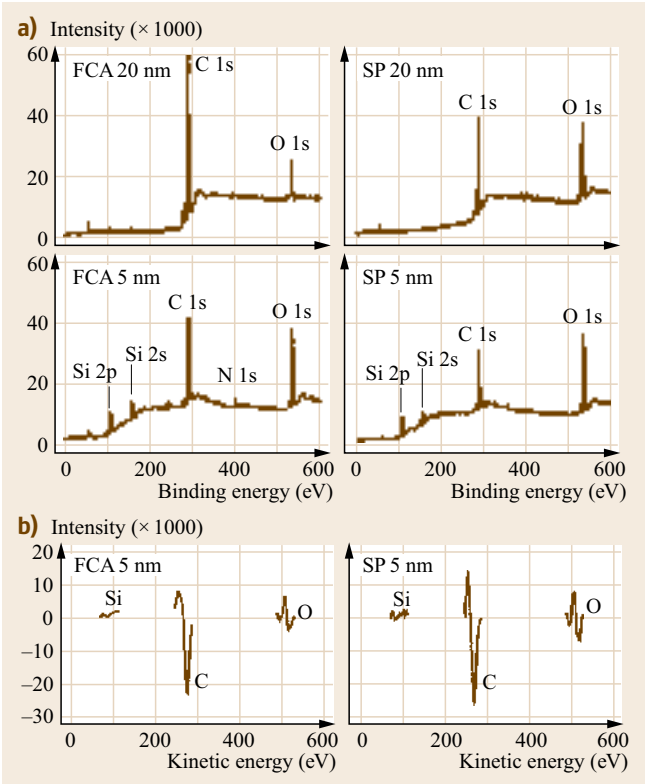

Fig. 33.33 **(a)** XPS spectra for FCA and SP coatings of 5 and 20 nm coating thicknesses on Si(100) substrate, and **(b)** AES spectra for FCA and SP coatings at 5 nm thickness on Si(100) substrate (after [33.51])

on FCA and SP 5 nm coatings at six different regions on each sample. Very little silicon was detected on this scale and the detected peaks were characteristic of oxides. The oxygen levels were comparable to that seen for the good coatings by XPS. These contrasts to the XPS measurements at a larger scale suggest that the coating possesses discontinuities only at isolated areas and that the 5 nm coatings are generally continuous on the microscale. Figure 33.33 shows representative XPS and AES spectra of selected samples.

33.4 Conclusion

Diamond material and its smooth coatings exhibit relatively low wear and friction. Major limitations of true diamond coatings are that they need to be deposited at high temperatures, can only be deposited on selected substrates, and require surface finishing. Mechanical, thermal, and optical properties of hard amorphous carbon (a-C), commonly known as DLC coatings, can be tailored to be similar to diamond. These can be deposited with a large range of thicknesses using a variety of deposition processes on a variety of substrates at or near room temperature. The coatings reproduce substrate topography, avoiding the need for postfinishing. Friction and wear properties of some DLC coatings can be very attractive for tribological applications. The largest industrial application of these coatings is in magnetic storage devices. They are also being used in MEMS/NEMS.

EELS and Raman spectroscopies can be used successfully for chemical characterization of amorphous carbon coatings. The prevailing atomic arrangement in DLC coatings is amorphous or quasiamorphous with small diamond (sp^3), graphite (sp^2), and other unidentifiable micro- or nanocrystallites. Most DLC coatings, except those produced by filtered cathodic arc, contain from a few to about 50 at.% hydrogen. Hydrogen is sometimes deliberately incorporated in the sputtered and ion-plated coatings to tailor their properties.

Amorphous carbon coatings deposited by various techniques exhibit different mechanical and tribological properties. The nanoindenter can be used successfully for measurement of hardness, elastic modulus, fracture toughness, and fatigue life. Microscratch and microwear experiments can be performed using either

a nanoindenter or an AFM. Thin coatings deposited by filtered cathodic arc, ion beam, and ECR-CVD hold promise for tribological applications. Coatings as thin as 5 nm or even thinner provide wear protection. Microscratch, microwear, and accelerated wear testing, if simulated properly, can be used successfully to screen coating candidates for industrial applications. In the examples shown in this chapter, trends observed in the microscratch, microwear, and accelerated macrofriction wear tests are similar to those found in functional tests.

34. Self-Assembled Monolayers for Nanotribology and Surface Protection

Bharat Bhushan

In many applications, hydrophobic and lubricating films are needed to minimize adhesion, stiction, friction, and wear. In various applications, surfaces need to be protected from exposure to the operating environment, and hydrophobic films are of interest. Self-assembled monolayers are molecularly thick, well organized, and chemically bonded to the substrate. Some can be insensitive to the environment and can provide lower adhesion, friction, and wear. Ordered molecular assemblies with high hydrophobicity and desirable nanotribological properties can be engineered using chemical grafting of various polymer molecules with suitable functional head groups, spacer chains, and nonpolar surface terminal groups.

In this chapter, we present an overview of self-assembled monolayers (SAMs) with hydrophobicity and desirable nanotribological properties. SAMs are produced by various organic precursors. We first present a primer to organic chemistry, followed by an overview of selected SAMs with various substrates, spacer chains, and terminal groups in the molecular chains, and an overview of nanotribological properties of SAMs. The contact angle, adhesion, friction, and wear properties of SAMs having various spacer chains with different surface terminal and head groups (hexadecane thiol, biphenyl thiol, perfluoroalkylsilane, alkylsilane, perfluoroalkylphosphonate, and alkylphosphonate) and on various substrates (Au, Si, and Al) are surveyed. Chemical degradation mechanisms and environmental effects are presented. Based on the contact angle and nanotribological properties of various SAM films discovered using an atomic force microscope (AFM), it is found that perfluoroalkylsilane and perfluorophosphonate SAMs exhibit attractive hydrophobic and nanotribological properties.

34.1 Background

The reliability concerns for engineering devices require the use of hydrophobic and lubricating films to minimize adhesion, stiction, friction, and wear [34.1–9]. In various applications, surfaces need to be protected from exposure to the operating environment. Examples include micro/nanoelectromechanical systems (MEMS/NEMS) and bioMEMS/bioNEMS, requiring relative motion, and magnetic storage devices such as magnetic rigid disk and tape drives. In some biomedical applications, such as biosensors and implantable

biomedical devices, undesirable protein adsorption, biofouling, and biocompatibility are some of the major issues [34.5, 6, 10]. In micro- and nanofluidic-based sensors, the fluid drag in micro- and nanochannels can be reduced by using hydrophobic coatings.

34.1.1 Need for Hydrophobic Surfaces for Nanotribology

The source of the liquid film at the interface can be either a preexisting film of liquid and/or capillary condensates of water vapor from the environment. If the liquid wets the surface ($0 \leq \theta < 90°$, where θ is the contact angle between the liquid-vapor interface and the liquid-solid interface for a liquid droplet sitting on a solid surface; Fig. 34.1a), the liquid surface is thereby constrained to lie parallel with the surface [34.11–13], and the complete liquid surface therefore is concave in shape; Fig. 34.1b. The direct measurement of contact angle is most widely made from sessile drops. The angle is generally measured by aligning a tangent with the drop profile at the point of contact with the solid surface using a telescope equipped with a goniometer eyepiece. Surface tension results in a pressure difference across any meniscus surface, referred to as capillary pressure or Laplace pressure, and is negative for a concave meniscus [34.14, 15]. The negative Laplace pressure results in an intrinsic attractive (adhesive) force, which depends on the interface roughness (local geometry of interacting asperities and number of asperities), the surface tension, and the contact angle.

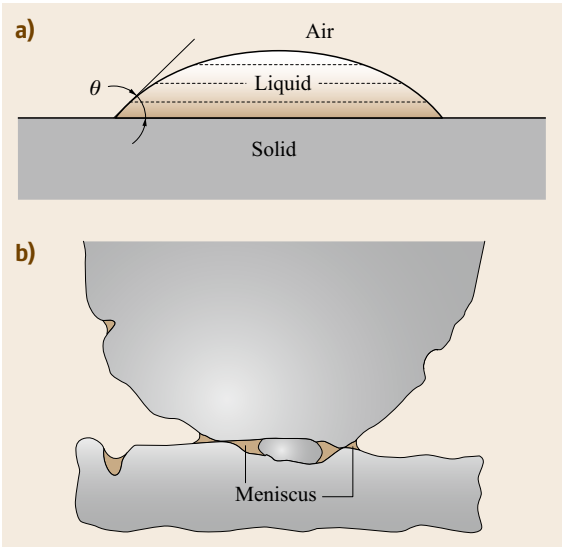

Fig. 34.1 (a) Schematic of a sessile drop on a solid surface and the definition of contact angle, and (b) formation of meniscus bridges as a result of liquid present at an interface

During normal separation, this intrinsic force needs to be overcome [34.14–16]. During sliding, frictional effects need to be overcome, not only because of external load but also because of intrinsic adhesive force. The measured value of high static friction force, contributed largely by liquid-mediated adhesion (meniscus contribution), is generally referred to as *stiction*. It becomes a major concern in micro- and nanodevices operating at ultralow loads as the liquid-mediated adhesive force may be on the same order as the external load. The effect of liquid-mediated adhesion can be minimized by increasing surface roughness and/or the use of a liquid with low surface tension with a film thickness on the order of surface roughness, as well as its chemical bonding to the substrate [34.14–22]. The formation of menisci and/or condensation of water vapor from the environment at the interface can be minimized by the use of hydrophobic (water-fearing) coatings. The surfaces can be made superhydrophobic by the introduction of controlled roughness on the surfaces to take advantage of the so-called Lotus effect [34.10, 23, 24].

34.1.2 Surface Films for Nanotribology and Surface Protection

Surfaces can be treated or coated with a liquid with relatively low surface tension or certain solid films to make them hydrophobic and/or to control adhesion, stiction, friction, and wear.

The classical approach to lubrication uses freely supported multimolecular layers of liquid lubricants [34.2, 4, 14, 15, 21, 25–29]. Boundary lubricant films are formed by either physisorption, chemisorption, or chemical reaction. The physisorbed films can be either monomolecularly or polymolecularly thick. The chemisorbed films are monomolecular, but stoichiometric films formed by chemical reaction can be multilayers. In general, stability and durability of surface films decrease in the following order: chemically reacted films, chemisorbed films, and physisorbed films. A good boundary lubricant should have a high degree of interaction between its molecules and the sliding surface. As a general rule, liquids will have a more desirable performance when they are polar and thus able to grip on solid surfaces (or be adsorbed). Polar lubricants contain reactive functional end groups. Boundary lubrication properties are also dependent upon the molecular conformation and lubricant spreading. It should be noted that the liquid films with the thickness on the order of a few nm may be discontinuous, and may deposit in an island form with nonuniform thickness with a lateral resolution on the nm scale.

Solid films are also commonly used for controlling hydrophobicity and/or adhesion, stiction, friction, and

wear. Hydrophobic films have nonpolar surface terminal groups (to be described later) that repel water. These films have low surface energy (15–30 dyn/cm) and a high contact angle ($\theta \geq 90°$), which minimize wetting [34.26, 30, 31]. Multimolecularly thick (few tenths of nm) films of conventional solid-lubricants have been studied. *Hansma* et al. [34.32] reported the deposition of multimolecularly-thick, highly oriented polytetrafluoroethylene (PTFE) films from the melt, vapor phase or from solution by a mechanical deposition technique involving dragging the polymer at controlled temperature, pressure and speed against a smooth glass substrate. *Scandella* et al. [34.33] reported that the coefficient of nanoscale friction of MoS_2 platelets on mica, obtained by the exfoliation of lithium intercalated MoS_2 in water, was a factor of 1.4 less than that of mica itself. However, MoS_2 is reactive to water, and its friction and wear properties degrade with an increase in humidity [34.14, 15].

Amorphous diamond-like carbon (DLC) coatings can be produced with extremely high hardness and are commercially used as wear-resistant coatings [34.27, 34]. They are widely used in magnetic storage devices [34.2]. Doping of the DLC matrix with elements like hydrogen, nitrogen, oxygen, silicon, and fluorine influences their hydrophobicity and tribological properties [34.27, 35, 36]. Nitrogen and oxygen reduce the contact angle (or increase the surface energy) due to the strong polarity that is formed when these elements are bonded to carbon. On the other hand, silicon and fluorine increase the contact angle ranging from 70 to 100° (or reduce the surface energy to 20–40 dyn/cm), making them hydrophobic [34.37, 38]. Nanocomposite coatings with a diamond-like carbon (a-C:H) network and a glass-like a-Si:O network are generally deposited using a PECVD (plasma-enhanced chemical vapor deposition) technique in which plasma is formed from a siloxane precursor using a hot filament. For a fluorinated DLC, CF_4 as the fluorocarbon source is added to an acetylene plasma. In addition, fluorination of DLC can be achieved by the postdeposition treatment of DLC coatings in a CF_4 plasma. Silicon- and fluorine-containing DLC coatings mainly reduce their polarity due to the loss of sp^2-bonded carbon (due to polarization potential of the involved π electrons) and dangling bonds of the DLC network. As silicon and fluorine are unable to form double bonds, they force carbon into a sp^3 bonding state [34.38]. Friction and wear properties of both silicon-containing and fluorinated DLC coatings have been reported to be superior to those of conventional DLC coatings [34.39, 40]. However, DLC coatings require a line-of-sight deposition process that prevents deposition on complex geometries. Furthermore, it has been reported that some self-assembled monolayers (SAMs) are superior to DLC coatings in hydrophobicity and tribological performance [34.41, 42].

Organized and dense molecular-scale layers of, preferably, long-chain organic molecules are known to be superior lubricants on both macro- and micro/nanoscales as compared with freely supported multimolecular layers [34.4]. Common techniques to produce molecular-scale organized layers are Langmuir–Blodgett (L–B) deposition and chemical grafting of organic molecules to realize SAMs [34.30, 31]. In the L–B technique, organic molecules from suitable amphiphilic molecules are first organized at the air-water interface and then physisorbed on a solid surface to form mono- or multimolecular layers [34.43]. In the case of SAMs, the functional groups of molecules chemisorb on a solid surface, which results in the spontaneous formation of robust, highly ordered, oriented, and dense monolayers [34.31]. In both cases, the organic molecules used have well-distinguished amphiphilic properties (a hydrophilic functional head and a hydrophobic aliphatic tail) so that an adsorption of such molecules on an active inorganic substrate leads to their firm attachment to the surface. Direct organization of SAMs on the solid surfaces allows coating in inaccessible areas. The weak adhesion of classical L–B films to the substrate surface restricts their lifetimes during sliding, whereas certain SAMs can be very durable. As a result, SAMs are of great interest in tribological applications.

Much research into the application of SAMs has been carried out using the so-called soft lithographic technique [34.44, 45]. This is a nonphotolithographic technique. Photolithography is based on a projection-printing system used for projection of an image from a mask to a thin-film photoresist, and its resolution is limited by optical diffraction limits. In soft lithography, an elastomeric stamp or mold is used to generate micropatterns of SAMs by either contact printing (known as microcontact printing or μCP [34.46]), by embossing (nanoimprint lithography) [34.47], or by replica molding [34.48], which circumvent the diffraction limits of photolithography. The stamps are generally cast from photolithographically generated patterned masters, and the stamp material is generally polydimethylsiloxane (PDMS). In μCP, the ink is a SAM precursor to produce nm-thick resists with lines thinner than 100 nm. Soft lithography requires little capital investment. μCP and embossing techniques may be used to produce microdevices that are substantially cheaper and more flexible in choice of material for construction than conventional photolithography (e.g., SAMs and non-SAM entities for μCP and elastomers for embossing).

The largest industrial application for SAMs is in digital micromirror devices (DMDs) used in optical

projection displays [34.49, 50]. The chip set of a DMD consists of half a million to more than two million independently controlled reflective aluminum alloy micromirrors of about 12 μm square. These micromirrors switch forward and backward at a frequency on the order of 5–7 kHz with a rotation of ±12° with respect to the horizontal plane; the movement is limited by a mechanical stop. Mechanical contact leads to stiction and wear in contacting surfaces. A SAM of vapor-deposited perfluorinated *n*-alkanoic acid ($C_nF_{2n-1}O_2H$) (e.g., perfluorodecanoic acid, or PFDA, $CF_3(CF_2)_8COOH$) is used to coat contacting surfaces to make them hydrophobic and thus to minimize meniscus formation. Furthermore, the entire DMD chip set is hermetically sealed in order to prevent particulate contamination and excessive condensation of water at the contacting surfaces. A so-called *getter* strip of PFDA is included inside the hermetically sealed enclosure containing the chip, which acts as a reservoir in order to maintain a PFDA vapor within the package. Degradation mechanisms of SAMs leading to stiction have been studied by *Liu* and *Bhushan* [34.51, 52]. Nanotribological studies of various SAMs on Al substrates have been carried out by *Tambe* and *Bhushan* [34.53], *Bhushan* et al. [34.54], *Hoque* et al. [34.55, 56] and *DeRose* et al. [34.57].

There are various other micro/nanodevices that require SAMs for hydrophobicity in order to minimize meniscus formation. Examples include micromotors, microgears, microvalves, microswitches, mirror-based optical switches, and atomic force microscopy probes [34.5, 6, 10]. Nanotribological studies on Si substrates have been carried out by *Bhushan* et al. [34.58–60], *Kasai* et al. [34.61], *Lee* et al. [34.62], *Tambe* and *Bhushan* [34.53] and *Tao* and *Bhushan* [34.63, 64]. SAMs deposition on Cu surfaces are also being explored for corrosion inhibition for micro/nanoelectronics and/or heat-exchange surfaces exploiting dropwise condensation [34.65–67].

Other industrial applications for SAMs are in the areas of biochemical and optical sensors, devices for use as drug-delivery vehicles, and in the construction of electronic components [34.10, 68–71]. Biochemical sensors require highly sensitive organic layers with tailored biological properties that can be incorporated into electronic, optical, or electrochemical devices. Self-assembled microscopic vesicles are being developed to ferry potentially lifesaving drugs to cancer patients. By assembling organic, metal, and phosphonate molecules (complexes of phosphorous and oxygen atoms) themselves into conductive materials, these can be produced as self-made sandwiches for use as electronic components. Several applications have been proposed based on silicon, glass, or polymer nanochannels, including cell immunoisolation chambers, DNA separation devices, and biocapsules for drug delivery [34.5, 6].

SAMs are also being considered for protection of the surfaces from exposure to the operating environment. They are being developed to reduce corrosion and oxidation of Cu in heat exchangers [34.65–67]. They are being developed to minimize undesirable protein adsorption, biofouling and improve biocompatibility in biosensors and implantable biomedical devices [34.53, 54, 58–63, 72, 73]. These films can also be used to reduce fluid drag in micro/nanochannels.

34.1.3 Scope of the Chapter

An overview of molecularly thick layers of liquid lubricants and conventional solid lubricants can be found in various references, such as [34.2, 4, 10, 14, 15, 18, 19, 21, 27, 29]. In this chapter, we present an overview of SAMs for high hydrophobicity, low adhesion, friction, and wear. SAMs are produced by various organic precursors. We first present a primer on organic chemistry followed by an overview of suitable substrates, spacer chains and end groups in the molecular chains, an overview of contact angle, adhesion, friction, and wear properties of various SAMs, and some concluding remarks.

34.2 A Primer on Organic Chemistry

All organic compounds contain the carbon atom. Carbon, in combination with hydrogen, oxygen, nitrogen, sulfur and phosphor results in a large number of organic compounds. The atomic number of carbon is 6, and its electron structure is $1s^2 2s^2 2p^2$. Two stable isotopes of carbon, ^{12}C and ^{13}C, exist. With four electrons in its outer shell, carbon forms four covalent bonds with each bond resulting from two atoms sharing a pair of electrons. The number of electron pairs that two atoms share determines whether or not the bond is single or multiple. In a single bond, only one pair of electrons is shared by the atoms. Carbon can also form multiple bonds by sharing two or three pairs of electrons between the atoms. For example, the double bond formed by sharing two electron pairs is stronger than a single bond, and it is shorter than a single bond. An organic compound is classified as saturated if it contains only single bonds and as unsaturated if the

molecules possess one or more multiple carbon-carbon bonds.

34.2.1 Electronegativity/Polarity

When two different kinds of atoms share a pair of electrons, a bond is formed in which electrons are shared unequally: one atom assumes a partial positive charge and the other a negative charge with respect to each other. This difference in charge occurs because the two atoms exert unequal attraction in the pair of shared electrons. The attractive force that an atom of an element has for shared electrons in a molecule or polyatomic ion is known as its electronegativity. Elements differ in their electronegativities. A scale of relative electronegatives, in which the most electronegative element, fluorine, is assigned a value of 4.0, was developed by L. Pauling. Relative electronegativities of the elements in the periodic table can be found in most undergraduate chemistry textbooks [34.74]. Relative electronegativity of the nonmetals is high as compared to that of metals. Relative electronegativity of selected elements of interest with high values is presented in Table 34.1.

The polarity of a bond is determined by the difference in electronegativity values of the atoms forming the bond. If the electronegativities are the same the bond is nonpolar, and the electrons are shared equally. In this type of bond, there is no separation of positive and negative charge between atoms. If the atoms have greatly different electronegativities the bond is very polar. A dipole is a molecule that is electrically asymmetrical, causing it to be oppositely charged at two points. As an example, in hydrogen chloride, HCl, both hydrogen and chlorine need one electron to form stable electron configurations. They share a pair of electrons. Chlorine is more electronegative and therefore has a greater attraction for the shared electrons than does hydrogen. As a result, the pair of electrons is displaced towards the chlorine atom, giving it a partial negative charge and leaving the hydrogen atom with a partial positive charge (Fig. 34.2). However, the entire molecule, HCl, is electrically neutral. The hydrogen atom with a partial positive charge (exposed proton on one end) can be easily attracted to the negative charge of other molecules and this is responsible for the polarity of the molecule. A partial charge is usually indicated by δ, and the electronic structure of HCl is given as

$$\overset{\delta+}{\mathrm{H}} : \overset{\delta-}{\underset{\cdot\cdot}{\overset{\cdot\cdot}{\mathrm{Cl}}}} :$$

Similar to the HCl molecule, hydrofluoric acid (HF) is polar, and both behave as a small dipole. On the other hand, methane (CH_4), carbon tetrachloride (CCl_4), and carbon dioxide (CO_2) are nonpolar. In CH_4 and CCl_4, the four C−H and C−Cl polar bonds are identical, and because these bonds emanate from the center to the corners of a tetrahedron in the molecule, the effect of their polarities cancels one another. CO_2 (O=C=O) is nonpolar because carbon-oxygen dipoles cancel each other by acting in opposite directions. Water (H−O−H) is a polar molecule. If the atoms in water were linear as in CO_2, two O−H dipoles would cancel each other, and the molecule would be nonpolar. However, water has a bent structure with an angle of 105° between the two bonds, which is responsible for the water being a polar molecule.

Table 34.1 Relative electronegativity of selected elements

Element	Relative electronegativity
F	4.0
O	3.5
N	3.0
Cl	3.0
C	2.5
S	2.5
P	2.1
H	2.1

34.2.2 Classification and Structure of Organic Compounds

Table 34.2 presents selected organic compounds grouped into classes.

Hydrocarbons

Hydrocarbons are compounds that are composed entirely of carbon and hydrogen atoms bonded to each other by covalent bonds. Saturated hydrocarbons (alkanes) contain single bonds. Unsaturated hydrocarbons that contain carbon-carbon double bonds are called

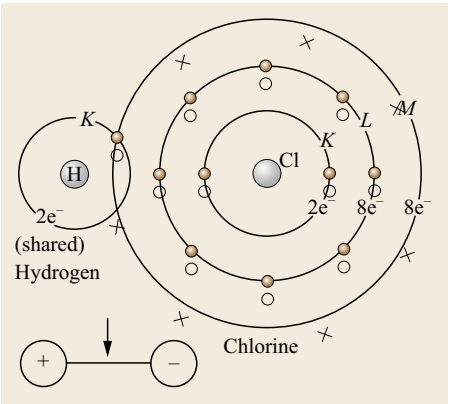

Fig. 34.2 Schematic representation of the formation of a polar HCl molecule

alkenes, and ones with triple bonds are called alkynes. Unsaturated hydrocarbons that contain aromatic rings, e.g., benzene rings, are called aromatic hydrocarbons.

Saturated Hydrocarbons: Alkanes. The alkanes, also known as paraffins, are saturated hydrocarbons: straight- or branched-chain hydrocarbons with only single covalent bonds between the carbon atoms. The general molecular formula for alkanes is C_nH_{2n+2}, where n is the number of carbon atoms in the molecule. Each carbon atom is connected to four other atoms by four single covalent bonds. These bonds are separated by angles of 109.5° (the angle by lines drawn from the center of a regular tetrahedron to its corners). Alkane molecules contain only carbon-carbon and carbon-hydrogen bonds, which are symmetrically directed towards the corners of a tetrahedron. Therefore alkane molecules are essentially nonpolar.

Common alkyl groups have the general formula C_nH_{2n+1} (one hydrogen atom less than the corresponding alkane). The missing H atom may be detached from any carbon in the alkane. The name of the group is formed from the name of the corresponding alkane by replacing the -ane with an -yl ending. Some examples are shown in Table 34.2.

Unsaturated Hydrocarbons. Unsaturated hydrocarbons consist of three families of compounds that contain fewer hydrogen atoms than the alkane with the corresponding number of carbon atoms, and contain multiple bonds between carbon atoms. These include alkenes (with carbon-carbon double bonds), alkynes (with carbon-carbon triple bonds), and aromatic compounds (with benzene rings, which are arranged in a six-membered ring with one hydrogen atom bonded to each carbon atom). Some examples are shown in Table 34.2.

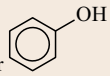

Table 34.2 Names and formulas of selected hydrocarbons

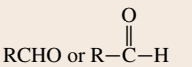
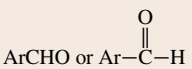
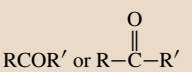
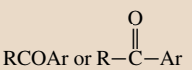
Name	Formula
Saturated hydrocarbons	
Straight-chain alkanes	C_nH_{2n+2}
e.g., methane	CH_4
ethane	C_2H_6 or CH_3CH_3
Alkyl groups	C_nH_{2n+1}
e.g., methyl	$-CH_3$
ethyl	$-CH_2CH_3$
Unsaturated hydrocarbons	
Alkenes	$(CH_2)_n$
e.g., ethene	C_2H_4 or $CH_2{=}CH_2$
propene	C_3H_6 or $CH_3CH{=}CH_2$
Alkynes	
e.g., acetylene	$HC \equiv CH$
Aromatic hydrocarbons	
e.g., benzene	C_6H_5OH or 

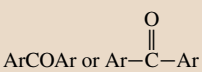
Alcohols, Ethers, Phenols, and Thiols











Organic molecules with certain functional groups are synthesized for desirable properties. Alcohols, ethers and phenols are derived from the structure of water by replacing the hydrogen atoms of water with alkyl groups (R) or aromatic (Ar) rings. For example, phenol is a class of compounds that has a hydroxy group

Table 34.3 Names and formulas of selected alcohols, ethers, phenols and thiols

Name	Formula[a]
Alcohols	R−OH
e.g., methanol	CH_3OH
ethanol	CH_3CH_2OH
Ethers	R−O−R′
e.g., dimethyl ether	$CH_3{-}O{-}CH_3$
diethyl ether	$CH_3CH_2{-}O{-}CH_2CH_3$
Phenols	 C_6H_5OH or
Thiols	−SH
e.g., methanethiol	CH_3SH

[a] The letters R- and R′- represent an alkyl group. The R- groups in ethers can be the same or different and can be alkyl or aromatic (Ar) groups

Table 34.4 Names and formulas of selected aldehydes and ketones

Name	Formula[a]
Aldehydes	 RCHO or R−C(=O)−H
	 ArCHO or Ar−C(=O)−H
e.g., methanal or formaldehyde	HCHO
ethanal or acetaldehyde	CH_3CHO
Ketones	 RCOR′ or R−C(=O)−R′
	 RCOAr or R−C(=O)−Ar
	 ArCOAr or Ar−C(=O)−Ar
e.g., butanone or methyl ethyl ketone	$CH_3COCH_2CH_3$

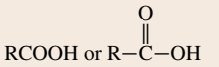
[a] The letters R and R′ represent an alkyl group and Ar represents an aromatic group

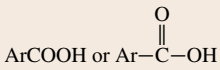
attached to an aromatic ring (benzene ring). Organic compounds that contain the –SH group are analogs of alcohols, and are known as thiols. Some examples are shown in Table 34.3.

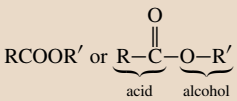
Aldehydes and Ketones

Both aldehydes and ketones contain the carbonyl group C=O, a carbon-oxygen double bond. Aldehydes have at least one hydrogen atom bonded to the carbonyl group, whereas ketones have only alkyl or aromatic group bonded to the carbonyl group. The general formula for the saturated homologous series of aldehydes and ketones is $C_nH_{2n}O$. Some examples are shown in Table 34.4.

Carboxyl Acids and Esters



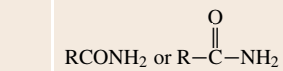


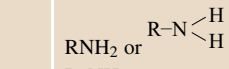


The functional group of the carboxylic acids is known as a carboxyl group represented as −COOH. Carboxylic acids can be either aliphatic (RCOOH) or aromatic (ArCOOH). The carboxylic acids with even numbers of carbon atoms, n, ranging from 4 to about 20 are called fatty acids (e.g., $n = 10$, 12, 14, 16 and 18 are called capric acid, lauric acid, myristic acid, palmitic acid, and stearic acid respectively).

Esters are alcohol derivatives of carboxylic acids. Their general formula is RCOOR′, where R may be a hydrogen, alkyl group, or aromatic group, and R′ may be an alkyl group or aromatic group, but not a hydrogen. Esters are found in fats and oils. Some examples are shown in Table 34.5.

Amides and Amines

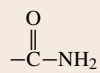


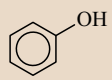


Amides and amines are organic compounds containing nitrogen. Amides are nitrogen derivatives of carboxylic acids. The carbon atom of a carbonyl group is bonded

Table 34.5 Names and formulas of selected carboxylic acids and esters

Name	Formula
Carboxylic acid[a]	 RCOOH or R–C(=O)–OH
	 ArCOOH or Ar–C(=O)–OH
e.g., methanoic acid (formic acid)	HCOOH
ethanoic acid (acetic acid)	CH_3COOH
octadecanoic acid (stearic acid)	$CH_3(CH_2)_{16}COOH$
Esters[b]	 RCOOR′ or R–C(=O)–O–R′ (acid, alcohol)
e.g., methyl propanoate	$CH_3CH_2COOCH_3$





[a] The letter R represents an alkyl group and Ar represents an aromatic group
[b] The letter R represents hydrogen, alkyl group or aromatic group and R′ represents alkyl group or aromatic group

Table 34.6 Names and formulas of selected organic nitrogen compounds (amides and amines)

Name	Formula[a]
Amides	 $RCONH_2$ or R–C(=O)–NH_2
e.g., methanamide (formamide)	$HCONH_2$
ethanamide (acetamide)	CH_3CONH_2
Amines	 RNH_2 or R_2NH or R_3N
e.g., methylamine	CH_3NH_2
ethylamine	$CH_3CH_2NH_2$

[a] The letter R represents an alkyl group or aromatic group

Table 34.7 Some examples of polar (hydrophilic) and nonpolar (hydrophobic) groups

Name	Formula[a]
Polar	
Alcohol (hydroxyl)	−OH
Carboxyl acid	−COOH
Aldehyde	−COH
Ketone	 R–C(=O)–R
Ester	−COO−
Carbonyl	>C=O
Ether	R−O−R
Amine	$-NH_2$
Amide	 –C(=O)–NH_2
Phenol	 OH
Thiol	−SH
Trichlorosilane	$SiCl_3$
Nonpolar	
Methyl	$-CH_3$
Trifluoromethyl	$-CF_3$
Aryl (benzene ring)	

[a] The letter R represents an alkyl group

directly to a nitrogen atom of an $-NH_2$, $-NHR$, or $-NR_2$ group. The characteristic structure of amide is $RCONH_2$.

An amine is a substituted ammonia molecule which, has a general structure of RNH_2, R_2NH or R_3N, where R is an alkyl or aromatic group. Some examples are shown in Table 34.6.

34.2.3 Polar and Nonpolar Groups

Table 34.7 summarizes polar and nonpolar groups commonly used in the construction of hydrophobic and hydrophilic molecules. Table 34.8 lists the relative polarity of selected polar groups [34.75]. Thiol, silane, carboxylic acid, and alcohol (hydroxyl) groups are the most commonly used polar anchor groups for their attachment to surfaces. Silane anchor groups are commonly used for Si or SiO_2 surfaces as $-Si-O-$ bonds are strong. Methyl and trifluoromethyl are commonly used as end groups for hydrophobic film surfaces.

Table 34.8 Organic groups listed in the increasing order of polarity

Alkanes
Alkenes
Aromatic hydrocarbons

Thiols
Amines
Alcohols, phenols
Amides
Carboxylic acids

34.3 Self-Assembled Monolayers: Substrates, Spacer Chains, and End Groups in the Molecular Chains

SAMs are formed as a result of spontaneous self-organization of functionalized organic molecules onto the surfaces of appropriate substrates into stable, well-defined structures; Fig. 34.3. The final structure is close to or at thermodynamic equilibrium, and as a result it tends to form spontaneously and rejects defects. SAMs consist of three building groups: a head group that binds strongly to a substrate, a surface terminal (tail or end) group that constitutes the outer surface of the film, and a spacer chain (backbone chain) that connects the head and surface terminal groups. The SAMs are named based on the surface terminal group followed by the spacer chain and the head group (or type of compound formed at the surface). In order to control hydrophobicity, adhesion, friction, and wear, it should be strongly adherent to the substrate, and the surface terminal group of the organic molecular chain should be nonpolar. For a strong attachment of the organic molecules to the substrate, the head group of the molecular chain should contain a polar terminal group resulting in the exothermic process (energies on the order of tens of kcal/mol), i. e., it results in an apparent pinning of the head group to a specific site on the surface through a chemical bond. Furthermore, the molecular structure and any cross-linking would have a significant effect on their friction and wear performance. The substrate surface should have a high surface energy (hydrophilic), so that there will be a strong tendency for molecules to adsorb on the surface. The surface should be highly functional with polar groups and dangling bonds (generally unpaired electrons) so that they can react with organic molecules and provide a strong bond. Because of the exothermic head group-substrate interactions, molecules try to occupy every available binding site on the surface, and during this process they generally push together molecules that have already adsorbed. The process results in the formation of ordered molecular assemblies. The interactions between molecular chains are van der Waals or electrostatic types with energies on the order of a few (< 10) kcal/mol, exothermic. The molecular chains in SAMs are not perpendicular to the surface; the tilt angle depends on the anchor group as well

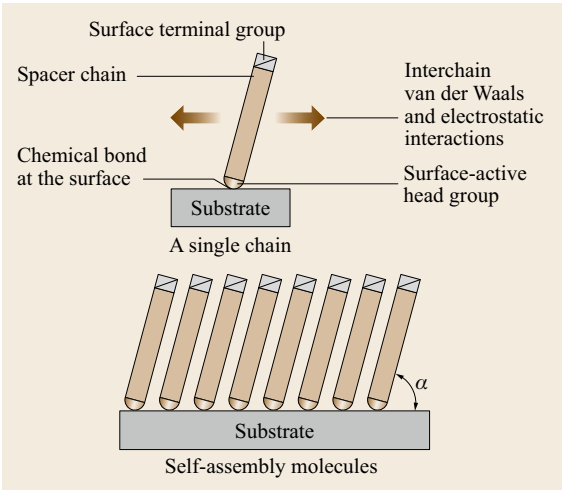

Fig. 34.3 Schematic of a self-assembled monolayer on a surface and the associated forces

as on the substrate and the spacer group. For example, the tilt angle for alkanethiolate on Au is typically about a 30–35° angle with respect to substrate normal.

Table 34.9 lists selected systems that have been used for the formation of SAMs [34.45]. The spacer chain of the SAM is mostly an alkyl chain ($(-CH_2)_n$) or made of a derivatized alkyl group. By attaching different terminal groups at the surface, the film surface can be made to attract or repel water. The commonly used surface terminal group of a hydrophobic film with low surface energy, in the case of a single alkyl chain, is a nonpolar methyl ($-CH_3$) or trifluoromethyl ($-CF_3$) group. For a hydrophilic film, the commonly used surface terminal groups are alcohol ($-OH$) or carboxylic acid ($-COOH$) groups. The surface active head groups most commonly used are thiol ($-SH$), silane (e.g., trichlorosilane or $-SiCl_3$), and carboxyl ($-COOH$) groups. The substrates most commonly used are gold, silver, platinum, copper, hydroxylated (activated) surfaces of SiO_2 on Si, Al_2O_3 on Al, and glass.

As an example of substrate, epitaxial Au film on glass, mica or single-crystal silicon, produced by e-beam evaporation, is commonly used because it can be deposited on smooth surfaces as a film that is atomically flat and defect free. Bulk single-crystal Si, sputtered Al film and bulk Al sheets, and copper disks with natural oxide layers, have been selected because of their use in the construction of MEMS/NEMS (e.g., digital projection displays) and heat exchange applications respectively. The substrate surface should be clean before deposition. For silicon substrates, a concentrated HF solution (typically 49% HF) is commonly used to remove the oxide layer followed by a rinse with deionized (DI) water [34.60, 62]. Hydrogen passivates the surface by saturating the dangling bonds, and this results in a hydrogen-terminated silicon surface with hydrophobic properties. For deposition of multimolecularly thick polymer films with nonpolar ends, hydrophobic substrates may lead to a coated surface with a high contact angle, and are preferred. For SAM deposition, the substrate should be hydrophilic in order to form strong interfacial bonds with their head groups. Hydroxylation of oxide surfaces is carried out to make them hydrophilic. Silicon and other metals get oxidized and get hydroxylated to some degree when exposed to the environment. Bulk silicon, polysilicon film or SiO_2 film surfaces are commonly treated to produce a hydroxylated silica surface by immersion in piranha solution (a mixture of typically 3 : 1 v/v 98% H_2SO_4 : 30% H_2O_2) at temperatures of about 90 °C for about 30 min followed by a rinse in deionized water [34.29, 60, 62]. Piranha solution also removes any organic and metallic contaminants, whereas HF would not necessarily remove organics. Oxygen plasma is another technique used for hydroxylation for SiO_2 as well as polymer surfaces [34.59, 61, 64, 73]. For complex silicon geometries or fine structures, such as AFM tips, oxygen plasma may be preferable. Figure 34.4 shows the schematics of surfaces after various surface treatments. Surfaces after piranha or oxygen plasma treatment remain hydrophilic for a few hours to about a day and become hydrophobic when they come in contact with carbon. They can retain hydrophilicity longer in dry nitrogen. To retain hydrophobicity, polymers are generally stored in DI water. Treated surfaces with HF remain hydrophobic for about 2–3 h and can retain hydrophobicity longer in dry nitrogen.

Table 34.9 Selected substrates and precursors that have commonly been used for formation of SAMs

Substrate	Precursor	Binding with substrate[a]
Au	R SH (thiol)	RS-Au
Au	Ar SH (thiol)	ArS-Au
Au	RSSR′ (disulfide)	RS-Au
Au	RSR′ (sulfide)	
Si/SiO_2, glass	R $SiCl_3$ (trichlorosilane)	Si–O–Si (siloxane)
Si/Si–H	R COOH (carboxyl)	R–Si
Metal oxides (e.g., Al_2O_3, SnO_2, TiO_2)	RCOOH (carboxyl)	RCOO–…MO_n

[a] R represents alkane (C_nH_{2n+2}) and Ar represents aromatic hydrocarbon. It consists of various surface active head groups with mostly methyl terminal groups

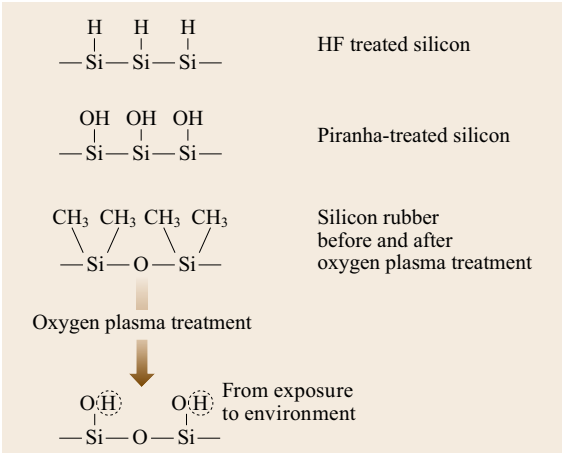

Fig. 34.4 Schematic showing HF-treated silica and the hydroxylation process occurring on a silica and elastomeric surface using piranha solution and oxygen plasma, respectively

For organic molecules to pack together and provide a better ordering, a substrate for given molecules should be selected such that the cross-sectional diameter of the spacer chains of the molecule is equal to or smaller than the distance between the anchor groups attached to the substrate. For the case of alkanethiol film, the advantage of Au substrate over SiO_2 substrate is that it results in better ordering because the cross-sectional diameter of the alkane molecule is slightly smaller than the distance between sulfur atoms attached to the Au substrate (≈ 0.53 nm). The thickness of the film can be controlled by varying the length of the hydrocarbon chain, and the surface properties of the film can be modified by the terminal group.

SAMs are usually produced by immersing a substrate in a solution containing the precursor (ligand) that is reactive to the substrate surface or by exposing the substrate to the vapor of the reactive chemical precursors [34.30]. A schematic of the vapor deposition system is shown in Fig. 34.5 [34.59, 60, 73]. Samples are placed in the quartz reaction tube. The silane bubbler is used for introducing gas-phase silane into the quartz reaction tube placed in an oven at a controlled temperature. An inert gas flow (N_2) is used as a carrier gas. A by-products condenser is used for trapping the by-products and/or nonreacted silanes.

Research on some SAMs has been widely reported. SAMs of long-chain fatty acids $C_nH_{2n+1}COOH$ or $(CH_3)(CH_2)_nCOOH$ ($n = 10$, 12, 14 or 16) on glass or alumina substrates have been widely studied since the 1950s [34.25, 26, 30, 31, 76]. Probably the most studied SAMs to date are *n*-alkanethiolate (*n*-alkyl and *n*-alkane are used interchangeably) monolayers $CH_3(CH_2)_nS$-prepared from the adsorption of alkanethiol $-(CH_2)_nSH$ solution onto an Au film [34.45, 77–81] and *n*-alkylsiloxane monolayers. Siloxane (Si–O–Si) refers to the bond and silane (Si_nX_{2n+2}, which includes covalently bonded compounds containing the elements Si and other atoms or groups such as H and Cl to form SiH_4 and $SiCl_4$ respectively) refers to the head group of the precursor. These terms are used interchangeably. Monolayers are produced by adsorption of *n*-alkyltrichlorosilane $-(CH_2)_nSiCl_3$ onto a hydroxylated Si/SiO_2 substrate with siloxane (Si–O–Si) binding; see Fig. 34.6 [34.53, 58–63, 82]. *Tambe* and *Bhushan* [34.53], *Bhushan* et al. [34.54], *Hoque* et al. [34.55, 56, 65–67, 83]. *DeRose* et al. [34.57] have produced perfluoroalkylsilane and perfluoroalkylphosphonate on Al and Cu surfaces.

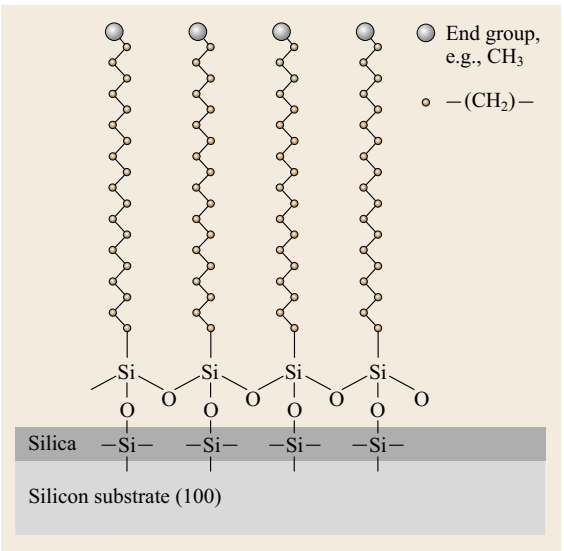

Fig. 34.6 Schematics of a methyl-terminated, *n*-alkylsiloxane monolayer on Si/SiO_2

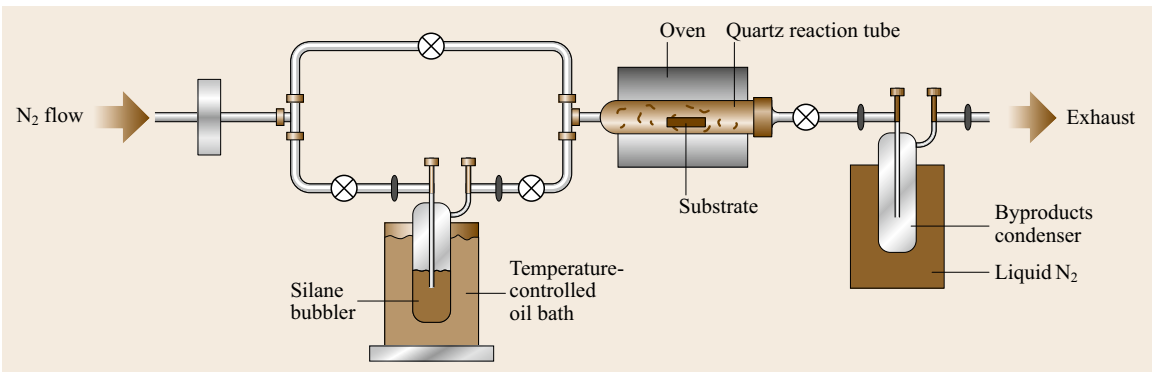

Fig. 34.5 Schematic showing vapor-phase deposition system for silane SAMs (after [34.59])

34.4 Contact Angle and Nanotribological Properties of SAMs

The basis for the molecular design and tailoring of SAMs should start from a complete knowledge of the interrelationships between the molecular structure and contact angle and nanotribological properties of SAMs, as well as a deep understanding of the adhesion, friction, and wear mechanisms of SAMs at the molecular level. Friction and wear studies of SAMs have been carried out on macro- and nanoscales. Macroscale tests are conducted using a so-called pin-on-disk tribotester apparatus in which a ball specimen slides against a lubricated flat specimen [34.14, 15]. Nanoscale tests are conducted using an atomic force/friction force microscope (AFM/FFM) [34.1, 4, 14, 15, 84]. In the AFM/FFM experiments, a sharp tip of a radius ranging from about 5 to 50 nm slides against a SAM specimen. A Si_3N_4 tip is commonly used for friction studies, and a Si or natural diamond tip is commonly used for scratch, wear, and indentation studies.

In early studies, the effect of chain length of the carbon atoms of fatty acid monolayers on the coefficient of friction and wear on the macroscale was studied by *Bowden* and *Tabor* [34.25] and *Zisman* [34.26]. *Zisman* [34.26] reported that for the monolayers deposited on a glass surface sliding against a stainless steel surface, there is a steady decrease in friction with increasing chain length. At a significantly long chain length, the coefficient of friction reaches a lower limit; Fig. 34.7a. He further reported that monolayers having a chain length below 12 carbon atoms behave as liquids (poor durability), and those with a chain length of 12–15 carbon atoms behave like a plastic solid (medium durability), whereas those with a chain length above 15 carbon atoms behave like a crystalline solid (high durability). Investigations by *Ruhe* et al. [34.86] indicated that the lifetime of the alkylsilane monolayer coating on a silicon surface increases greatly with an increase in the chain length of the alkyl substituent. *DePalma* and *Tillman* [34.87] showed that a monolayer of *n*-octadecyltrichlorosilane (n-$C_{18}H_{37}SiCl_3$, OTS) is an effective lubricant on silicon.

With the development of AFM techniques, researchers have successfully characterized the nanotribological properties of self-assembled monolayers [34.1, 4, 6, 84]. Studies by *Bhushan* et al. [34.58] showed that C_{18} alkylsiloxane films exhibit the lowest coefficient of friction and can withstand a much higher normal load during sliding as compared to L–B films, soft Au films, and hard SiO_2 coatings. *McDermott* et al. [34.85] studied the effect of the length of alkyl chains on the frictional properties of methyl-terminated *n*-alkylthiolate $CH_3(CH_2)_nS-$ films chemisorbed on Au(111) using an AFM. They reported that the longer-chain monolayers exhibit a markedly lower friction and a reduced propensity to wear than shorter-chain monolayers; Fig. 34.7b. These results are in good agreement with the macroscale results by *Zisman* [34.26]. They also conducted infrared reflection spectroscopy to measure the bandwidth of the methylene stretching mode ($\nu_a(CH_2)$), which exhibits a qualitative correlation with the packing density of the chains. It was

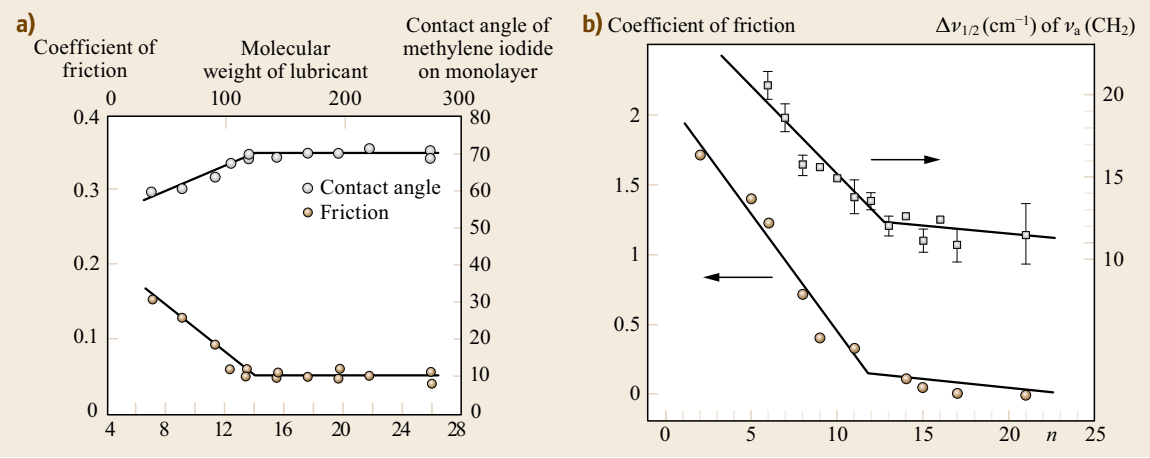

Fig. 34.7 **(a)** Effect of chain length (or molecular weight) on coefficient of macroscale friction of stainless steel sliding on glass lubricated with a monolayer of fatty acid, and contact angle of methyl iodide on condensed monolayers of fatty acid on glass (after [34.26]). **(b)** Effect of chain length of methyl-terminated *n*-alkanethiolate over Au film $AuS(CH_2)_nCH_3$ on the coefficient of microscale friction and peak bandwidth at half maximum ($\Delta\nu_{1/2}$) for the bandwidth of the methylene stretching mode ($\nu_a(CH_2)$) (after [34.85])

found that the chain structures of monolayers prepared with longer chain lengths are more ordered and more densely packed in comparison to those of monolayers prepared with shorter chain lengths. They further reported that the ability of the longer-chain monolayers to retain molecular-scale order during shear leads to a lower observed friction. Monolayers having a chain length of more than 12 carbon atoms, preferably 18 or more, are desirable for tribological applications. (Incidentally, monolayers with 18 carbon atoms, octadecanethiol films, have been widely studied.)

Xiao et al. [34.88] and *Lio* et al. [34.89] also studied the effect of the length of the alkyl chains on the frictional properties of *n*-alkanethiolate films on gold and *n*-alkylsilane films on mica. Friction was found to be particularly high with short chains of less than eight carbon atoms. Thiols and silanes exhibit similar friction forces for the same n when $n > 11$, while for $n < 11$, silanes exhibit higher friction, larger than that for thiols by a factor of about 3 for $n = 6$. The increase in friction was attributed to the large number of dissipative modes in the less ordered chains that occurs when going from a thiol to a silane anchor or when decreasing n. Longer chains ($n > 11$), stabilized by van der Waals attraction, form more compact and rigid layers and act as better lubricants. *Schonherr* and *Vancso* [34.90] also correlated the magnitude of friction with the order of the alkane chains. The disorder of the short-chain hydrocarbon disulfide SAMs was found to result in a significant increase in the magnitude of friction.

Tsukruk and *Bliznyuk* [34.91] studied the adhesion and friction between a Si sample and a Si_3N_4 tip, in which both surfaces were modified by $-CH_3$-, $-NH_2$- and $-SO_3H$-terminated silane-based SAMs. Various polymer molecules for the backbone were used. They reported that a very broad maximum adhesive force in a pH range from 4 to 8 with a minimum adhesion at pH > 9 and pH < 3 were observed for all of the studied mating surfaces. This observation can be understood by considering a balance of electrostatic and van der Waals interaction between composite surfaces with multiple isoelectric points. The friction coefficient of NH_2/NH_2 and SO_3H/SO_3H mating SAMs was very high in aqueous solutions. Cappings of NH_2-modified surfaces (3-aminopropyltriethoxysilane) with rigid and soft polymer layers resulted in a significant reduction in adhesion to a level lower than that of untreated surface [34.92]. *Fujihira* et al. [34.93] studied the influence of surface terminal groups of SAMs and functional tips on adhesive force. It was found that the adhesive forces measured in air increase in the order of CH_3/CH_3, CH_3/COOH, and COOH/COOH.

Bhushan and *Liu* [34.79], *Liu* et al. [34.80], and *Liu* and *Bhushan* [34.81, 94] studied adhesion, friction and wear properties of alkylthiol and biphenylthiol SAMs on Au(111) films. They explained the friction mechanisms using a molecular spring model in which local stiffness and intermolecular forces govern the friction properties. They studied the influence of relative humidity, temperature, and velocity on adhesion and friction. They also investigated the wear mechanisms of SAMs by a continuous microscratch AFM technique.

Fluorinated carbon (fluorocarbon) molecules are known to have low surface energy and are commonly used for lubrication [34.14, 15]. *Bhushan* and *Cichomski* [34.73] deposited fluorosilane SAMs on polydimethylsiloxane (PDMS). To make the hydrophobic PDMS surface chemically active, it was oxygenated using an oxygen plasma, which introduces silanol groups (SiOH). They reported that SAM-coated PDMS was more hydrophobic with lower adhesion, friction, and wear. *Bhushan* et al. [34.59, 60], *Kasai* et al. [34.61], *Lee* et al. [34.62], *Tambe* and *Bhushan* [34.53] and *Tao* and *Bhushan* [34.64] studied the adhesion, friction, and wear of methyl- and/or perfluoro-terminated alkylsilanes on silicon. They reported that perfluoroalkylsilane SAMs exhibited lower surface energy, higher contact angle, lower adhesive force, and lower wear as compared to that of alkylsilanes. *Kasai* et al. [34.61] also reported the influence of relative humidity, temperature, and velocity on adhesion and friction. *Tao* and *Bhushan* [34.63] studied degradation mechanisms of alkylsilanes and perfluoroalkylsilane SAMs on Si. They reported that oxygen in the air causes thermal oxidation of SAMs.

Tambe and *Bhushan* [34.53], *Bhushan* et al. [34.54], *Hoque* et al. [34.55, 56] and *DeRose* et al. [34.57] studied the nanotribological properties of methyl- and perfluoro-terminated alkylphosphonate, perfluorodecyldimethylchlorosilane, and perfluorodecanoic acid on aluminum, which is of industrial interest. *Hoque* et al. [34.83] and *DeRose* et al. [34.57] studied the nanotribological properties of alkylsilanes and perfluroalkylsilanes on aluminum. *Hoque* et al. [34.65–67] studied the nanotribological properties of alkylphosphonate and perfluoroalkylsilane SAMs on copper. The authors found that these SAMs on aluminum and copper perform well irrespective of the substrate used. They confirmed the presence of respective films using x-ray photoelectron spectroscopy (XPS).

Hoque et al. [34.65–67] studied the chemical stability of various SAMs deposited on Cu substrates via exposure to various corrosive conditions. *DeRose* et al. [34.57] studied the chemical stability of various SAMs deposited on Al substrates via exposure to corrosive conditions (aqueous nitric acid solutions of a low pH of 1.8 at temperatures ranging from 60 to 80 °C for times ranging from 30 to 70 min). The exposed samples

were characterized by XPS and contact angle measurements. They reported that perfluorodecanoic acid/Al is less stable than perfluorodecylphosphonate/Al and octadecylphosphonate/Al, but more stable than perfluorodecyldimethylchlorosilane/Al, which has implications in DMD applications, discussed earlier. In general, chemical stability data of various SAMs deposited on Cu and Al surfaces to corrosive environments have been reported by these authors. Based on these studies, it was concluded that chemisorption occurs at the interface and is responsible for strong interfacial bonds.

To date, the contact angle and nanotribological properties of alkanethiol, biphenylthiol, alkylsilane, perfluoroalkylsilane, alkylphosphonate and perfluoroalkylphosphane SAMs have been widely studied. In this chapter, we review, in some detail, the nanotribological properties of various SAMs having alkyl and biphenyl spacer chains with different surface terminal groups ($-CH_3$, $-CF_3$) and head groups ($-S-H$, $-Si-O-$, $-OH$, and $P-O-$), which have been investigated by AFM at various operating conditions; Fig. 34.8a,b [34.53, 54, 59, 61, 63, 79–81, 94]. Hexadecane thiol (HDT), 1,1′-biphenyl-4-thiol (BPT), and cross-linked BPT (BPTC) were deposited on Au(111) films on Si(111) substrates by immersing the substrate in a solution containing the precursor (ligand) that is reactive to the substrate surface. Crosslinked BPTC was produced by irradiation of BPT monolayers with low-energy electrons. Perfluoroalkylsilane and alkylsilane SAMs were deposited on Si(100) by exposing the substrate to the vapor of the reactive chemical precursors. Perfluoroalkylphosphonate and alkylphosphonate SAMs were deposited on sputtered Al film on Si substrate as well as bulk Al substrates. Representative data follow.

34.4.1 Measurement Techniques

Experimental techniques used for measurement of the static contact angle, surface energy, adhesion, friction, and wear are described next.

Static Contact Angle and Surface Energy Measurements Using DI Water

The static contact angle, a measure of water repellency, was measured using a Rame–Hart model 100 contact angle goniometer (Mountain Lakes, NJ, USA) [34.95, 96]. Typically, 10 µl droplets of DI water were used for making contact angle measurements. At least two measurements of the contact angle were made and were

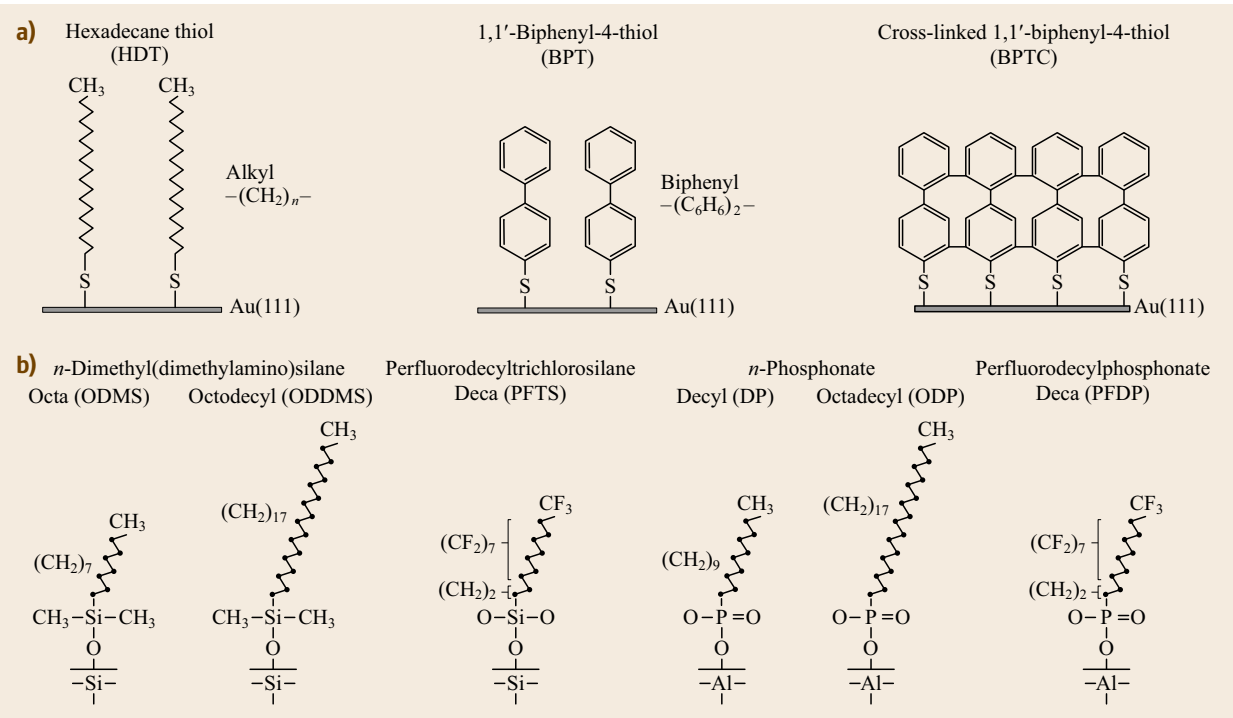

Fig. 34.8a,b Schematics of the structures of **(a)** hexadecane and biphenyl thiol SAMs on Au(111) substrates, and **(b)** perfluoroalkylsilane and alkylsilane SAMs on Si with native oxide substrates, and perfluoroalkylphosphonate and alkylphosphonate SAMs on Al with native oxide

found to be reproducible within $\pm 2^\circ$. The critical surface tension, a measure of interfacial surface energy, was obtained from the so-called Zisman plot. Contact angles of SAMs with liquids with a range of surface tensions were measured. The cosines of the contact angles were plotted as a function of surface tension of the various *n*-alkane liquids (hexadecane, dodecane, undecane and decane) used. The plot is a linear line for low-polarizable SAMs. The horizontal intercept of the line passing through cos(contact angle)= 1 provides the critical surface tension, which is a measure of the surface energy of the SAM [34.59].

AFM Adhesion and Friction Measurements

The adhesion and friction tests were conducted using a commercial AFM system. Square pyramidal Si_3N_4 tips with a 30–50 nm tip radius on gold back-coated triangular Si_3N_4 cantilevers with a typical spring constant of 0.58 N/m were used. Adhesion can be calculated using either force calibration plots or from the negative intercepts on the friction force versus normal plot loads. Both methods generally yield similar results. The force calibration plot technique was used in this study. The coefficient of friction was obtained from the slope of the friction force versus normal load plots. Normal loads typically ranged from 5 to 100 nN. Friction force measurements were generally performed at a scan rate of 1 Hz along the fast scan axis and over a scan size of 2 μm by 2 μm. The fast scan axis was perpendicular to the longitudinal direction of the cantilever. The friction force was calibrated by the method described in [34.4, 6, 84].

AFM Wear Measurements

Wear tests were conducted using a diamond tip with a nominal radius of 50 nm and nominal cantilever stiffness of 10 N/m. Wear tests were performed on a 1 μm × 1 μm scan area at the desired normal load and at a scan rate of 1 Hz. After each wear test, a 3 μm × 3 μm area was imaged, and the average wear depth was calculated.

Effect of Relative Humidity, Temperature, and Sliding Velocity

The influence of relative humidity on adhesive force, friction force, and wear was studied in an environmentally controlled chamber. Relative humidity was controlled by introducing a mixture of dry and moist air inside the chamber. The temperature was maintained at $22 \pm 1\,^\circ$C. The sample was kept in the environmental chamber at desired humidity for at least 2 h prior to the tests so that the system could reach equilibrium conditions.

In order to study the effect of temperature on adhesion and friction force, the samples were placed on a thermal stage during the measurements. A glass plate was placed under the thermal stage to prevent the heat from being transported away. The temperature range studied was from 20 to 110 °C. The relative humidity was maintained at $50 \pm 5\%$ during the temperature effect measurements.

The effect of sliding velocity on friction force was monitored in ambient conditions using a high-velocity piezoelectric stage designed for achieving high relative sliding velocities on a commercial AFM setup [34.97]. The traveling distance of the sample, i. e., the scan size, was set at 25 μm, while the scan frequency was varied between 0.1 Hz (5 μm/s) and 100 Hz (5000 μm/s).

Chemical Degradation and Environmental Studies

The chemical degradation experiments were carried out in a high-vacuum tribotest apparatus [34.98, 99]. The system was equipped with a mass spectrometer so that gaseous emissions from the interface could be monitored in situ during the sliding in high vacuum and other controlled environments. The normal loads and friction forces at the contacting interface were measured using resistive-type strain-gage transducers. For the sliding tests, the coated flat sample was glued on a flat surface at the end of a rotating shaft. The sample was slid against a Si(100) wafer mounted on the flat surface of a slider integrated with a flexible cantilever used in magnetic rigid disk drives. The sliding speed used was 0.3 m/s, and the applied pressure was 50 kPa. The environmental effects were investigated in high vacuum (2×10^{-7} Torr), argon, dry air (less than 2% relative humidity (RH)), ambient air (30% RH), and high-humidity air (70% RH).

34.4.2 Hexadecane Thiol and Biphenyl Thiol SAMs on Au(111)

Hexadecane thiol on Au(111) film was selected as it is a widely studied film. Biphenyl thiol was selected to study the effect of rigidity on nanotribological performance. Biphenyl thiol film was cross-linked to further increase its stiffness.

Surface Roughness, Adhesion, and Friction

Surface height and friction force images of SAMs were recorded simultaneously on an area of 1 μm × 1 μm by an AFM, and adhesive forces were measured by using the force calibration mode in an AFM [34.79].

For further analysis, presented later in this chapter, the measured roughness, thickness, tilt angles, and spacer chain lengths of Si(111), Au(111) and various SAMs are listed in Table 34.10 [34.79]. The roughness of BPT is very close to that of Au(111), but the

Table 34.10 The R_a roughness, thickness, tilt angles and spacer chain lengths of SAMs

Samples	R_a roughness[a] (nm)	Thickness[b] (nm)	Tilt angle[b] (deg)	Spacer length[c] (nm)
Si(111)	0.07			
Au(111)	0.37			
HDT	0.92	1.89	30	1.91
BPT	0.36	1.25	15	0.89
BPTC	0.14	1.14	25	0.89

[a] Measured by an AFM with 1 μm × 1 μm scan size, using Si_3N_4 tip under 3.3 nN normal load
[b] The thickness and tilt angles of BPT and BPTC are reported by *Geyer* et al. [34.78]. The thickness and tilt angles of HDT are reported by *Ulman* [34.31]
[c] The spacer chain lengths of alkylthiols were calculated by the method reported by *Miura* et al. [34.100]. The spacer chain lengths of biphenyl thiols were calculated by the data reported by *Ratajczak-Sitarz* et al. [34.101]

roughness of BPTC is lower than that of Au(111) and BPT; this is caused by electron irradiation. Table 34.10 indicates that the roughness value of HDT is much higher than its substrate roughness of Au(111). This is caused by local aggregation of organic compounds on the substrates during SAM deposition. Table 34.10 also indicates that the thicknesses of biphenyl thiol SAMs are generally smaller than the alkylthiol, because of shorter spacer chains in biphenyl thiol.

The average values and standard deviation of the adhesive force and coefficient of friction are presented in Fig. 34.9 [34.79]. Based on the data, the adhesive force and coefficient of friction of SAMs are less than

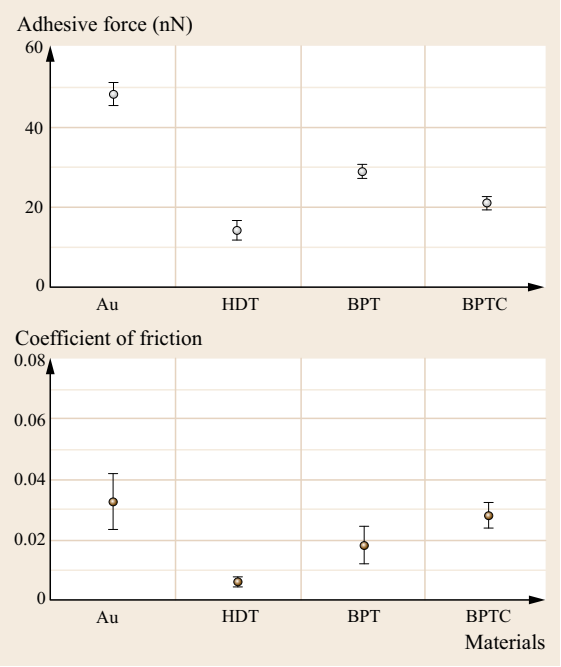

Fig. 34.9 Adhesive forces and coefficients of friction of Au(111) and various SAMs

those of their corresponding substrates. Among various films, HDT exhibits the lowest values. The ranking of adhesive forces F_a is in the following order: $F_{a\text{-Au}} > F_{a\text{-BPT}} > F_{a\text{-BPTC}} > F_{a\text{-HDT}}$, and the ranking of the coefficients of friction μ is in the following order: $\mu_{Au} > \mu_{BPTC} > \mu_{BPT} > \mu_{HDT}$. The ranking of various SAMs for adhesive force and coefficient of friction are similar. It suggests that alkylthiol and biphenyl thiol SAMs can be used as effective molecular lubricants for micro/nanodevices.

In micro/nanoscale contact, liquid capillary condensation is one of the sources for the adhesion and friction. In the case of a sphere in contact with a flat surface, the attractive Laplace force caused by water capillary is [34.14, 15],

$$F_L = 2\pi R\gamma_{la}(\cos\theta_1 + \cos\theta_2)\,, \tag{34.1}$$

where R is the radius of the sphere, γ_{la} is the surface tension of the liquid against air, and θ_1 and θ_2 are the contact angles between liquid and flat and spherical surfaces respectively. In an AFM adhesive study, the tip-flat sample contact is just like a sphere in contact with a flat surface, and the liquid is water. Since a single tip was used in the adhesion measurements, $\cos\theta_2$ can be treated as a constant. Therefore,

$$\begin{aligned} F_L &= 2\pi R\gamma_{la}(1+\cos\theta_1) - 2\pi R\gamma_{la}(1-\cos\theta_2) \\ &= 2\pi R\gamma_{la}(1+\cos\theta_1) - C\,, \end{aligned} \tag{34.2}$$

where C is a constant.

Based on the following Young–Dupre equation, the work of adhesion W_a (the work required to pull apart the unit area of the solid-liquid interface) can be written as [34.12]

$$W_a = \gamma_{la}(1+\cos\theta_1)\,. \tag{34.3}$$

It indicates that W_a is determined by the contact angle of SAMs, i. e., is influenced by the surface chemistry properties (polarization and hydrophobicity) of SAMs. By substituting (34.3) into (34.2), F_L can be expressed as

$$F_L = 2\pi R W_a - C \,. \tag{34.4}$$

When the influence of other factors, such as van der Waals force, are very small on the adhesive force, then adhesive force $F_a \approx F_L$. Thus the adhesive force F_a should be proportional to the work of adhesion W_a.

Contact angle is a measure of the wettability of a solid by a liquid and determines the W_a value [34.95, 96]. The static contact angles of distilled water on Au(111) and SAMs were measured and are summarized in Fig. 34.10a [34.79]. For water, $\gamma_{la} = 72.6\,\mathrm{mJ/m^2}$ at 22 °C, and by using (34.3), the W_a data are obtained and presented in Fig. 34.10b. The W_a can be ranked in the following order: $W_{a\text{-}Au}(97.1) > W_{a\text{-}BPT}(86.8) > W_{a\text{-}BPTC}(82.1) > W_{a\text{-}HDT}(61.4)$. Except $W_{a\text{–}Au}$, this order exactly matches the order of adhesion force in Fig. 34.9. The relationship between F_a and W_a is summarized in Fig. 34.11 [34.79]. It indicates that the adhesive force F_a (nN) increases with the work of adhesion $W_a(\mathrm{mJ/m^2})$ by the linear relationship

$$F_a = 0.57 W_a - 22 \,. \tag{34.5}$$

These experimental results agree well with the modeling prediction presented earlier in (34.4). It proves that on the nanoscale at ambient conditions the adhesive force of SAMs is mainly influenced by the water capillary force. Though neither HDT nor BPT has polar surface groups, the surface terminal of HDT has a symmetrical structure, which causes a smaller electrostatic attractive force and yields a smaller adhesive force than BPT. It is believed that the easy attachment of Au onto the tip should be one of the reasons behind the large adhesive force, which does not fit the linear relationship described by (34.5).

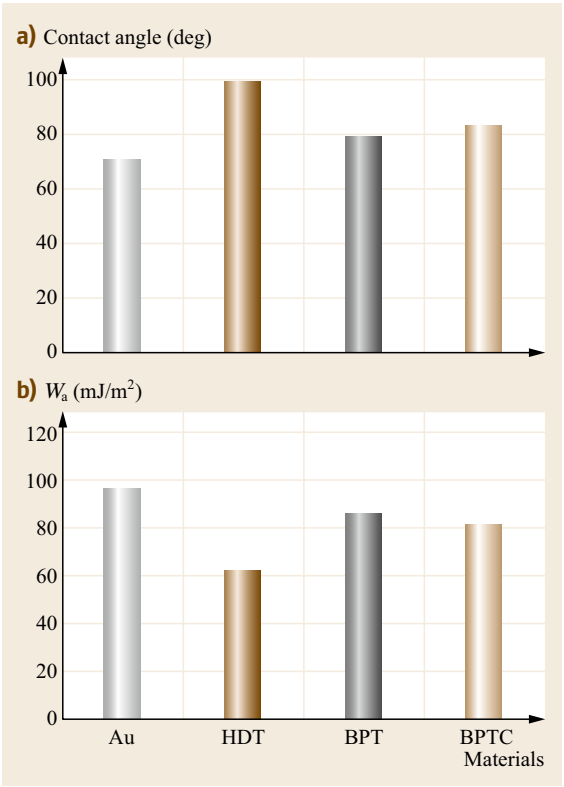

Fig. 34.10 (a) The static contact angle, and (b) work of adhesion of Au(111) and various SAMs. All of the points in this figure represent the mean value of six measurements. The uncertainty associated with the average contact angle is within ±2°

Stiffness, Molecular Spring Model, and Micropatterned SAMs

Next the friction mechanisms of SAMs were examined. The Monte Carlo simulation of the mechanical relaxation of a $CH_3(CH_2)_{15}SH$ self-assembled monolayer performed by *Siepman* and *McDonald* [34.102] indicated that SAMs compress and respond nearly elastically to microindentation by an AFM tip when the load is below a critical normal load. Compression can lead to major changes in the mean molecular tilt (i. e., orientation), but the original structure is recovered as the normal load is removed. *Garcia-Parajo* et al. [34.103] also reported the compression and relaxation of octadecyltrichlorosilane (OTS) film during loading and unloading.

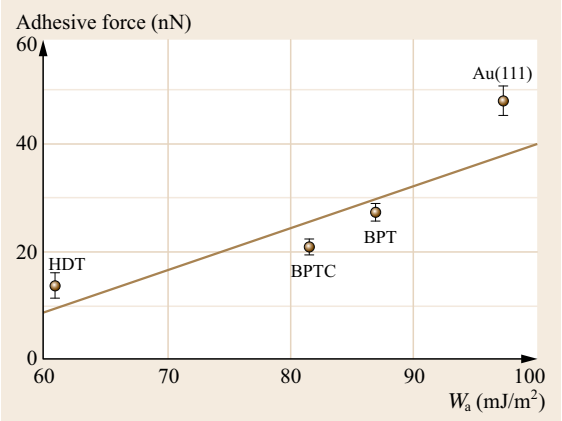

Fig. 34.11 Relationship between the adhesive forces and work of adhesion for different specimens

To study the difference in the stiffness of various films, the stiffness properties were measured by an AFM in force modulation mode [34.4, 6, 81, 84]. They reported that BPT was stiffer than HDT. Since BPT has a rigid benzene structure, it is more difficult to compress than HDT. Figure 34.12 shows the variation of the displacement with normal load during indentation mode. It clearly indicates that SAMs can be compressed. At a given normal load, long carbon chain structure SAMs such as HDT are easily compressed as compared to rigid benzene ring structure SAMs such as BPT, which implies that BPT is more rigid than HDT.

In order to explain the frictional difference of SAMs, based on the friction and stiffness measurements by AFM and the Monte Carlo simulation, a molecular spring model is presented in Fig. 34.13. It is believed that the self-assembled molecules on a substrate are just like assembled molecular springs anchored to the substrates [34.79]. An AFM tip sliding on the surface of SAMs is like a tip sliding on the top of *molecular springs or brush*. The molecular spring assembly has compliant features and can experience compression and orientation under normal load. The orientation of the molecular springs or brush reduces the shearing force at the interface, which in turn reduces the friction force. The possibility of orientation is determined by the spring constant of a single molecule (local stiffness), as well as the interaction between the neighboring molecules, which can be reflected by packing density or packing energy. It should be noted that the orientation can lead to conformational defects along the molecular chains, which leads to energy dissipation. In the study of BPT by AFM, it was found that after the first several scans, the friction force is significantly reduced, but the surface height does not show any apparent change. This suggests that the molecular orientation can be facilitated by initial sliding and is reversible [34.94].

Based on the stiffness measurements obtained using Fig. 34.12 and the view of molecular structures in Fig. 34.13, biphenyl is a more rigid structure due to the contribution of two rigid benzene rings. Therefore the spring constant of BPT is larger than that of HDT. The hydrogen (H^+) in a biphenyl chain has an electrostatic attractive force with the π electrons in the neighboring benzene ring. Thus the intermolecular force between biphenyl chains is stronger than that for alkyl chains. The larger spring constant and stronger intermolecular force of BPT require a larger external force to allow it to orient, thus causing a higher coefficient of friction. The cross-linking of BPT leads to a larger packing energy for BPTC. Therefore it requires a larger external force to allow BPTC orientation, i. e., the coefficient of friction of BPTC is higher than that of BPT.

An elegant way to demonstrate the influence of molecular stiffness on friction is to investigate SAMs with different structures on the same wafer. For this purpose, a micropatterned SAM was prepared. First the biphenyldimethylchlorosilane (BDCS) was deposited on silicon by a typical self-assembly method [34.81]. Then the film was partially cross-linked using a mask technique by low-energy electron irradiation. Finally the micropatterned BDCS films were realized, which had the as-deposited and cross-linked coating regions on the same wafer. The local stiffness properties of these micropatterned samples were investigated by the force modulation AFM technique [34.104]. The variation in the deflection amplitude provides a measure

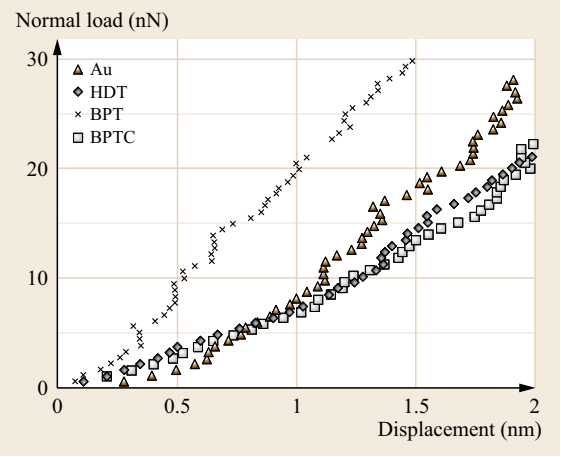

Fig. 34.12 Normal load versus displacement curves of Au(111) and various SAMs

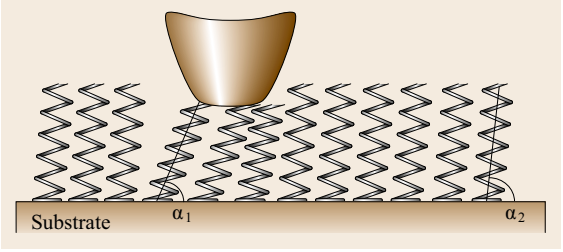

Fig. 34.13 Molecular spring model of SAMs. In this figure, $\alpha_1 < \alpha_2$, which is caused by the orientation under the normal load applied by an AFM tip. The orientation of the molecular springs reduces the shearing force at the interface, which in turn reduces the friction force. The molecular spring constant, as well as the intermolecular forces can determine the magnitude of the coefficients of friction of SAMs. In this figure, the size of the tip and molecular springs are not exactly to scale (after [34.79])

of the relative local stiffness of the surface. Surface height, stiffness, and friction images of the micropatterned biphenyldimethylchlorosilane (BDCS) specimen were obtained and are presented in Fig. 34.14. The circular areas correspond to the as-deposited film and the remaining area to the cross-linked film. Figure 34.14a indicates that cross-linking caused by the low-energy electron irradiation leads to about a 0.5 nm decrease of the surface height of BDCS films. The corresponding stiffness images indicate that the cross-linked area has a higher stiffness than the as-deposited area. Figure 34.14b indicates that the as-deposited area (area with higher surface height) has a lower friction force. Obviously, these data on the micropatterned sample proves that the local stiffness of SAMs has an influence on their friction performance. Higher stiffness leads to larger friction force. These results provide strong proof of the suggested molecular spring model.

In summary, it is found that SAMs exhibit compliance and can experience compression and orientation under normal load. The orientation of SAMs reduces the shear stress at the interface; therefore SAMs can serve as good lubricants. The molecular spring constant (local stiffness), as well as the intermolecular forces, can influence the magnitude of the coefficients of friction of SAMs.

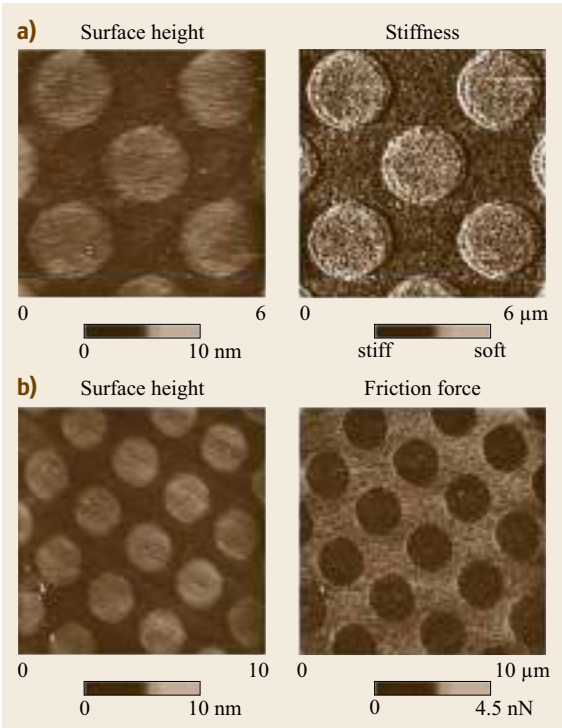

Fig. 34.14 (a) AFM grayscale surface height and stiffness images, and (b) AFM grayscale surface height and friction force images of micropatterned BDCS (after [34.81])

Wear and Scratch Resistance

Wear resistance was studied on an area of $1\,\mu m \times 1\,\mu m$. The variation of wear depth with normal loads is presented in Fig. 34.15 [34.79]. HDT exhibits the best wear resistance. For all of the tested SAMs, in the wear depth as a function of normal load curves, there appears a critical normal load, which is marked by arrows in Fig. 34.15. When the normal load is smaller than the critical normal load, the monolayer only shows a slight height change in the scan areas. When the normal load is higher than the critical value, the height change of SAM increases dramatically. Relocation and accumulation of BPT molecules has been observed during the initial several scans, which leads to the formation of a larger terrace. Wear studies of a single BPT terrace indicate that the wear life of BPT increases exponentially with terrace size [34.80, 81].

The scratch resistance of Au(111) and SAMs was studied by a continuous AFM microscratch technique. Figure 34.16a shows coefficient of friction profiles as a function of increasing normal load and corresponding tapping mode AFM surface height images of the scratches captured on Au(111) and SAMs [34.81]. Figure 34.16a indicates that there is an abrupt increase in the coefficient of friction for all of the tested samples. The normal load associated with this event is termed the critical load (indicated by the arrows labeled *A*). At the initial stages of the scratch, all the samples exhibit a low coefficient of friction indicating that the friction force is dominated by the shear component. This is in agreement with analysis of the AFM images, which shows negligible damage on the surfaces prior to the critical load. At the critical load, a clear groove is formed, which is accompanied by the formation of

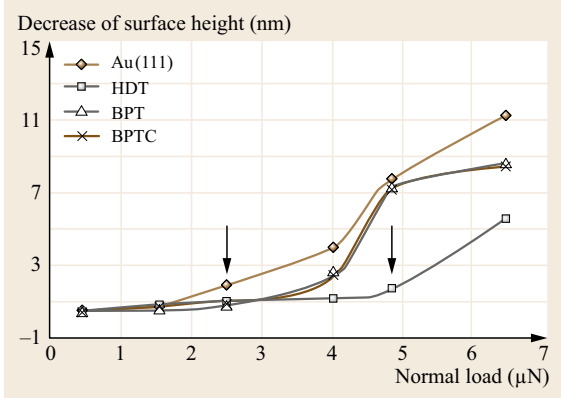

Fig. 34.15 Wear depth as a function of normal load after one scan cycle

material pileup at the sides of the scratch. This suggests that the initial damage that occurs at the critical load is due to plowing associated with plastic deformation, and this causes the sharp rise in the coefficient of friction. Beyond the critical load, debris can be seen in addition to material pileup at the sides of the scratch. Figure 34.16b summarizes the critical loads for the various samples obtained in this study. It clearly indicates that all SAMs can increase the critical load of the corresponding substrate.

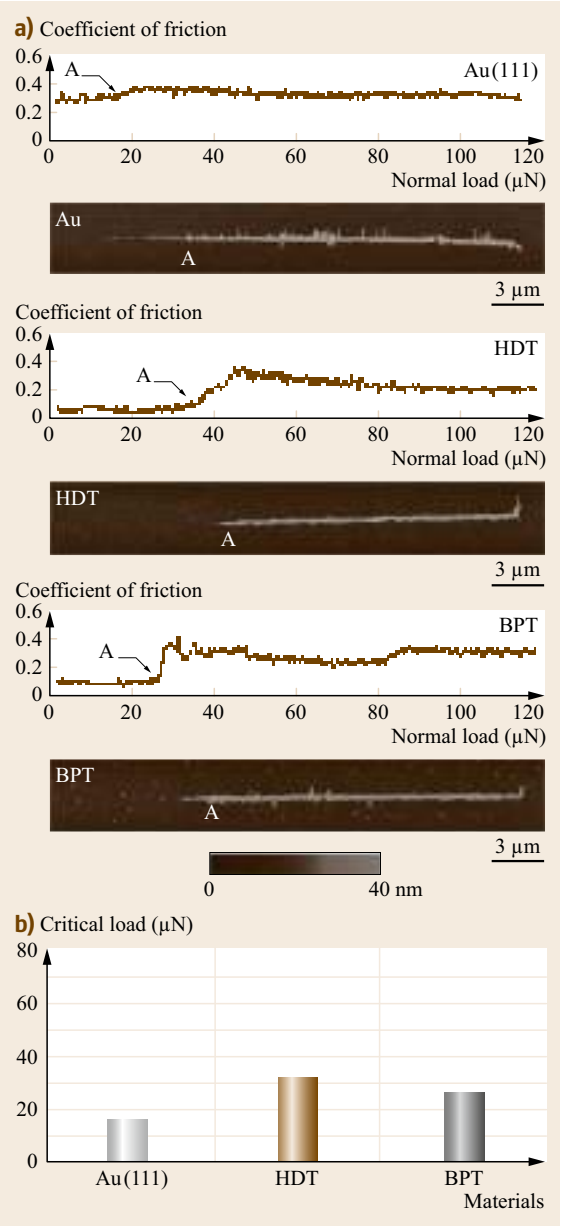

Fig. 34.16 (a) Coefficient of friction profiles during scratch as a function of normal load and corresponding AFM surface height images, and **(b)** critical loads estimated from the coefficient of friction profile and AFM images for Au(111), HDT/Au(111), and BPT/Au(111) (after [34.81])

The mechanisms responsible for a sudden drop in decrease in surface height with an increase in load during wear and scratch tests need to be understood. *Barrena* et al. [34.105] observed that the height of self-assembled alkylsilanes decreases in discrete amounts with normal load. This step-like behavior is due to the discrete molecular tilts, which are dictated by the geometrical requirements of the close packing of molecules. Only certain angles are allowed due to the zigzag arrangement of the carbon atoms. The relative height of the monolayer under pressure can be calculated by

$$\frac{h}{L} = \left[1 + \left(\frac{na}{d}\right)^2\right]^{-1/2}, \qquad (34.6)$$

where L is the total length of the molecule, h is the height of the SAMs in the tilt configuration (monolayer thickness), a is the distance between alternate carbon atoms in the molecule, d is the separation of the molecules, and n is the step number. The values of a (0.25 nm) and d (0.47 nm) are used in the calculation for HDT. The calculated and measured relative heights of HDT are listed in Table 34.11. When the normal loads are smaller than the critical values in Fig. 34.15, the measured relative height values of HDT are very close to the calculated values. It means that HDT underwent step tilting below critical normal loads.

The residual SAM thickness after wear under critical normal load was measured by profiling the worn film using an AFM. The results are listed in Table 34.12. For an alkanethiol monolayer, the relationship between

Table 34.11 Calculated $[1 + (na/d)^2]^{-1/2}$ and measured (h/L) relative heights of HDT self-assembled monolayers (after [34.79])

Steps (n)	Calculated[a] $[1 + (na/d)^2]^{-1/2}$	Measured (h/L)
1	0.883	
2	0.685	0.674[b]
3	0.531	0.532[c]
4	0.425	0.416[d]
5	0.352	0.354[e]
6	0.299	

[a] Calculations are based on the assumption that the molecules tilt in discrete steps (n), upon compression with a diamond AFM tip [34.105]
[b–e] These measured values correspond to the normal loads of 0.50, 1.57, 2.53, and 4.03 μN respectively

Table 34.12 Calculated L_0 and measured residual film thickness for SAMs under critical load

	L_0^a (nm)	Residual thickness[b] (nm)
HDT	0.24	0.25
BPT	0.39	0.42
BPTC	0.33	0.38

[a] Calculated by the equation of $h = b\cos(\alpha)n + L_0$ [34.100]
[b] Measured by AFM using diamond tip under critical normal load. All of the data are the mean value of three tests

the monolayer thickness h and intercept length L_0 can be expressed as (Fig. 34.17)

$$h = b\cos(\alpha)n + L_0\,, \tag{34.7}$$

where b is the length of the projection of the C–C bond onto the main chain axis ($b = 0.127$ nm for alkanethiol), n is the chain length defined by $CH_3(CH_2)_nSH$, and α is the tilt angle [34.100]. For BPT and BPTC, based on the same principle, and using the bond lengths reported in reference [34.101], the L_0 values are also calculated; Table 34.12. It indicates that the measured residual thickness values of SAMs under critical load are very close to the calculated intercept length L_0 values. It means that under the critical normal load, the Si_3N_4 tip approaches the interface, and SAMs wear away severely from the substrate. This is due to the interface chemical adsorption bond strength (S-Au) being generally smaller than the other chemical bond strengths in SAM spacer chains (Table 34.14, to be introduced later).

According to the wear and scratch results reported here and the above discussion, the transition of the wear mechanisms of SAMs with increasing normal load is illustrated in Fig. 34.18. Below the critical normal load SAMs undergo step orientation, at the critical load SAMs wear away from the substrate due to the weak interface bond strengths, while above the critical normal load severe wear take place on the substrate. In order to improve wear resistance, the interface bond must be enhanced; a rigid spacer chain and a hard substrate are also preferred.

34.4.3 Perfluoroalkylsilane and Alkylsilane SAMs on Si(100), and Perfluoroalkylphosphonate and Alkylphosphonate SAMs on Al

Perfluorodecyltricholorosilane (PFTS),

$$CF_3{-}(CF_2)_7{-}(CH_2)_2{-}SiCl_3\,,$$

n-octyldimethyl (dimethylamino)silane (ODMS),

$$CH_3{-}(CH_2)_n{-}Si(CH_3)_2{-}N(CH_3)_2 \quad (n = 7)\,,$$

and *n*-octadecyldimethyl(dimethylamino)silane ($n = 17$) (ODDMS) vapor-deposited on Si(100) substrate and perfluorodecylphosphonate (PFDP)

$$CF_3{-}(CF_2)_7{-}(CH_2)_2{-}\underset{\underset{O}{\|}}{\overset{\overset{O}{|}}{P}}{-}OH\,,$$

decylphosphonate (DP)

$$CH_3{-}(CH_2)_n{-}\underset{\underset{O}{\|}}{\overset{\overset{O}{|}}{P}}{-}OH \quad (n = 9)\,,$$

and octadecylphosphonate (ODP) ($n = 17$) liquid-deposited on sputtered Al film on Si substrate were selected. Perfluoro SAMs were selected because fluorinated films are known to have low surface energy. Two chain lengths of alkylsilanes (with 8 and 18 carbon atoms) were selected to compare their nanotribological

performance with that of the former as well as to study the effect of chain length. Al substrate was selected because of the application of Al micromirrors in digital projection displays. Perfluoroalkylphosphane (with 10 carbon atoms) and alkylphosphonate SAMs (with 10 and 18 carbon atoms) on Al were selected.

Static Contact Angle and Surface Free Energy Measurements

Static contact angles and surface energy were measured to get a measure of the hydrophobicity. Figure 34.19 shows a Zisman plot for the SAMs deposited on Si and their surface energy values using various alkane liquids [34.59]. Critical surface tension, a measure of surface energy values for the two SAMs, are presented in the figure. Zisman analysis for the Si substrate was not available because the alkane liquids used for the measurement instantly spread on these surfaces. For PFTS, significant reduction in the critical surface tension or surface energy was observed (12.9 mN/m for PFTS/Si), as compared to ODMS (24.7 mN/m for ODMS/Si) and ODDMS (23.9 mN/m for ODDMS/Si). The surface energy for ODMS and ODDMS was comparable. It suggests that the surface was comparably covered by the SAMs without bare substrate appearing.

For comparison, static contact angles were measured for various SAMs on Si and Al substrates. The measured values are compared among the samples in Fig. 34.20a [34.54, 59]. A summary of root-mean-square (RMS) roughnesses measured by using an AFM, and static contact angles and film thickness measured using an ellipsometer, are summarized in Table 34.13 [34.54, 61]. Significant improvement

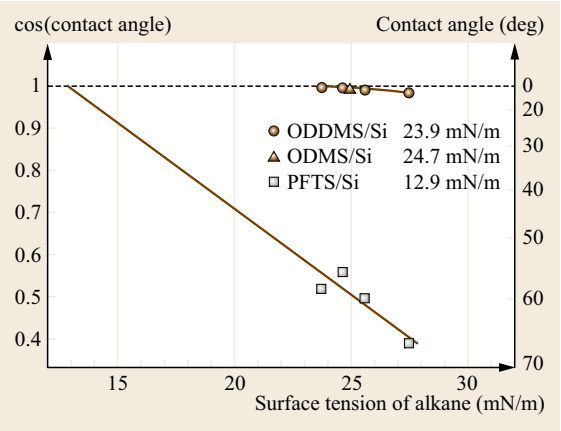

Fig. 34.19 Zisman plot for PFTS/Si, ODMS/Si, and ODDMS/Si used for calculating critical surface tension, a measure of surface energy, which is given by the *x*-intercept (cos(contact angle) = 1) of the fitted line to the data

in the water repellency was observed for perfluorinated SAMs as compared to bare Si and Al substrates. Static contact angles of alkylsilanes and alkylphosphonates were also higher than corresponding substrates, but lower than corresponding perfluorinated films. The contact angle generally increased with a decrease in surface energy [34.106], which is consistent with the data obtained. The contact angles can be influenced by the packing density as well as the sample roughness [34.107]. The higher contact angles for the SAMs deposited on Al substrates than those on Si substrate are probably due to this effect. The $-CH_3$ groups in ODMS, ODDMS, DP, and ODP are nonpolar and are known to contribute to the water repellency. Perfluorinated SAMs exhibited the highest contact angle among the SAMs tested in this study.

AFM Adhesion and Friction Measurements Under Ambient Conditions

Figure 34.20a shows the adhesive force, friction force, and the coefficient of friction measured under ambient conditions using an AFM, and Fig. 34.20b shows the friction force versus normal load plots for various SAMs deposited onto the Si and Al substrates [34.54, 59]. Figure 34.21 shows surface height and friction force maps for Si and PFTS, ODMS, and ODDMS on Si [34.59].

The bare substrates showed higher adhesive force than the SAMs coatings. ODMS and ODDMS shows an adhesive force comparable to DP and ODP despite their lower water contact angles. These SAMs have the same tail groups, and during AFM measurements the AFM tip interacts only with the tail groups, whereas the contact angles can also be influenced by the head groups in these SAMs. This is probably the reason why the adhesive forces for these SAMs are comparable. PFTS and PFDP, which have the highest contact angles, showed the lowest adhesion.

Friction force images of SAMs on Si exhibit more uniform contrast than those of bare Si. The coefficient of friction was higher for the bare substrates as compared to the corresponding SAMs deposited on them. The SAMs deposited on the Si substrate showed lower coefficients of friction than those deposited on the Al substrates. The primary reason for this is believed to be the higher roughness of the Al substrates. The SAMs with fluorocarbon backbone chains were found to have higher coefficients of friction than those with hydrocarbon backbone chains. This might be attributed to the higher stiffness of the fluorocarbon backbone [34.54, 61]. For the fluorocarbon backbone chains, it is harder to rotate the backbone structure due to the larger size of the F atoms in comparison to the H atoms [34.108]. The C–C bonds of hydrocarbon chains can, on the other

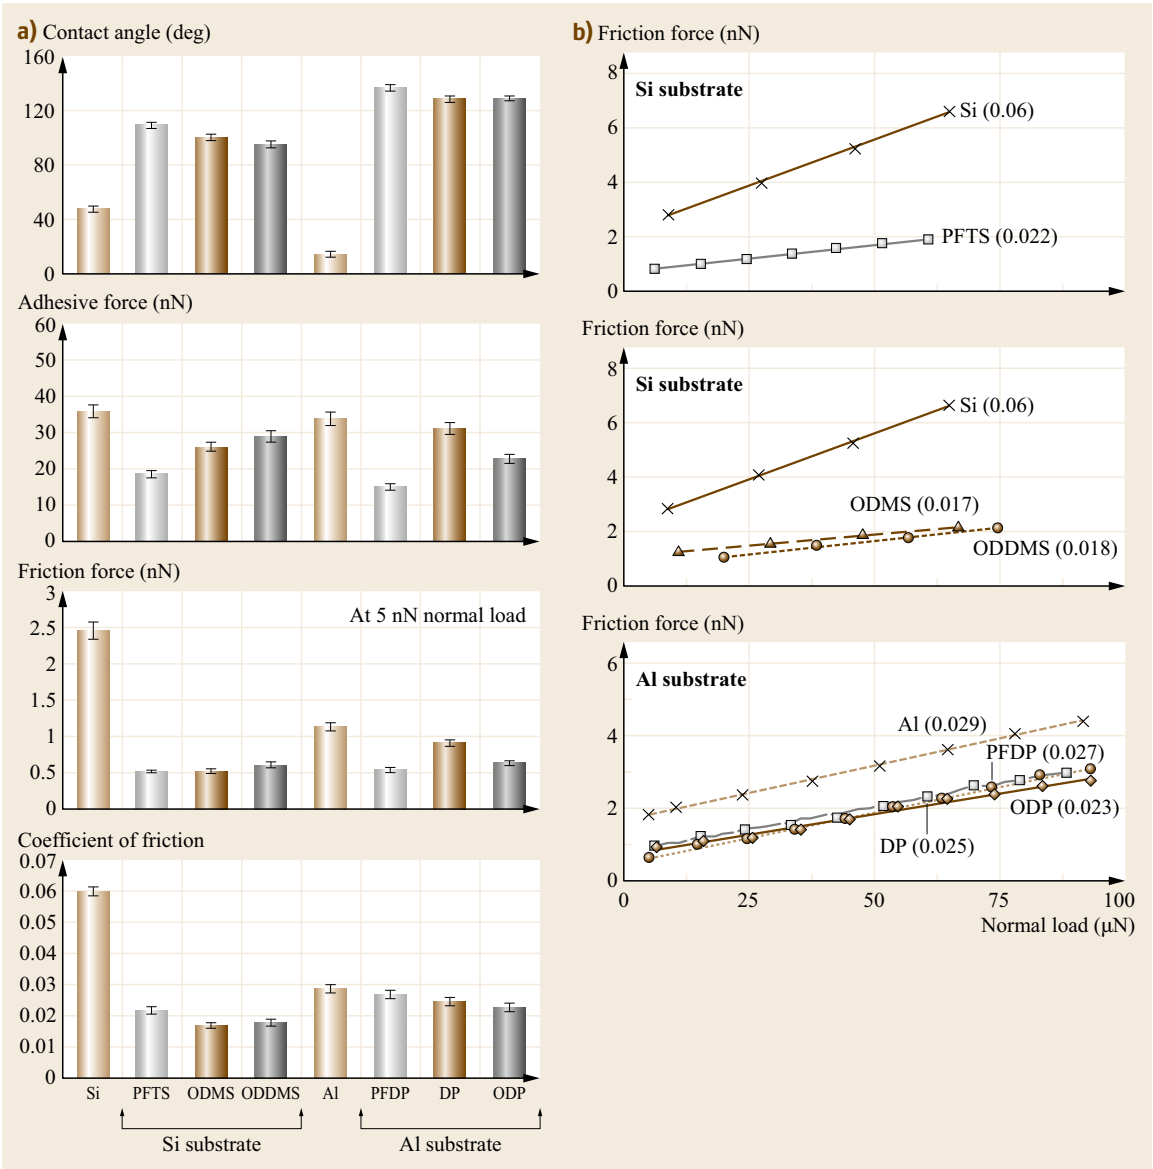

Fig. 34.20 (a) The static contact angle, adhesive force, friction force and coefficient of friction measured using an AFM for various SAMs on Si and Al substrates, and (b) friction force versus normal load plots for various SAMs on Si and Al substrates (after [34.54, 59])

hand, rotate more freely. We have presented earlier a molecular spring or brush model to explain why less-compliant SAMs show larger friction. The SAMs with a higher spring constant or stiffer backbone structure may need more energy to be elastically deformed during sliding; therefore friction is higher for these SAMs. In terms of the chain length effect, it has been reported that the coefficient of friction for SAM surfaces decreases with the carbon backbone chain length (n) up to 12 carbon atoms ($n \approx 12$) [34.85]. This chain length effect for the coefficient of friction was not obvious in these data.

Effect of Relative Humidity, Temperature, and Sliding Velocity on AFM Adhesion and Friction

The effect of relative humidity for various SAMs on adhesion and friction was studied. Adhesive force, friction force at 5 nN of normal load, coefficient of friction, and microwear data are presented in Fig. 34.22 [34.54,

Table 34.13 A summary of RMS roughness, contact angle and film thickness of various SAMs

SAM/substrate	Acronym	RMS roughness (nm)	Contact angle (deg)	Film thickness (nm)
Silicon(111)[a]	Si	0.07	48	–
Perfluorodecyltricholorosilane/Si[a]	PFTS/Si	0.09	112	≈ 1.8
n-Octyldimethyl(dimethylamino)silane/Si[a]	ODMS/Si	0.10	99	≈ 1.9
n-Octadecyldimethyl(dimethylamino)silane/Si[b]	ODDMS/Si	0.10	92	≈ 2.1
Aluminum[b]	Al	32	< 15	–
Perfluorodecylphosphonate	PFDP	34	137	≈ 1.9
Decylphosphonate/Al[b]	DP/Al	31	129	≈ 1.9
Octadecylphosphonate/Al[b]	ODP/Al	36	130	≈ 2.1

[a] *Kasai* et al. [34.61]
[b] *Bhushan* et al. [34.54]

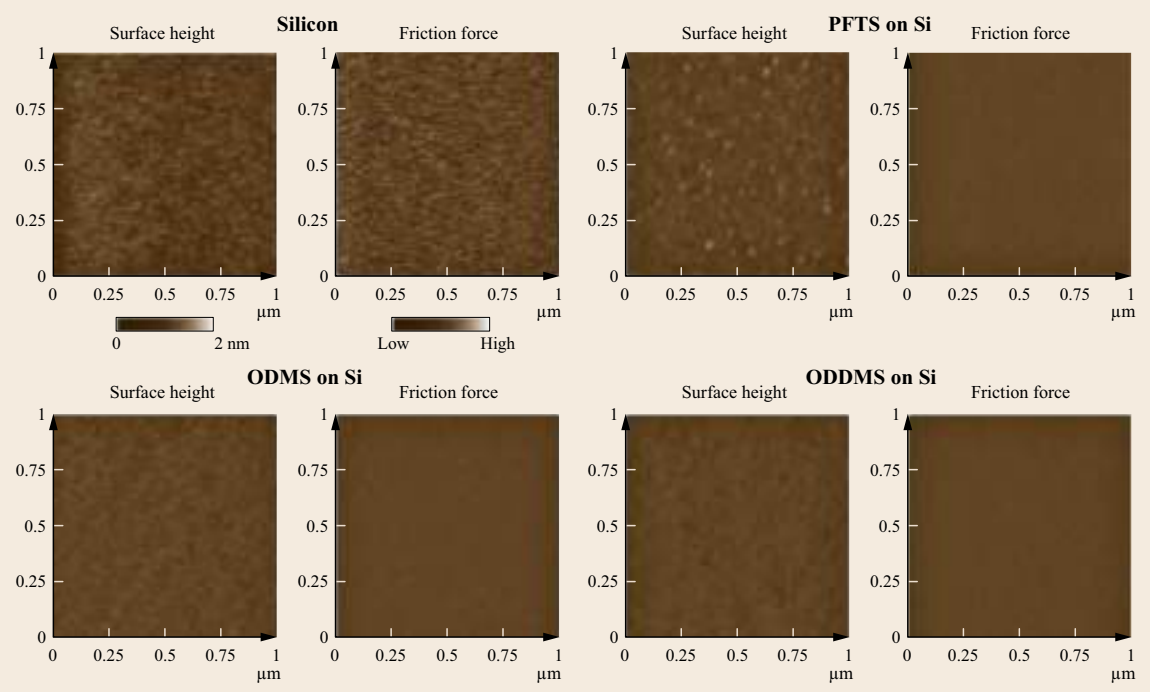

Fig. 34.21 Surface height and friction force maps for Si, PFTS/Si, ODMS/Si, and ODDMS/Si (after [34.59])

61]. The result of adhesive force for silicon showed an increase with relative humidity; Fig. 34.22a. This is expected since the surface of silicon is hydrophilic, as shown in Fig. 34.20a. More condensation of water at the tip–sample interface at higher humidity increases the adhesive force due to the capillary effect. On the other hand, the adhesive force for the SAMs showed a very weak dependency on the change in humidity. This occurs since the surface of the SAMs is hydrophobic. The adhesive force of ODMS/Si and ODDMS/Si showed a slight increase from 75 to 90% RH. Such an increase was absent for PFTS/Si, possibly because of the hydrophobicity of PFTS/Si. The Al substrate is hydrophilic and hence shows relative humidity dependence, Fig. 34.22b. The PFDP, DP, and ODP SAMs deposited on Al substrates showed almost no change in adhesive force with humidity. The highly hydrophobic nature of these monolayers means that the contribution of water menisci to the overall adhesive force is negligible at all humidities.

The friction force of silicon showed an increase with relative humidity up to about 75% RH and a slight decrease beyond this point; Fig. 34.22a. The initial increase can result from the increase in adhesive force. The decrease in friction force at higher humidity could be attributed to the lubricating effect of the water layer.

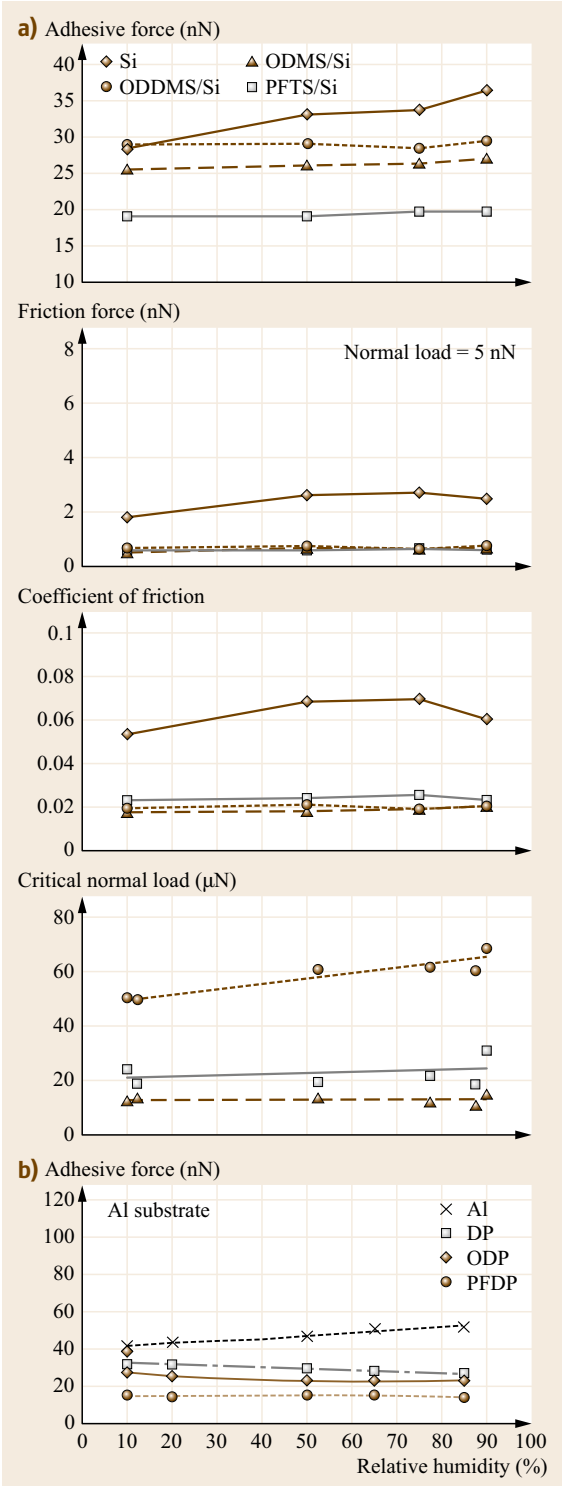

Fig. 34.22a,b Relative humidity effect on **(a)** adhesive force, friction force, coefficient of friction and microwear for various SAMs on Si substrates (after [34.61]), and **(b)** adhesive force for various SAMs on Al substrates (after [34.54]) ◀

This effect is more pronounced in the coefficient of friction. Since the adhesive force increased and coefficient of friction decreased in this range, those effects cancel each other out and the resulting friction force showed only slight changes. On the other hand, the friction force and coefficient of friction of SAMs showed very small changes with relative humidity, like those found for adhesive force. This suggests that the adsorbed water layer on the surface maintained a similar thickness throughout the relative humidity range tested. The differences among the SAM types were small within the measurement error, however a closer look at the coefficient of friction for ODMS/Si showed a slight increase from 75 to 90% RH as compared to PFTS/Si, possibly due to the same reason as for the adhesive force increment. The inherent hydrophobicity of SAMs means that they did not show much relative humidity dependence.

Figure 34.23a shows the effect of temperature on adhesive force, friction force at 5 nN of normal load, and coefficient of friction for various SAMs on Si substrate [34.61]. Figure 34.23b shows the effect of temperature on the adhesive force for SAMs on Al [34.54]. The adhesive force for silicon showed an increase with the temperature, from room temperature (RT) to about 55 °C, followed by a decrease from 55 to 75 °C, and eventually leveled off from 75 to 110 °C. The adhesive force increased for Al substrates up to 50 °C and then decreased to a stable value for higher temperatures. The initial increase of adhesive force for Si and Al substrates at lower temperatures is not well understood. The observed decrease could be attributed to the desorption of water molecules on the surface. After almost full depletion of the water layer, the adhesive force remains constant. The SAMs with hydrocarbon backbones on both Si and Al substrates showed similar behavior as those of the Si and Al substrates, but the initial increase in the adhesive force with temperature was smaller. The SAMs with fluorocarbon backbone chains showed almost no temperature dependence. For the SAMs with hydrocarbon backbone chains, the initial increase in adhesive force is believed to be caused by the melting of the SAM film. The melting point for a linear carbon chain molecule such as $CH_3(CH_2)_{14}CH_2OH$ is 50 °C [34.109]. With an increase in temperature, the SAM film softens, thereby increasing the real area of contact and consequently the adhesive force. Once the temperature is higher than the melting point, the lubrication regime is changed from boundary lubrication in a solid SAM to liquid lubrication in the melted SAM [34.81].

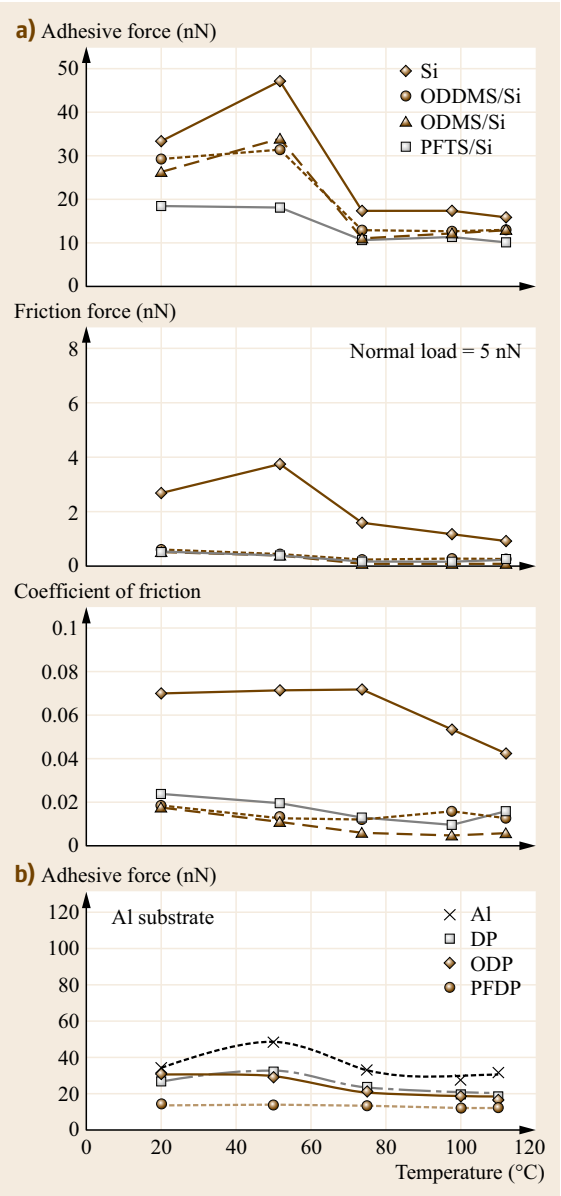

Fig. 34.23a,b Temperature effect **(a)** on adhesive force, friction force, and coefficient of friction for various SAMs on Si substrates (after [34.61]), and **(b)** on adhesive force for various SAMs on Al substrates (after [34.54])

The friction force for silicon showed an increase with temperature followed by a steady decrease. The friction force is highly affected by the change in adhesion. The decrease in friction can result from the depletion of the water layer. The coefficient of friction for silicon remained constant followed by a decrease starting at about 80 °C. For SAMs, the coefficient of friction exhibited a monotonic decrease with temperature. The decrease in friction and coefficient of friction for SAMs possibly results from the decrease in stiffness. As introduced before, the spring model suggests a smaller friction for more compliant SAMs [34.81]. The difference among the SAM types was not significant. PFTS could maintain its stiffness more than ODMS and ODDMS when temperature was increased [34.110], however it was not pronounced in the results.

Figure 34.24a shows the effect of sliding velocity on adhesive force, friction force and coefficient of friction for various SAMs on a Si substrate [34.61]. The adhesive force for silicon remained rather constant at a lower sliding velocity, and then increased rapidly. A similar trend was found for the SAMs. The increase in adhesive force for silicon is believed to be the result of a tribochemical reaction at the tip–sample interface [34.29] and increase of contact area by mechanical plowing. For the SAMs, the higher adhesive force at the higher velocity can result from viscous drag of the SAM molecules [34.111]. SAMs can be detached from the surface and attached to an AFM tip. In addition, another reason may be an increase of contact area, which may be caused by more penetration of the AFM tip into the SAMs. The rate of increase was larger for ODMS than PFTS, presumably because of the higher stiffness and more densely packed structure of PFTS.

Coefficient of friction showed an increase with sliding velocity and reached a plateau for Si, ODMS/Si, and ODDMS/Si. As the sliding speed is increased, the reorientation of the SAMs needs additional work, which might lead to increases in friction. For PFTS, coefficient of friction decreased at larger sliding velocity, forming a peak. The peak structure may result from the viscoelastic property of SAMs [34.112].

Figure 34.24b shows the effect of sliding velocity on the friction force for various SAMs on Al substrates [34.54]. Friction force increases slowly at lower sliding velocities for the bare Al substrate and SAMs, followed by a rapid increase at higher sliding velocities, except for PFDP. The increase in friction force at high velocities ($> 1\,\mathrm{mm/s}$) is the result of asperity impacts and a corresponding high frictional energy dissipation at the sliding interface for Al [34.113]. *Tambe* and *Bhushan* [34.111] extended the *molecular spring* model presented by *Bhushan* and *Liu* [34.79] to explain this velocity-dependent increase in friction force for compliant SAM molecules. Based on this model for the DP and ODP SAMs, the increase in friction force is believed to result from the reorientation of the SAM molecules under the tip load and during tip motion. The reorientation of the SAMs can act as an additional hindrance to tip motion when the AFM tip reverses during scanning and thus results in higher friction. The

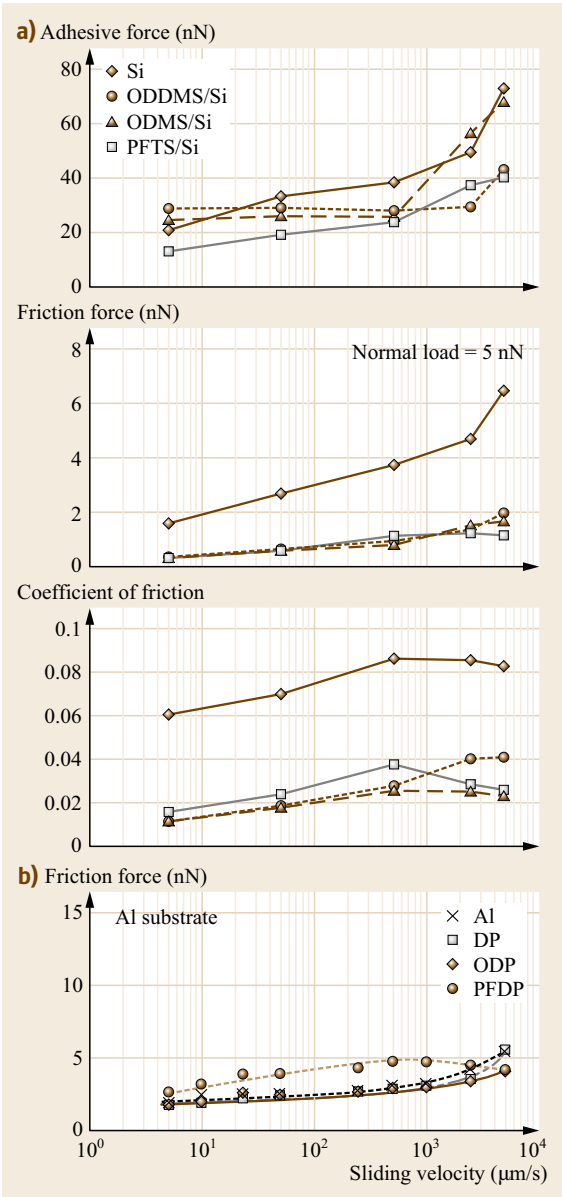

Fig. 34.24a,b Sliding velocity effect **(a)** on adhesive force, friction force, and coefficient of friction for various SAMs on Si substrates (after [34.61]), and **(b)** on friction force for various SAMs on Al substrates (after [34.54])

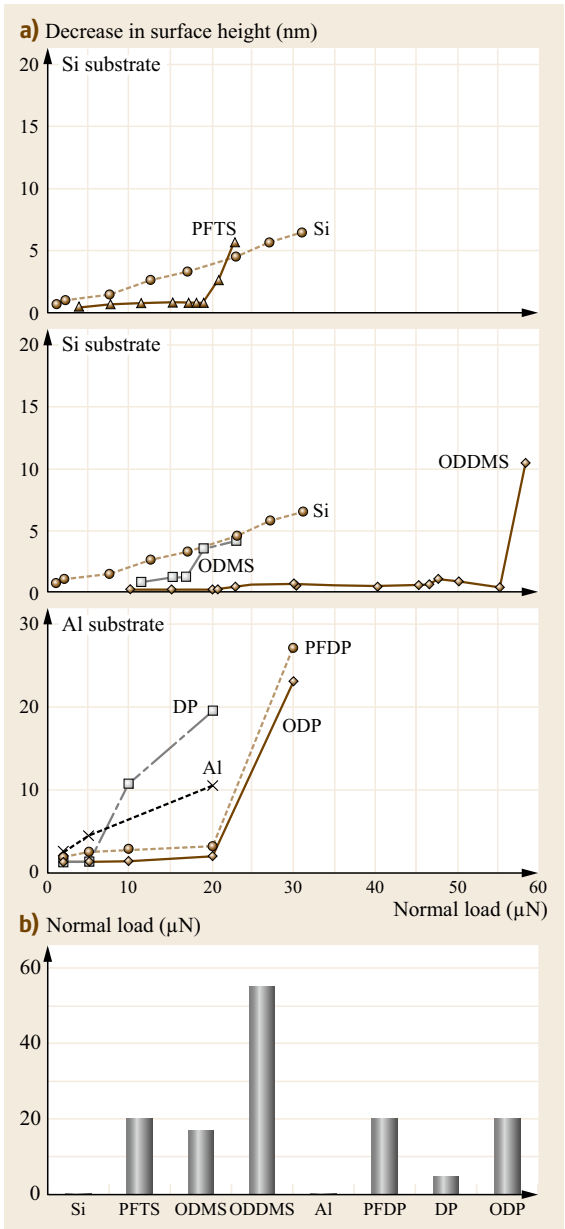

Fig. 34.25 **(a)** Decrease in surface height as a function of normal load after one scan cycle for various SAMs on Si and Al substrates, and **(b)** comparison of critical loads for failure during wear tests for various SAMs (after [34.54, 61])

molecules can consequently get entangled and/or get detached from the substrate and attach to the AFM tip.

AFM Wear Measurements

Figure 34.25a shows the relationship between the decrease in surface height as a function of the normal load during wear tests [34.54, 61]. As shown in the figure, the SAMs exhibit a critical normal load, beyond which the surface height drastically decreases. Figure 34.25a also shows the wear behavior of the Al and Si substrates. Unlike the SAMs, the substrates show a monotonic decrease in surface height with the increasing normal load with wear initiating from the

very beginning, i. e., even for low normal loads. Si (Young's modulus of elasticity, $E = 130$ GPa [34.114, 115], hardness, $H = 11$ GPa [34.27]) is relatively hard in comparison to Al ($E = 77$ GPa, $H = 0.41$ GPa), and hence the decrease in surface height for Al is much larger than that for Si for similar normal loads.

The critical loads corresponding to the sudden failure of SAMs are shown in Fig. 34.25b. Amongst all the SAMs, ODDMS shows the best performance in the wear tests, and this is believed to be because of the longer chain length effect. Fluorinated SAMs – PFTS and PFDP – show a higher critical load as compared to ODMS and DP with similar chain lengths. ODP shows a higher critical load as compared to DP because of its longer chain length. The mechanism of failure of compliant SAMs during wear tests has been presented earlier in Fig. 34.18. It is believed that the SAMs fail mostly due to shearing of the molecule at the head group, that is, by means of shearing of the molecules off the substrate. Table 34.14 gives the bond strengths for various intermolecular bonds. The weakest bonds are at the interface, and hence failure is expected to be initiated at the interface.

To study the effect of relative humidity, wear tests were performed at various humidities. The bottom of Fig. 34.22a shows critical normal load as a function of relative humidity. The critical normal load showed weak dependency on relative humidity for ODMS/Si and PFTS/Si and was larger for ODMS/Si than PFTS/Si throughout the humidity range. This suggests that water molecules could penetrate into the ODDMS, which might work as lubricants [34.81, 118]. This effect was absent for PFTS/Si and ODMS/Si.

34.4.4 Chemical Degradation and Environmental Studies

Chemical degradation and environmental studies were carried out for HDT/Au, PFTS/Si, ODMS/Si, and ODDMS/Si films.

Chemical Degradation Studies

The coefficient of friction and detected gaseous products for HDT/Au are shown in Fig. 34.26a [34.63]. A normal pressure of 50 kPa was applied to HDT films. The coefficient of friction increased after a sliding distance of about 10 m. During sliding, $(CH_2)_{15}S$, C_2H_3, CH_3, CH_2, and H_2 were detected by mass spectrometer. The partial pressure of HS fragments is of interest as it corresponds to the interface bonds, and it is reported here. The increase of partial pressure for $(CH_2)_{15}S$ was much more than that of other species, due to the breaking of the S-Au bond. Partial pressures of C_2H_3, CH_3, CH_2, and H_2 were also found to increase during the sliding. There was no noticeable change in the partial pressure of HS.

HDT film is deposited on an Au(111) layer. The bond strength of S–Au is 184 kJ/mol (Table 34.14), which is lower than that of C–C bonds (425 kJ/mol), C−H bonds (422 kJ/mol), and C–S bonds (286 kJ/mol) in the alkyl chain. Since the S–Au bond is the weakest bond in the alkanethiol chain, the whole chain should be sheared away from the substrate. Because the upper

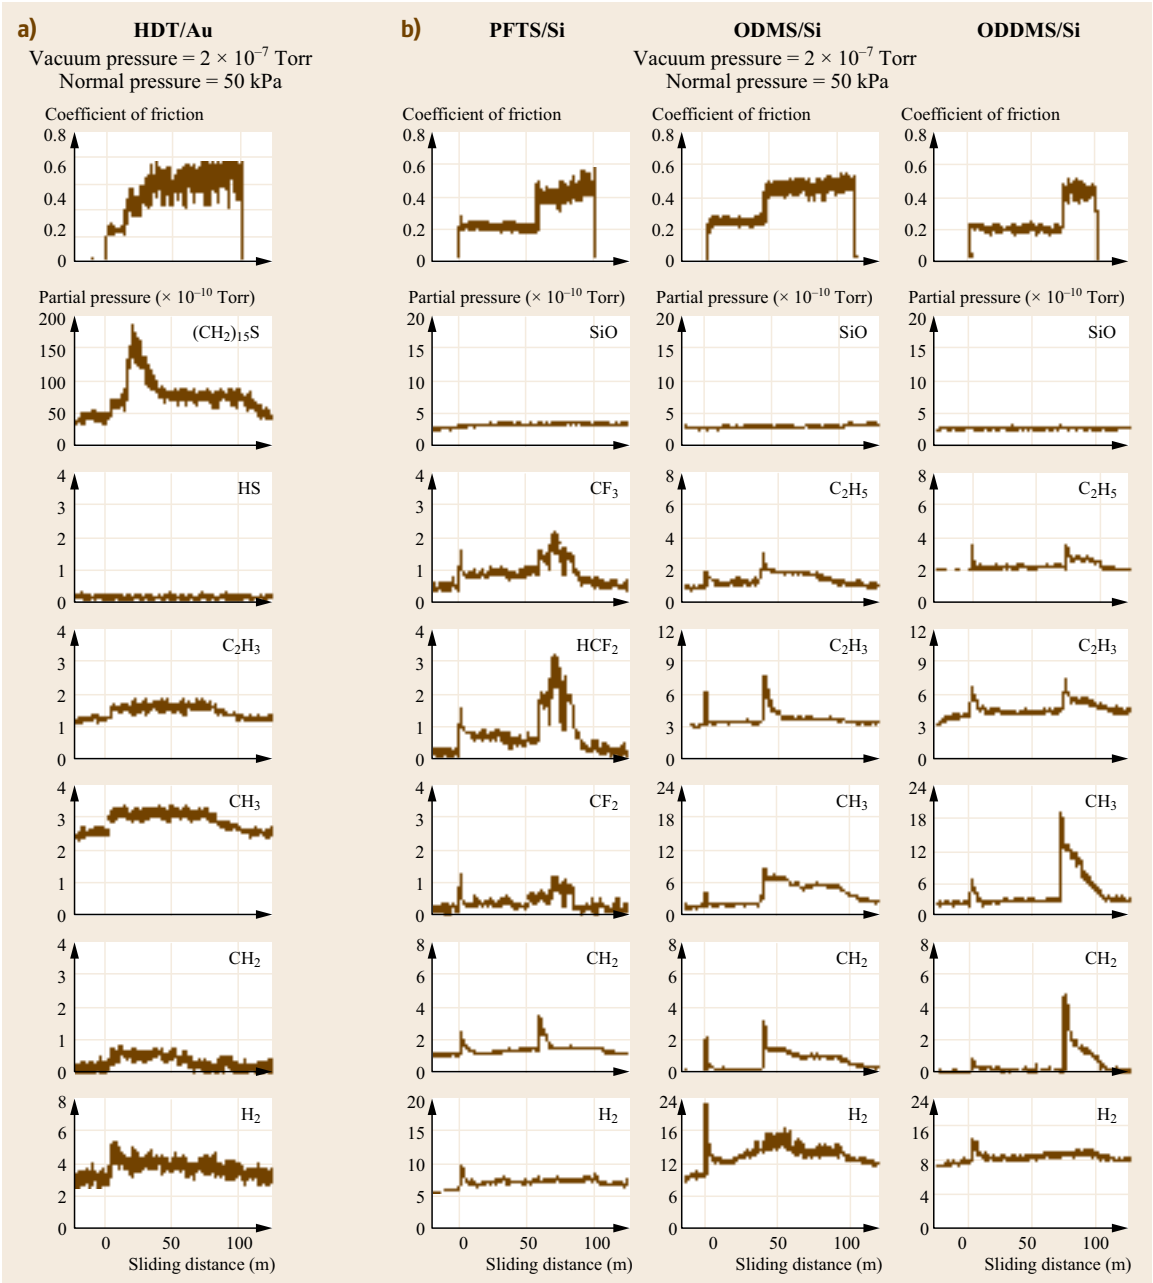

Fig. 34.26a,b Coefficients of friction and mass spectral data on **(a)** HDT/Au (1.9 nm), and **(b)** PFTS/Si (1.8 nm), ODMS/Si (≈ 1.9 nm), and ODDMS/Si (≈ 2.1 nm) in high vacuum (after [34.63])

atomic mass unit (amu) limit of the mass spectrometer used is 250, we monitored $(CH_2)_{15}S$ (amu = 242), which is the chain with CH_3 sheared. The rate of generation of $(CH_2)_{15}S$ is much larger than that of other species. This suggests that the mechanical shear of the whole alkanethiol chain is the dominant factor causing the failure of the HDT film. The cleavage of the S–Au bonds has been reported in the literature. Based on the bond strength as well as the above studies, mechanical shearing of the C–C bonds and C–H bonds does not likely happen during sliding. The reaction induced by low-energy electrons, generated by triboelectrical emission during the sliding, could be responsible for the degradation of the alkanethiol chain. Thermal desorp-

tion of HDT from Au is another possible degradation mechanism of HDT.

The coefficient of friction and generated gaseous products for PFTS/Si, ODMS/Si, and ODDMS/Si are shown in Fig. 34.26b [34.63]. The coefficients of friction for PFTS/Si, ODMS/Si, and ODDMS/Si increase sharply after a certain sliding distance, which indicates the degradation of the film. At the same time, gaseous products of CF_3, HCF_2, CF_2, CH_2, and H_2 were detected for PFTS/Si, and C_2H_5, C_2H_3, CH_3, CH_2, and H_2 were detected for ODMS/Si, and ODDMS/Si.

PFTS/Si showed lower friction than ODMS/Si in the tests. ODDMS/Si showed lower friction than both PFTS/Si and ODMS/Si. This is because of the chain length effect. It has been reported that the coefficient of friction for SAM surfaces decreases with the carbon backbone chain length (n) when the carbon atoms are less than 12. For chains with more than 12 carbons, the change of carbon atoms will not influence the coefficient of friction to a noticeable extent.

PFTS/Si showed a higher durability than ODMS/Si. For the case of a perfluorinated carbon backbone, it is harder to rotate the backbone structure (due to the different sizes of F atoms versus H atoms), which implies that this structure is more rigid than a hydrocarbon backbone [34.108]. *Chambers* [34.119] reported that the C–C bond strength increases when hydrogen is replaced with fluorine. This suggests that the rigid perfluorinated carbon backbone may be responsible for the increased durability. The length of the alkyl chain also influences the desorption energy of alkanes. Based on studies of the adsorption of alkanes on Cu(100), Au(111), Pt(110), and others, the physisorption energy increases with the alkyl chain length [34.120–122]. Therefore, ODDMS is more durable than ODMS.

During sliding on PFTS films, gaseous products of CF_3, HCF_2, CF_2, CH_2, and H_2 were detected. From the structure of perfluoroalkylsilane, the only source of H on the molecular chain that would cause a partial pressure increase of H_2 is from the $(CH_2)_2$, which is located at the bottom of the chain. Since the partial pressure of H_2 increases immediately after sliding and remains high until the end of sliding, it is probably generated by the low-energy electrons coming from a triboelectrical emission. The partial pressure of CH_2 had a sharp peak at the beginning of sliding and at the moment when friction changed. Meanwhile, the partial pressures of CH_3, HSF_2, and CF_2 increased significantly when the friction increased. For ODMS and ODDMS, C_2H_5, C_2H_3, CH_3, CH_2, and H_2 were detected during sliding. The partial pressure of the carbon-related products increases considerably when the friction is increased. The SiO, which is related to the interface bonds, has no noticeable change during sliding.

Perfluoroalkylsilanes and alkylsilanes are attached to the naturally oxidized silicon by Si–O bonds. The Si–O bond strength varies over a large range (Table 34.14), depending on the forming condition. In the alkylsilane chain, C–Si bond strength (414 kJ/mol) is slightly lower than C–C bond strength. Based on Table 34.14, interfacial bonds (Si–O) are weaker than the C–C bonds in the backbone. It is believed that the cleavage of films occurs at the interface. We have previously reported evidence of the cleavage of the interfacial bonds using an AFM. To explain the hydrogen, C_1 and C_2 hydrocarbon (in the tests for PFTS/Si, ODMS/Si, and ODDMS/Si) or fluorocarbon (in the tests for PFTS/Si) products, *Kluth* et al. [34.123] suggested that the alkylsilane (perfluoroalkylsilane as well) chains break and create radicals. The radical could remain on the surface and decompose to generate a shorter radical and an alkene. The radical could repeatedly decompose to ever-shorter radicals and alkenes as long as it remains on the surface.

A summary of the coefficients of friction and durability of all films in a vacuum is presented in Fig. 34.27 [34.63].

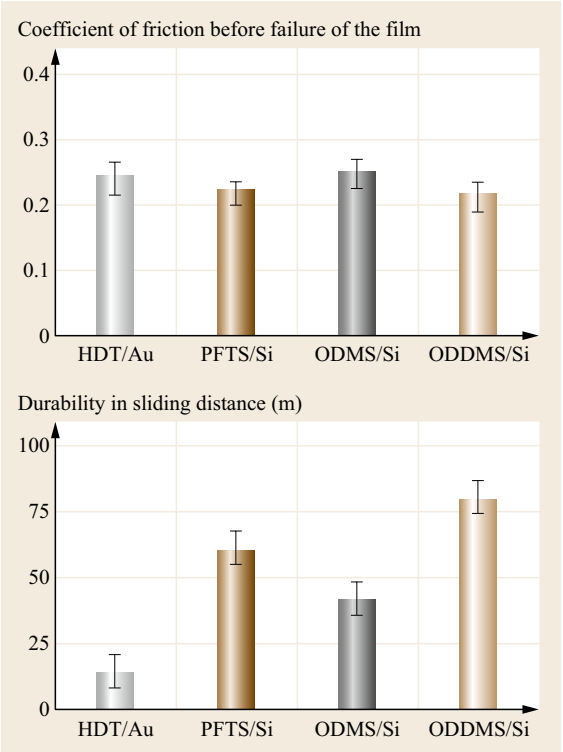

Fig. 34.27 Coefficient of friction and durability comparison of HDT/Au, PFTS/Si, ODMS/Si, and ODDMS/Si in high vacuum. Error bars represent $\pm 3\sigma$ based on five measurements (after [34.63])

Environmental Studies

To study the effect of environment, the friction tests on HDT/Au, PFTS/Si, ODMS/Si, and ODDMS/Si were conducted in high vacuum, argon, dry air (less than 2% RH), air with 30% RH, and air with 70% RH; see Fig. 34.28 [34.63]. By comparing the coefficient of friction in different environments, it was found that the friction in argon is the lowest for the SAMs tested. In high vacuum, the intimate contact leads to high friction. In dry air, the friction is higher than in the argon. This shows that oxygen has an apparent effect on the performance of SAMs. *Kim* et al. [34.124] studied the thermal stability of alkylsiloxane SAMs in air. They found that the alkylsiloxane decomposes at about 200 °C, which is much lower than the decomposition temperature of 470 °C in vacuum reported by *Kluth* et al. [34.123]. This difference could be attributed to the oxygen in air. The water contained in the air is found to have a significant influence on the friction of SAMs. A humidity effects study of alkylsilane on mica substrate by *Tian* et al. [34.118] indicated that the water molecules can

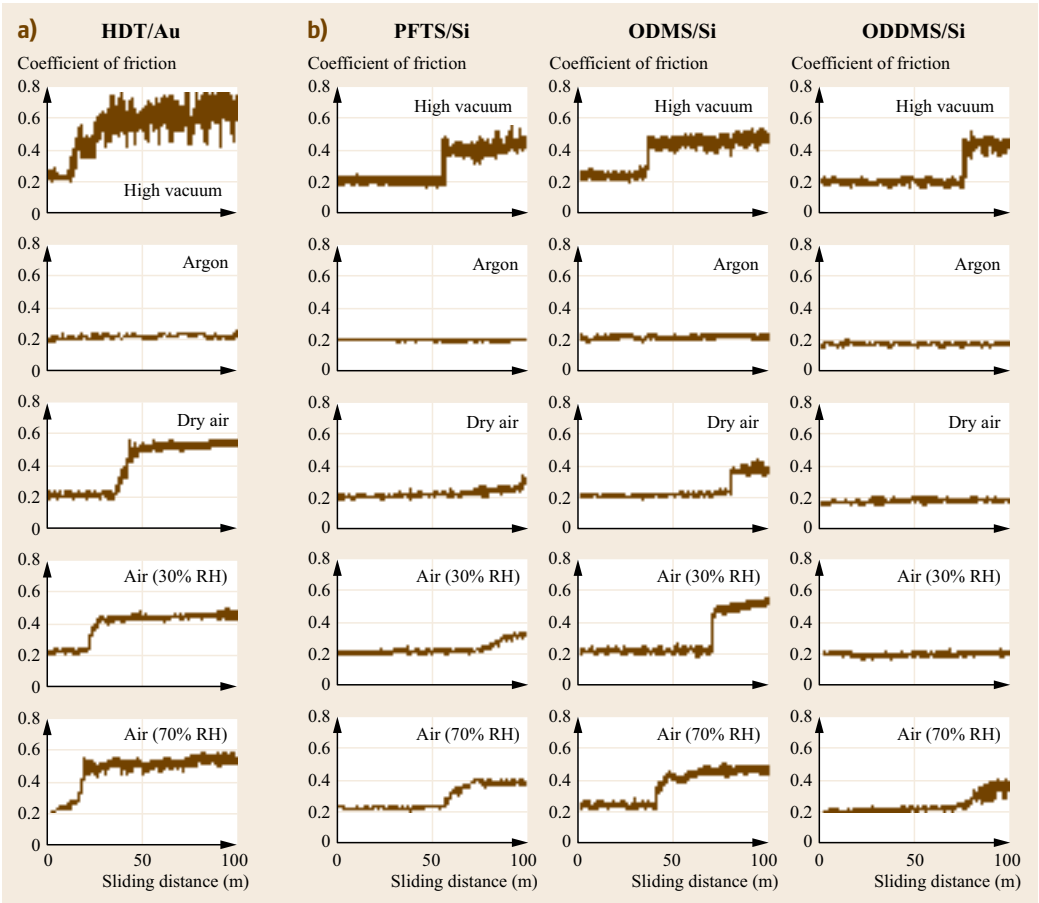

Fig. 34.28 Coefficient of friction data in high vacuum, argon, and air with different humidity levels of **(a)** HDT/Au (1.9 nm) and **(b)** PFTS/Si (1.8 nm), ODMS/Si ($\approx$ 1.9 nm), and ODDMS/Si ($\approx$ 2.1 nm) (after [34.63])

penetrate the alkylsilane film, which alters their molecular chain ordering and can also detach the alkylsilane molecules from the substrate.

A summary of the coefficients of friction before the failure of the lubricant films in various environments is presented in Fig. 34.29 [34.63]. The data in Fig. 34.29 are average values based on five measurements. To summarize the highlights, friction of tested lubricant films is high in high vacuum because of the intimate contact between the lubricants and the counterpart surface. Friction of tested lubricant films is lower in argon than in dry air. Friction of SAMs is significantly influenced by water molecules.

34.5 Conclusion

The adhesive force can be significant in an interface with ultrasmooth surfaces and it can be on the same order as the external load if the latter is small, such as in micro- and nanodevices. High adhesion also leads to stiction, friction, and wear issues in sliding surfaces. In various applications, surfaces need to be protected from exposure to the operating environment, and hydrophobic films are of interest. Films are also needed to provide low adhesion, stiction, friction, and wear. These films should be molecularly thick, well organized, chemically bonded to the substrate, and insensitive to environment. Ordered molecular assemblies with high hydrophobicity can be engineered using chemical grafting of various polymer molecules with suitable functional head groups and nonpolar surface terminal groups.

The contact angle, adhesion, friction, and wear properties of SAMs having alkyl, biphenyl, and perfluoroalkyl spacer chains with different surface terminal groups ($-CH_3$ and $-CF_3$) and head groups ($-SH$, $-Si-O-$, $-OH$, and $P-O-$) were presented in this chapter. It was found that the adhesive force varies linearly with the work of adhesion value of SAMs, which indicates that capillary condensation of water plays an important role to the adhesion of SAMs on the nanoscale at ambient conditions. SAMs with high-compliance long carbon spacer chains exhibited the lowest adhesive force and friction force. The friction data were explained using a molecular spring model, in which the local stiffness and intermolecular force govern frictional performance. The results of the stiffness and friction characterization of the micropatterned sample with different structures supports this model. Perfluoroalkylsilane and perfluoroalkylphosphonate SAMs exhibited lower surface energy, higher contact angle, and lower adhesive force as compared to that of alkylsilane and alkylphosphonate SAMs, respectively. The substrate had little effect. The coefficients of friction of various SAMs were comparable.

The influence of relative humidity on adhesion and friction of SAMs was dominated by the thickness of the adsorbed water layer. At higher humidity, water increases friction through increased adhesion by the meniscus effect in the contact zone. With an increase in temperature, in the case of Si(111), the desorption of the adsorbed water layer and reduction of the surface tension of water reduced the adhesive force and friction force. A decrease in adhesion and friction with temperature was found for all films. An increase in adhesive force and friction with sliding velocity was found for all films.

PFTS/Si showed a better wear resistance than ODMS/Si. ODDMS/Si showed a better wear resistance than ODMS/Si due to the chain length effect. Wear behavior of the SAMs was mostly determined by the molecule-substrate bond strengths. Similar trends were observed for films on Al substrates.

The nanotribological characterization studies of SAMs deposited on Si and Al substrates are summarized in Table 34.15 [34.53]. SAMs deposited on the Si and Al substrates showed low friction and low adhesion, both of which are desirable for MEMS/NEMS applications.

Table 34.15 Summary of nanotribological characterization studies for SAMs on Si and Al substrates

	SAMs property	Friction force	Adhesive force	Wear
Substrate	Hard	High	Low	Low
	Soft	Low	Low	High
Chemical structure	Linear chain molecule	High	Low	High
	Ring molecule	High	High	Low
Backbone	Fluorocarbon backbone	Low	Low	Low
	Hydrocarbon backbone	Low	High	High
Chain length	Long backbone chain		High	High
	Short backbone chain		Low	Low

Based on studies in high vacuum (2×10^{-7} Torr), the coefficients of friction of the SAMs are in the following order (from low to high): ODDMS/Si, PFTS/Si, HDT/Au, ODMS/Si. HDT on Au showed lower durability than perfluoroalkylsilane and alkylsilane on Si because of the weak interfacial bond. PFTS/Si had better durability than ODMS/Si. This indicates that fluorination of alkylsilane can improve durability. ODDMS/Si was more durable than ODMS/Si and PFTS/Si because of the chain length effect. The friction of SAMs in high vacuum was higher than in argon because of intimate contact. Based on studies in argon and air with various relative humidities, oxygen can increase friction and decrease durability of SAMs. The water molecule can detach SAM molecules from the substrate and result in high friction and low durability.

In summary, based on the contact angle, adhesion, friction, and wear measurements of SAM films by AFM, these films exhibit attractive hydrophobic and tribological properties. Fluorinated SAMs appear to exhibit superior performance. SAM films should find many applications including in micro- and nanodevices requiring good nanotribological properties and surface protection.

35. Nanoscale Boundary Lubrication Studies

Bharat Bhushan

Boundary films are formed by physisorption, chemisorption, and chemical reaction. A good boundary lubricant should have a high degree of interaction between its molecules and the solid surface. As a general rule, liquids are good lubricants when they are polar and thus able to grip solid surfaces (or be adsorbed). In this chapter, we present an overview of various perfluoropolyethers (PFPEs) and ionic liquid films. PFPEs exhibit the highest chemical and thermal stability. Ionic liquid films possess efficient heat transfer properties and some electrical conductivity properties of interest. We present a summary of nanodeformation, molecular conformation, and lubricant spreading studies, followed by an overview of the nanotribological properties of polar and nonpolar PFPEs and ionic liquid films studied by atomic force microscopy (AFM), and chemical degradation studies using a high vacuum tribotest apparatus.

Boundary films are formed by physisorption, chemisorption, and chemical reaction. With physisorption, no exchange of electrons takes place between the molecules of the adsorbate and those of the adsorbent [35.1, 2]. The physisorption process typically involves van der Waals forces, which are relatively weak. In chemisorption, there is an actual sharing of electrons or an electron interchange between the chemisorbed species and the solid surface. The solid surfaces very strongly bond to the adsorption species through covalent bonds. Chemically reacted films are formed by the chemical reaction of the solid surface with the environment. Physisorbed films can be either monomolecularly or polymolecularly thick. Chemisorbed films are monomolecular, but stoichiometric films formed by chemical reaction can have a large film thickness. In general, the stability and durability of surface films decrease in the following order: chemically reacted films, chemisorbed films, and physisorbed films. A good boundary lubricant should have a high degree of interaction between its molecules and the solid surface. As a general rule, liquids are good lubricants when they are polar and thus able to grip solid surfaces (or be adsorbed). Polar lubricants contain reactive functional groups with low ionization potential or groups having high polarizability [35.1–5]. Boundary lubrication properties of lubricants are also dependent upon the molecular conformation and lubricant spreading [35.6–9].

Perfluoropolyether (PFPE) films, self-assembled mono layers (SAMs), and Langmuir–Blodgett (L–B) films can be used as boundary lubricants [35.1–5, 10–14]. PFPEs exhibit the following properties: low surface tension and a low contact angle, which allow easy spreading on surfaces and provide hydrophobic properties; chemical and thermal stability, which minimize degradation under use; low vapor pressure, which provides low outgassing; high adhesion to substrate via organofunctional bonds; and good lubricity, which reduces the interfacial friction and wear [35.4, 5]. PFPE films are used exclusively for lubrication of magnetic rigid disks and metal evaporated magnetic tapes to reduce friction and wear of the head-medium interface [35.4]. The structure of the lubricants employed at the head-medium interface has not changed substantially over the past decade, except with the variations in the end groups. However, the thickness of the PFPE film used to lubricate the disk has steadily decreased from multilayer thicknesses to the submonolayer thickness regime [35.5, 13].

Molecularly thick PFPE films are also being considered for lubrication purposes for micro/nanoelectromechanical systems (MEMS/NEMS) [35.5, 15–17]. It is well known that the properties of molecularly thick liquid films confined to solid surfaces can be dramatically different from those of the corresponding bulk liquid. In order to efficiently develop lubrication systems that meet the requirements of advanced rigid disk drives and MEMS/NEMS applications, the nanotribology of thin films of PFPE lubricants should be fully understood [35.12, 18, 19]. It is also important to understand lubricant-substrate interfacial interactions and the influence of operating environment on the nanotribological performance of molecularly thick PFPE liquid films.

Ionic liquids have been considered as potential lubricants [35.16, 20, 21]. They possess efficient heat transfer properties. They are also electrically conducting, which is of interest in various MEMS/NEMS applications such as atomic force microscope probe-based data recording [35.22–24].

In this chapter, we present an overview of PFPE and ionic liquid films. We first present a summary of nanodeformation, molecular conformation, and lubricant spreading studies and an overview of nanotribological and electrical studies of commonly used polar and nonpolar PFPE and ionic liquid films using atomic force microscopy (AFM) and chemical degradation studies using a high vacuum tribotest apparatus.

35.1 Nanodeformation, Molecular Conformation, Spreading, Nanotribological and Electrical Studies, and Environmental Effects of Commonly Used PFPE Lubricant Films

The molecular structures of two commonly used typical PFPE lubricants (Z-15 and Z-DOL 2000) are schematically shown in Fig. 35.1 (Fomblin, Solvay Solexis Inc., Milan, Italy). Z-15 has nonpolar $-CF_3$ end groups, whereas Z-DOL is a polar lubricant with hydroxyl(–OH) end groups. Their typical properties are summarized in Table 35.1. It shows that Z-15 and Z-DOL have almost the same density and surface tension, but Z-15 has a larger molecular weight and higher viscosity. Both of them have low surface tension, low vapor pressure, low evaporation weight loss, and good oxidative stability [35.3, 4]. For nanotribological characterization, a single crystal Si(100) wafer with a native oxide layer has generally been used as a substrate for deposition of molecularly thick lubricant films. Z-15 and Z-DOL films can be directly deposited on the Si(100) wafer by a dip-coating technique. The clean silicon wafer is vertically submerged into a dilute solution of lubricant in a hydrocarbon solvent (HT-70, Solvay Solexis Inc., Milan, Italy). The silicon wafers are vertically pulled up from the solution with a motorized stage at a constant speed for deposition of desired thicknesses of Z-15 and Z-DOL lubricants [35.5, 13, 25]. The lubricant film thickness obtained in dip coating is a function of concentration and pulling-up speed, among other factors. The Z-DOL film is bonded to the silicon substrate by heating the as-deposited Z-DOL samples in an oven at 150 °C for about 30 min. The native oxide layer

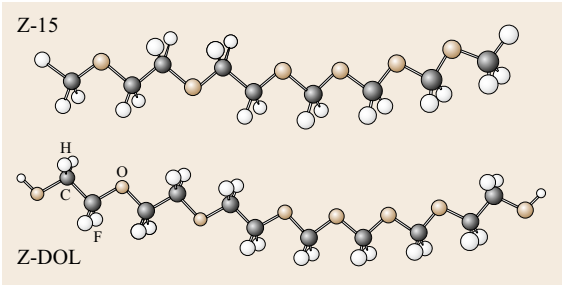

Fig. 35.1 Schematics of the molecular structures of Z-15 and Z-DOL 2000. Z-15 has nonpolar $-CF_3$ end groups, whereas Z-DOL is a polar lubricant with hydroxyl (−OH) end groups. In this figure, the m/n value, shown in Table 35.1, equals 2/3

of Si(100) wafer reacts with the –OH groups of the lubricants during thermal treatment [35.25–28]. Subsequently, fluorocarbon solvent (FC-72, 3M) washing of the thermal treated specimen removes loosely absorbed species leaving the chemically bonded phase on the substrate. The chemical bonding between Z-DOL molecules and the silicon substrate is illustrated in Fig. 35.2. The bonded and washed Z-DOL film is referred to as Z-DOL (fully bonded) in this chapter. The as-deposited Z-15 and Z-DOL films are mobile phase lubricants (i. e., liquid-like lubricant), whereas the Z-DOL (fully bonded) films are fully bonded soft solid phase (i. e., solid-like) lubricants.

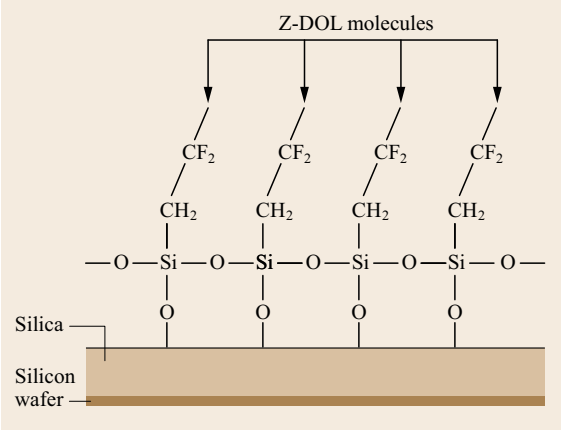

Fig. 35.2 Schematic of Z-DOL molecules that chemically bonded onto a Si(100) substrate surface (which has native oxide) after thermal treatment at 150 °C for 30 min

35.1.1 Nanodeformation, Molecular Conformation, and Spreading

Nanodeformation behavior of Z-DOL lubricants was studied using an AFM by *Blackman* et al. [35.29, 30]. Before bringing a tungsten tip into contact with a molecular overlayer, it was first brought into contact with a bare clean-silicon surface (Fig. 35.3). As the sample approaches the tip, the force initially is zero, but at point A the force suddenly becomes attractive (*top curve*), which increases until point B where the sample and tip come into intimate contact and the force becomes repulsive. As the sample is retracted, a pull-off force of 5×10^{-8} N (point D) is required to overcome adhesion between the tungsten tip and the silicon surface. When an AFM tip is brought into contact with an unbonded Z-DOL film, a sudden jump in adhesive contact is also observed. A much larger pull-off force is required to overcome the adhesion. The adhesion is initiated by the formation of a lubricant meniscus surrounding the tip. This suggests that the unbonded Z-DOL lubricant shows liquid-like behavior. However, when the tip was brought into contact with a lubricant film that was firmly bonded to the surface, the liquid-like behavior disappears. The initial attractive force (point A) is no longer sudden as with the liquid film, but rather gradually increases as the tip penetrates the film.

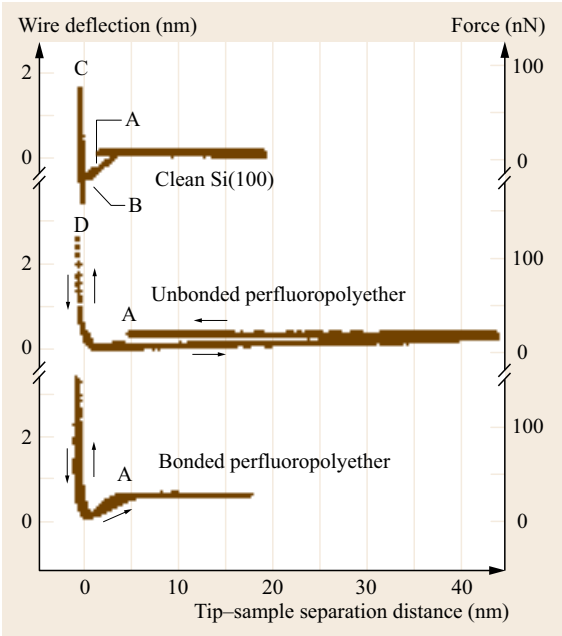

Fig. 35.3 Wire deflection (normal load) as a function of tip-sample separation distance curves comparing the behavior of a clean Si(100) surface to a surface lubricated with free and unbonded PFPE lubricant, and a surface where the PFPE lubricant film was thermally bonded to the surface (after [35.29])

According to *Blackman* et al. [35.29, 30], if the substrate and tip were infinitely hard with no compliance and/or deformation in the tip and sample supports, the line from B to C would be vertical with an infinite slope. The tangent to the force-distance curve at a given point is referred to as the stiffness at that point and was determined by fitting a least-squares line through the nearby data points. For silicon, the deformation is reversible (elastic) since the retracting (outgoing) portion of the curve (C to D) follows the extending (ingoing) portion (B to C). For bonded lubricant film, at the point where slope of the force changes gradually from attractive to repulsive, the stiffness changes gradually, indicating compression of the molecular film. As the load is increased, the slope of the repulsive force eventually approaches that of the bare surface. The bonded film was found to respond elastically up to the highest loads that could be applied, of 5 μN. Thus, bonded lubricant behaves as a soft polymer solid.

Figure 35.4 illustrates two extremes for the conformation on a surface of a linear liquid polymer without any reactive end groups and at submonolayer coverages [35.6, 8]. At one extreme, the molecules lie flat on the surface, reaching no more than their chain diameter δ above the surface. This would be the case if a strong attractive interaction exists between the molecules and the solid. On the other extreme, when a weak attraction exists between polymer segments and the solid, the molecules adopt conformation close to that of the molecules in the bulk, with the microscopic thickness equal to about the radius of gyration R_g. *Mate* and *Novotny* [35.8] used AFM to study conformation of 0.5–1.3 nm-thick Z-15 molecules on clean Si(100) surfaces. They found that the thickness measured by AFM is thicker than that measured by ellipsometry with the offset ranging from 3 to 5 nm. They found that the offset was the same for very thin submonolayer coverages. If the coverage is submonolayer and inadequate to make a liquid film, the relevant thickness is then the height (h_e) of the molecules extended above the solid surface. The offset should be equal to $2h_e$, assuming that the molecules extend the same height above both the tip and silicon surfaces. They thus concluded that the molecules do not extend more than 1.5–2.5 nm above a solid or liquid surface, much smaller than the radius of gyration of the lubricants ranging between 3.2 and 7.3 nm, and similar to the approximate cross-sectional diameter of 0.6–0.7 nm for the linear polymer chain. Consequently, the height that the molecules extend above the surface is considerably less than the diameter of gyration of the molecules and only a few molecular diameters in height, implying that the physisorbed molecules on a solid surface have an extended, flat conformation. They also determined the disjoining pressure of these liquid films from AFM measurements of the distance needed to break the liquid meniscus that forms between the solid surface and the AFM tip (also see [35.9]). For a monolayer thickness of about 0.7 nm, the disjoining pressure is about 5 MPa, indicating strong attractive interaction between the liquid molecules and the solid surface. The disjoining pressure decreases with increasing film thickness in a manner consistent with a strong attractive van der Waals interaction between the liquid molecules and the solid surface.

Rheological characterization shows that the flow activation energy of PFPE lubricants is weakly dependent on chain length, and is strongly dependent on the functional end groups [35.31]. PFPE lubricant films that contain polar end groups have lower mobility than those with nonpolar end groups of similar chain length [35.32]. The mobility of PFPE also depends on the surface chemical properties of the substrate. The spreading of Z-DOL on an amorphous carbon surface has been studied as a function of hydrogen or nitrogen content in the carbon film, using scanning microellipsometry [35.33]. The diffusion coefficient data presented in Fig. 35.5 are thickness dependent. It shows that the surface mobility of Z-DOL increased as hy-

drogen content increased, but decreased as nitrogen content increased. The enhancement of Z-DOL surface mobility by hydrogenation may be understood from the fact that the interactions between Z-DOL molecules and the carbon surface can be significantly weakened due to a reduction of the number of high-energy binding sites on the carbon surface. The stronger interactions between Z-DOL molecules and the carbon surface, as nitrogen content in the carbon coating increases, leads to the lowering of Z-DOL surface mobility.

Molecularly thick films may be sheared at very high shear rates, on the order of 10^8–10^9 s^{-1} during sliding, such as during magnetic disk drive operation. During such shear, lubricant stability is critical to the protection of the interface. For proper lubricant selection, viscosity at high shear rates and associated shear thinning need to be understood. Viscosity measurements of eight different types of PFPE films show that all eight lubricants display Newtonian behavior and their viscosity remains constant at shear rates up to 10^7 s^{-1} [35.34, 35].

35.1.2 Nanotribological Studies and Environmental Effects

AFM techniques have been used to investigate the nanotribological performance of PFPEs. *Mate* [35.36, 37], *O'Shea* et al. [35.38, 39], *Bhushan* et al. [35.18, 40], *Koinkar* and *Bhushan* [35.28, 41], *Bhushan* and *Sundararajan* [35.42], *Bhushan* and *Dandavate* [35.43], *Liu* and *Bhushan* [35.25], and *Palacio* and *Bhushan* [35.44, 45] used an AFM to provide insight into how PFPE lubricants function at the molecular level. *Mate* [35.36, 37] conducted friction experiments on bonded and unbonded Z-DOL, and he found that the coefficient of friction of the unbonded Z-DOL is about two times larger than the bonded Z-DOL (also see [35.38, 39]). *Koinkar* and *Bhushan* [35.28, 41] and *Liu* and *Bhushan* [35.25] studied the friction and wear performance of a Si(100) sample lubricated with Z-15, Z-DOL, and Z-DOL (fully bonded) lubricants. They found that using Z-DOL (fully bonded) could significantly improve the adhesion, friction, and wear performance of Si(100). They also discussed the lubrication mechanisms on the molecular level. *Bhushan* and *Sundararajan* [35.42] and *Bhushan* and *Dandavate* [35.43] studied the effect of tip radius and relative humidity on the adhesion and friction properties of Si(100) coated with Z-DOL (fully bonded).

In this section, we review the adhesion, friction, and wear properties of Z-15 and Z-DOL at various operating conditions (rest time, velocity, relative humidity, temperature, and tip radius). The experiments were carried out using a commercial AFM system with pyramidal Si_3N_4 and diamond tips. An environmentally controlled chamber and a thermal stage were used to perform relative humidity and temperature effect studies.

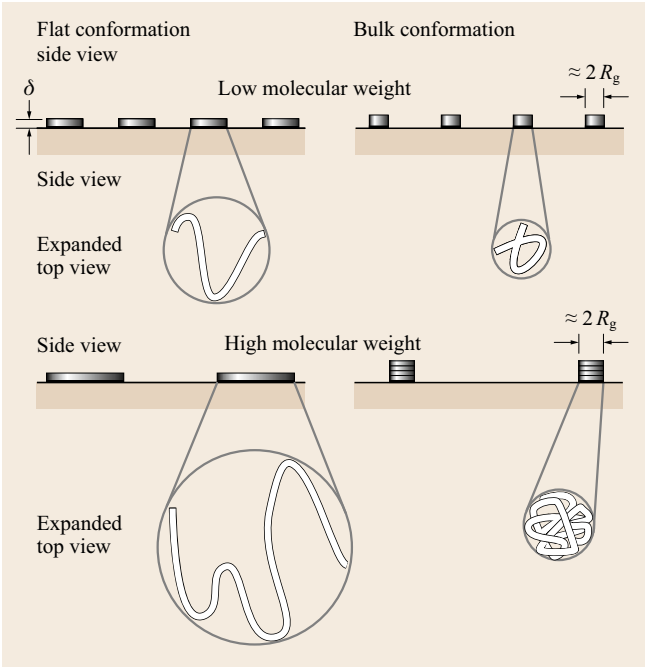

Fig. 35.4 Schematic representation of two extreme liquid conformations at the surface of the solid for low and high molecular weights at low surface coverage. δ is the cross-sectional diameter of the liquid chain and R_g is the radius of gyration of the molecules in the bulk (after [35.8])

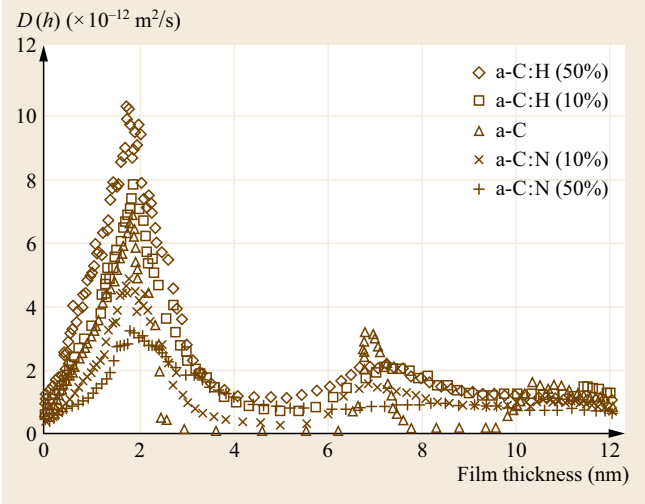

Fig. 35.5 Diffusion coefficient $D(h)$ as a function of lubricant film thickness for Z-DOL on different carbon films (after [35.33])

Friction and Adhesion

To investigate the friction properties of Z-15 and Z-DOL (fully bonded) films on Si(100), the friction force versus normal load curves were measured by making friction measurements at increasing normal loads [35.25]. The representative results of Si(100), Z-15, and Z-DOL (fully bonded) are shown in Fig. 35.6. An approximately linear response of all three samples is observed in the load range of 5−130 nN. The friction force of solid-like Z-DOL (fully bonded) is consistently smaller than that for Si(100), but the friction force of liquid-like Z-15 lubricant is higher than that of Si(100). *Sundararajan* and *Bhushan* [35.46] have studied the static friction force of silicon micromotors lubricated with Z-DOL by AFM. They also found that liquid-like lubricant of Z-DOL significantly increased the static friction force; on the contrary a solid-like Z-DOL (fully bonded) coating can dramatically reduce the static friction force. This is in good agreement with the results of *Liu* and *Bhushan* [35.25]. In Fig. 35.6, the nonzero value of the friction force signal at zero external load is due to the adhesive forces. It is well known that the following relationship exists between the friction force F and external normal load W [35.1, 2]

$$F = \mu(W + W_a)\,, \tag{35.1}$$

where μ is the coefficient of friction, and W_a is the adhesive force. Based on this equation and the data in Fig. 35.6, we can calculate the μ and W_a values. The coefficients of friction of Si(100), Z-15, and Z-DOL are 0.07, 0.09 and 0.04 respectively. Based on (35.1), the adhesive force values are obtained from the horizontal intercepts of the friction force versus normal load curves at a zero value of friction force. Adhesive force values of Si(100), Z-15, and Z-DOL are 52 nN, 91 nN, and 34 nN respectively.

The adhesive forces of these samples were also measured by using a force calibration plot (FCP) technique to obtain force-versus-distance curves. In this technique, the tip is brought into contact with the sample, and the maximum force needed to pull the tip and sample apart is measured as the adhesive force. Figure 35.7 shows the typical FCP curves of Si(100),

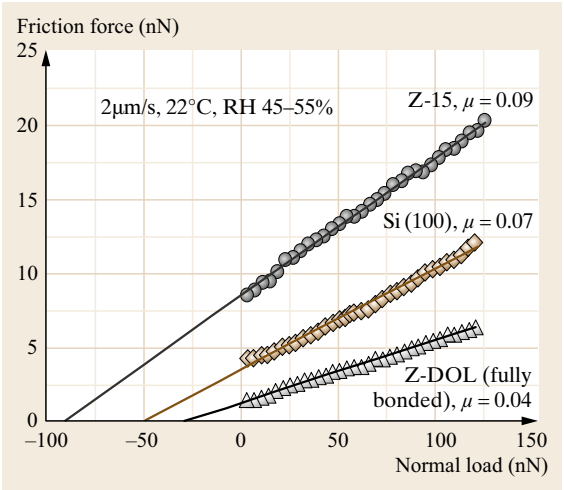

Fig. 35.6 Friction force versus normal load curves for Si(100), 2.8 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) film at 2 μm/s, and in ambient air sliding against a Si_3N_4 tip. Based on these curves, coefficient of friction μ and adhesion force of W_a can be calculated (after [35.25])

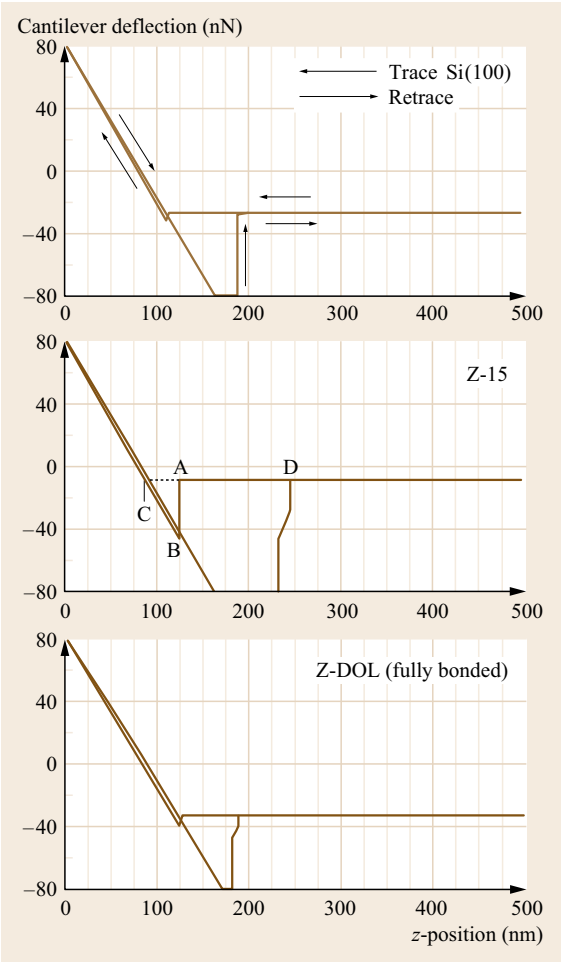

Fig. 35.7a–c Typical force calibration plots of **(a)** Si(100), **(b)** 2.8 nm-thick Z-15 film, and **(c)** 2.3 nm-thick Z-DOL (fully bonded) film in ambient air. The adhesive forces can be calculated from the horizontal distance between points C and D, and the cantilever spring constant of 0.58 N/m (after [35.25])

Z-15, and Z-DOL (fully bonded) [35.25]. As the tip approaches the sample within a few nanometers (A), an attractive force exists between the tip and the sample surfaces. The tip is pulled toward the sample, and contact occurs at point B on the graph. The adsorption of water molecules and/or presence of liquid lubricant molecules on the sample surface can also accelerate this so-called *snap-in*, due to the formation of a meniscus of the water and/or liquid lubricant around the tip. From this point on, the tip is in contact with the surface, and as the piezoelectric tube scanner extends further, the cantilever is further deflected. This is represented by the slope portion of the curve. As the piezoelectric tube scanner retracts, at point C the tip goes beyond the zero deflection (flat) line, because of the attractive forces, into the adhesive force regime. At point D, the tip snaps free of the adhesive forces and is again in free air. The adhesive force (pull-off force) is determined by multiplying the cantilever spring constant (0.58 N/m) by the horizontal distance between points C and D, which corresponds to the maximum cantilever deflection toward the samples before the tip is disengaged. Incidentally, the horizontal shift between the loading and unloading curves results from the hysteresis of the piezoelectric tube.

The adhesive forces of Si(100), Z-15, and Z-DOL (fully bonded) measured by FCP and friction force versus normal load plot are summarized in Fig. 35.8 [35.25]. The results measured by these two methods are in good agreement. Figure 35.8 shows that the presence of mobile Z-15 lubricant film increases the adhesive force as compared to that of Si(100). In contrast, the presence of solid phase Z-DOL (fully bonded) film reduces the adhesive force as compared that of Si(100). This result is in good agreement with the results of *Blackman* et al. [35.29] and *Bhushan* and *Ruan* [35.47]. Sources of adhesive forces between the tip and the sample surfaces are van der Waals attraction and long-range meniscus force [35.1, 2, 12]. Relative magnitudes of the forces from the two sources are dependent upon various factors including the distance between the tip and the sample surface, their surface roughness, their hydrophobicity, and relative humidity [35.48]. For most surfaces with some roughness, the meniscus contribution dominates at moderate to high humidities.

The schematic (*bottom*) in Fig. 35.8 shows the relative size and source of the meniscus. The native oxide layer (SiO_2) on the top of a Si(100) wafer exhibits hydrophilic properties, and some water molecules can be adsorbed on this surface. The condensed water will form a meniscus as the tip approaches the sample surface. In the case of a sphere (such as a single asperity

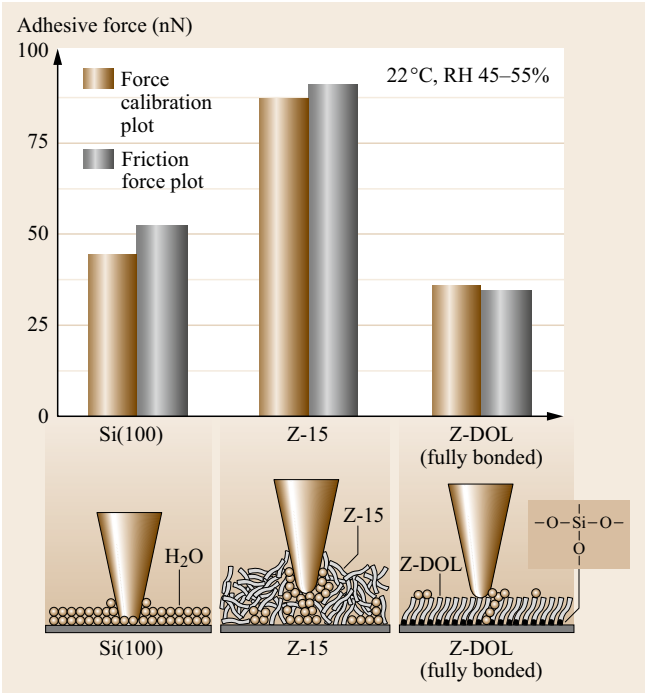

Fig. 35.8 Summary of the adhesive forces of Si(100), 2.8 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) film measured by force calibration plots and friction force versus normal load plots in ambient air. The schematic (*bottom*) showing the effect of a meniscus, formed between the AFM tip and the sample surface, on the adhesive and friction forces (after [35.25])

AFM tip) in contact with a flat surface, the attractive Laplace force F_L caused by the capillary is

$$F_L = 2\pi R\gamma(\cos\theta_1 + \cos\theta_2)\,, \qquad (35.2)$$

where R is the radius of the sphere, γ is the surface tension of the liquid against air, and θ_1 and θ_2 are the contact angles between liquid and flat and spherical surfaces respectively [35.1, 2, 49]. As the surface tension value of Z-15 (24 dyn/cm) is smaller than that of water (72 dyn/cm), the larger adhesive force in Z-15 cannot only be caused by the Z-15 meniscus. The nonpolar Z-15 liquid does not have complete coverage and strong bonding with Si(100). In the ambient environment, the condensed water molecules will permeate through the liquid Z-15 lubricant film and compete with the lubricant molecules present on the substrate. The interaction of the liquid lubricant with the substrate is weakened, and a boundary layer of the liquid lubricant forms puddles [35.28, 41]. This dewetting allows water molecules to be adsorbed on the Si(100) surface as aggregates along with Z-15 molecules, and both of them can form a meniscus while the tip approaches the surface. In ad-

dition, as the Z-15 film is pretty soft compared to the solid Si(100) surface, and penetration of the tip in the film occurs while pushing tip down, this leads to a large area of the tip involved in the formation of the meniscus at the tip-liquid interface (water aggregates along with Z-15). These two factors of the liquid-like Z-15 film result in higher adhesive force. It should also be noted that Z-15 has a higher viscosity compared to that of water, therefore Z-15 film provides higher resistance to sliding motion and results in a larger coefficient of friction. In the case of Z-DOL (fully bonded) film, both active groups of Z-DOL molecules are strongly bonded on the Si(100) substrate through the thermal and washing treatment, thus the Z-DOL (fully bonded) film has a relatively low free surface energy and cannot be displaced readily by water molecules or readily adsorb water molecules. Thus, the use of Z-DOL (fully bonded) can reduce the adhesive force. We further believe that the bonded Z-DOL molecules can be orientated under stress (behaves as a soft polymer solid), which facilitates sliding and reduces the coefficient of friction.

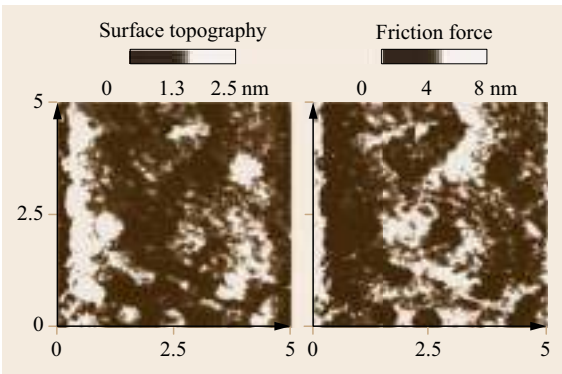

Fig. 35.9 Grayscale plots of the surface topography and friction force obtained simultaneously for unbonded 2.3 nm-thick Demnum-type PFPE lubricant film on silicon (after [35.28])

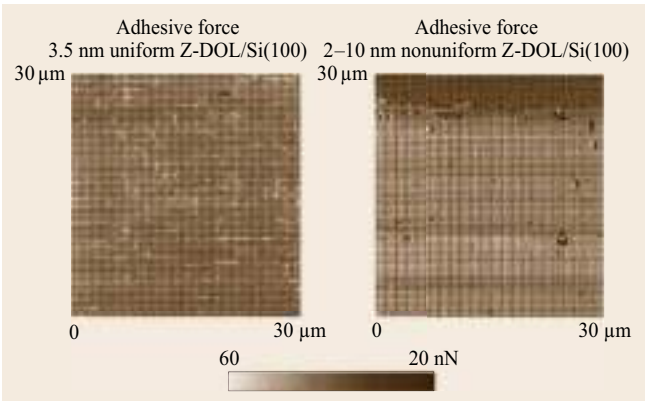

Fig. 35.10 Grayscale plots of the adhesive force distribution of a uniformly coated, 3.5 nm-thick unbonded Z-DOL film on silicon and a 3–10 nm-thick unbonded Z-DOL film on silicon that was deliberately coated nonuniformly by vibrating the sample during the coating process (after [35.43])

These studies suggest that if the lubricant films exist in a liquid-like phase, such as Z-15 films, they easily form menisci (by themselves and the adsorbed water molecules), and thus have higher adhesive force and higher friction force, whereas if the lubricant film exists in a solid-like phase, such as Z-DOL (fully bonded) films, they are hydrophobic with low adhesion and friction.

In order to study the uniformity of a lubricant film and its influence on friction and adhesion, friction force mapping and adhesive force mapping of PFPE have been carried out by *Koinkar* and *Bhushan* [35.41] and *Bhushan* and *Dandavate* [35.43] respectively. Figure 35.9 shows grayscale plots of surface topography and friction force images obtained simultaneously for an unbonded Demnum-type PFPE lubricant film on silicon [35.41]. Demnum-type PFPE lubricant (Demnum, Daikin, Japan) chains have $-CF_2-CH_2-OH$, a reactive end group on one end, whereas Z-DOL chains have the hydroxyl groups on both ends, as described earlier [35.5]. The friction force plot shows well distinguished low and high friction regions roughly corresponding to high and low surface height regions in the topography image (thick and thin lubricant regions). A uniformly lubricated sample does not show such a variation in the friction. Figure 35.10 shows the grayscale plots of the adhesive force distribution for silicon samples coated uniformly and nonuniformly with Z-DOL lubricant. It can be clearly seen that there exists a region that has an adhesive force distinctly different from the other region for the nonuniformly coated sample. This implies that the liquid film thickness is nonuniform giving rise to a difference in the meniscus forces.

Rest Time Effect

It is well known that in the computer rigid disk drive, the stiction force increases rapidly with an increase in rest time between the head and magnetic medium disk [35.4, 5]. Considering that stiction and friction are among the major issues that lead to the failure of computer rigid disk drives and MEMS, it is very important to find out if the rest time effect also exists on the nanoscale. First the rest time effect on the friction force, adhesive force, and coefficient of Si(100) sliding against a Si_3N_4 tip was studied (Fig. 35.11a) [35.25]. It was found that the friction and adhesive forces logarithmically increase up to a certain equilibrium time after which they remain constant. Figure 35.11a also

shows that the rest time does not affect the coefficient of friction. These results suggest that the rest time can result in growth of the meniscus, which causes a higher adhesive force, and in turn a higher friction force. However, in the whole testing range the friction mechanisms do not change with the rest time. Similar studies were also performed on Z-15 and Z-DOL (fully bonded) films. The results are summarized in Fig. 35.11b [35.25]. It is seen that a similar time effect has been observed on Z-15 film but not on Z-DOL (fully bonded) film.

An AFM tip in contact with a flat sample surface can be treated as a single asperity contact. Therefore, a Si_3N_4 tip in contact with Si(100) or Z-15/Si(100) can be modeled as a sphere in contact with a flat surface covered by a layer of liquid (adsorbed water and/or liquid lubricant), Fig. 35.12a. A meniscus forms around the contacting asperity and grows with time until equilibrium occurs [35.50]. The meniscus force, which is the product of meniscus pressure and meniscus area, depends on the flow of liquid phase toward the contact zone. The flow of the liquid towards the contact zone is governed by the capillary pressure P_c, which draws liquid into the meniscus, and the disjoining pressure Π, which tends to draw the liquid away from the meniscus. Based on the Young–Laplace equation, the

All of the measurements were carried out at 70 nN, 2 μm/s, and in ambient air (after [35.25])

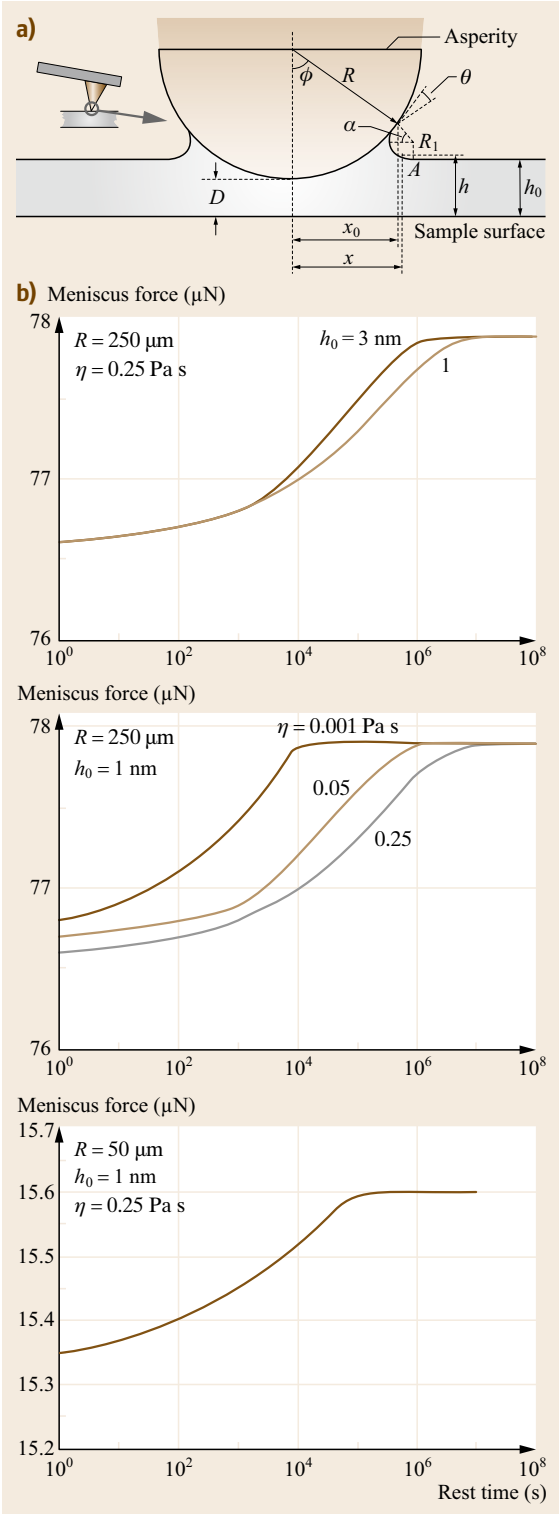

Fig. 35.12 **(a)** Schematic of a single asperity in contact with a smooth flat surface in the presence of a continuous liquid film when ϕ is large. **(b)** Results of the single asperity model. Effect of viscosity of the liquid, radius of the asperity and film thickness is studied with respect to the time-dependent meniscus force (after [35.50]) ◀

capillary pressure, P_c is

$$P_c = 2\kappa\gamma \,, \tag{35.3}$$

where 2κ is the mean meniscus curvature ($= \kappa_1 + \kappa_2$, where κ_1 and κ_2 are the curvatures of the meniscus in the contact plane and perpendicular to the contact plane). *Mate* and *Novotny* [35.8] have shown that the disjoining pressure decreases rapidly with increasing liquid film thickness in a manner consistent with a strong van der Waals attraction. The disjoining pressure, Π for these liquid films can be expressed as

$$\Pi = \frac{A}{6\pi h^3} \,, \tag{35.4}$$

where A is the Hamaker constant, and h is the liquid film thickness. The driving forces that cause the lubricant flow that result in an increase in the meniscus force are the disjoining pressure gradient due to a gradient in film thickness and capillary pressure gradient due to curved liquid-air interface. The driving pressure, P, can then written as

$$P = -2\kappa\gamma - \Pi \,. \tag{35.5}$$

Based on these three basic relationships, the following differential equation has been derived by *Chilamakuri* and *Bhushan* [35.50], which can describe the meniscus at time t

$$2\pi x_0 \left(D + \frac{x_0^2}{2R} - h_0\right) \frac{\mathrm{d}x_0}{\mathrm{d}t} = \frac{2\pi h_0^3 \gamma}{3\eta} \frac{(1+\cos\theta)}{D + a - h_0} - \frac{A x_0}{3\eta h} \cot\alpha \,, \tag{35.6}$$

where η is the viscosity of the liquid, and a is given as

$$a = R(1-\cos\phi) \approx \frac{R\phi^2}{2} \approx \frac{x_0^2}{2R} \,. \tag{35.7}$$

The differential (35.6) was solved numerically using Newton's iteration method. The meniscus force at any time t less than the equilibrium time is proportional to

the meniscus area and meniscus pressure ($2\kappa\gamma$), and it is given by

$$f_m(t) = 2\pi R\gamma(1+\cos\theta)\left(\frac{x_0}{(x_0)_{eq}}\right)^2\left(\frac{\kappa}{\kappa_{eq}}\right), \quad (35.8)$$

where $(x_0)_{eq}$ is the value of x_0 at the equilibrium time

$$\left[(x_0)_{eq}\right]^2 = 2R\left[\frac{-6\pi h_0^3(1+\cos\theta)}{A} + |h_0 - D|\right]. \quad (35.9)$$

This modeling work (at the microscale) showed that the meniscus force initially increases logarithmically with the rest time up to a certain equilibrium time, after which it remains constant. Equilibrium time decreases with an increase in liquid film thickness, a decrease in viscosity, and a decrease in the tip radius, Fig. 35.12b. This early numerical modeling work and the data at the nanoscale in Fig. 35.11a are in good agreement.

Velocity Effect

To investigate the velocity effect on friction and adhesion, the friction force versus normal load relationships of Si(100), Z-15, and Z-DOL (fully bonded) at different velocities were measured (Fig. 35.13) [35.25]. Based on these data, the adhesive force and coefficient of friction values can be calculated by (35.1). The variation of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (fully bonded) as a function of velocity are summarized in Fig. 35.14. It indicates that for Si(100) the friction force decreases logarithmically with increasing velocity. For Z-15, the friction force decreases with increasing velocity up to 10 μm/s, after which it remains almost constant. The velocity has very little effect on the friction force of Z-DOL (fully bonded); it reduced slightly only at very high velocity. Figure 35.14 also indicates that the adhesive force of Si(100) is increased when the velocity is higher than 10 μm/s. The adhesive force of Z-15 is reduced dramatically with a velocity increase up to 20 μm/s, after which it is reduced slightly, and the adhesive force of Z-DOL (fully bonded) is also decreased at high velocity. In the testing range of velocity, only the coefficient of friction of Si(100) decreases with velocity, but the coefficients of friction of Z-15 and Z-DOL (fully bonded) remain almost constant. This implies that the friction mechanisms of Z-15 and Z-DOL (fully bonded) do not change with the variation of velocity.

The mechanisms of the effect of velocity on adhesion and friction are explained based on schematics

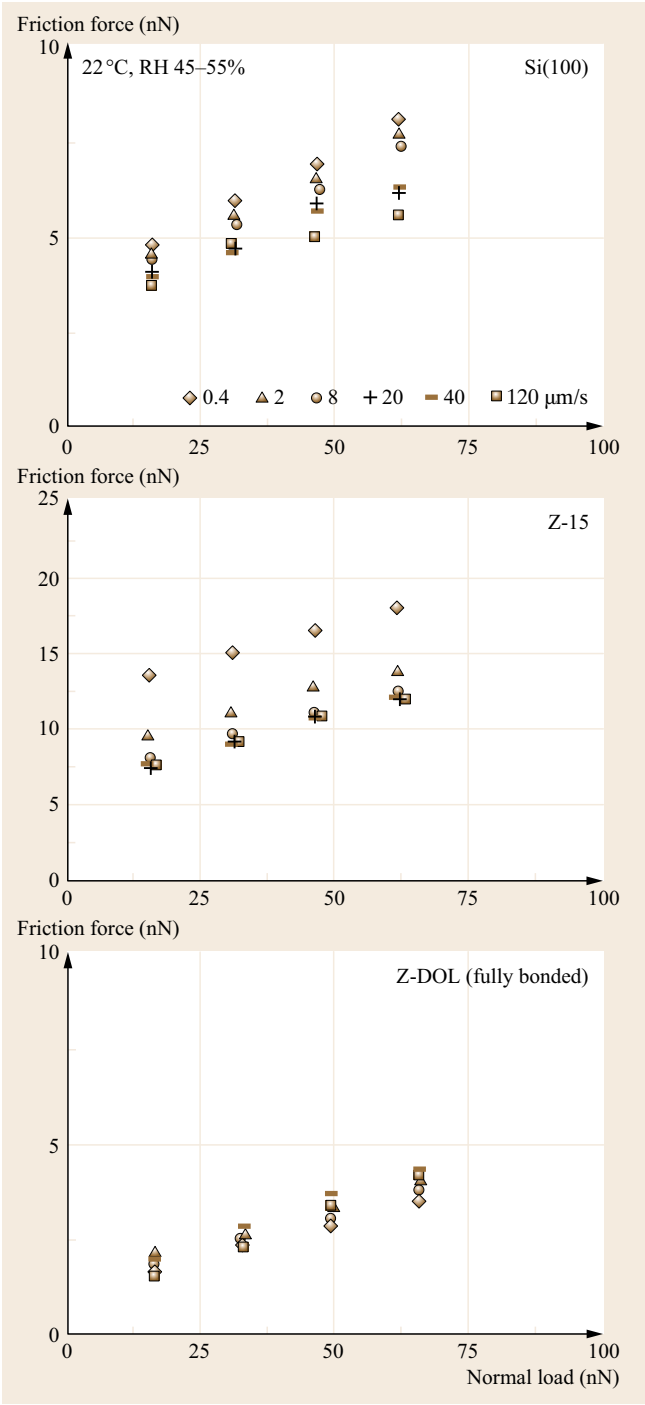

Fig. 35.13a–c Friction forces versus normal load data of **(a)** Si(100), **(b)** 2.8 nm-thick Z-15 film, and **(c)** 2.3 nm-thick Z-DOL (fully bonded) film at various velocities in ambient air (after [35.25])

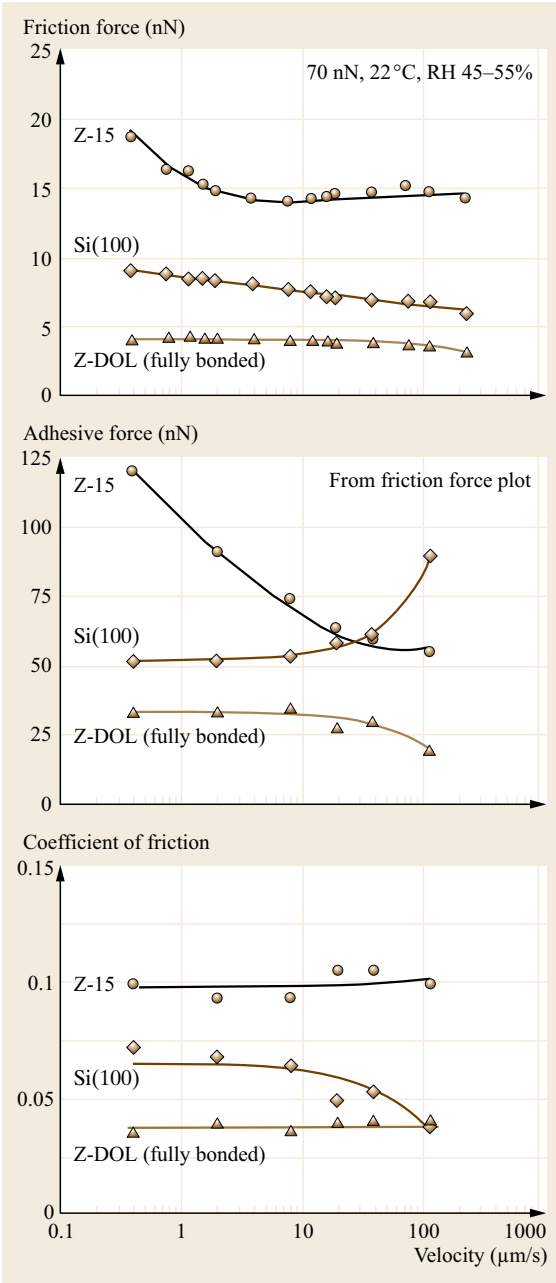

Fig. 35.14 The influence of velocity on the friction force, adhesive force and coefficient of friction of Si(100), 2.8 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) film at 70 nN, in ambient air

shown in Fig. 35.15. For Si(100), tribochemical reaction plays a major role. Although, at high velocity, the meniscus is broken and does not have enough time to rebuild, the contact stresses and high velocity lead to tribochemical reactions of the Si(100) wafer and Si_3N_4 tip, which have native oxide (SiO_2) layers with water molecules. The following reactions occur

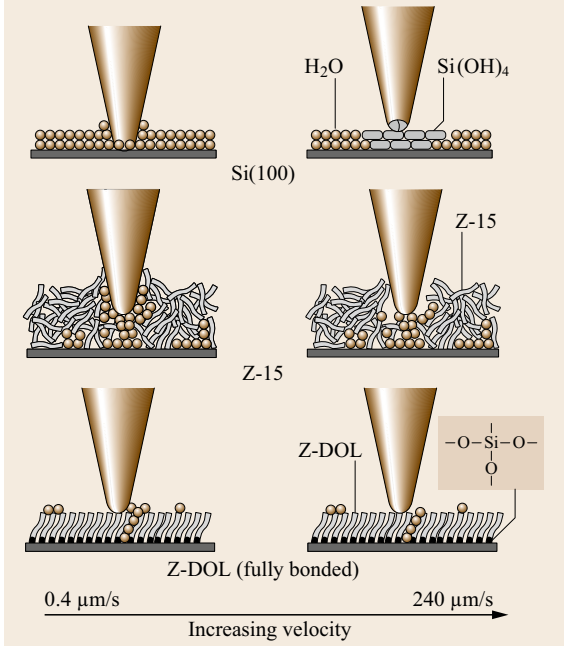

Fig. 35.15 The schematic shows the change of surface composition (by tribochemical reaction) and change of meniscus while increasing the velocity (after [35.25])

$$SiO_2 + 2H_2O \rightarrow Si(OH)_4 \quad (35.10)$$

$$Si_3N_4 + 16H_2O \rightarrow 3Si(OH)_4 + 4NH_4OH \quad (35.11)$$

The $Si(OH)_4$ is removed and continuously replenished during sliding. The $Si(OH)_4$ layer between the tip and Si(100) surface is known to be of low shear strength and causes a decrease in friction force and coefficient of friction in the lateral direction [35.51–55]. The chemical bonds of Si–OH between the tip and Si(100) surface induce a large adhesive force in the normal direction. For Z-15 film, at high velocity the meniscus formed by condensed water and Z-15 molecules is broken and does not have enough time to rebuild; therefore, the adhesive force and consequently friction force is reduced. For Z-DOL (fully bonded) film, the surface can adsorb a few water molecules in the ambient condition, and at high velocity these molecules are displaced, resulting in a slight decrease in friction force and adhesive force. Even at a high velocity range, the friction mechanisms for Z-15 and Z-DOL (fully bonded) films still are shearing of the viscous liquid and molecular orientation respectively. Thus the coefficients of friction of Z-15 and Z-DOL (fully bonded) do not change with velocity.

Koinkar and *Bhushan* [35.28, 41] have suggested that in the case of samples with mobile films such as condensed water and Z-15 films, alignment of liquid molecules (shear thinning) is responsible for the drop in friction force with an increase in scanning velocity. This could be another reason for the decrease in friction force for Si(100) and Z-15 film with velocity in this study.

Relative Humidity and Temperature Effect

The influence of relative humidity on friction and adhesion were studied in an environmentally controlled chamber. The friction force was measured by making measurements at increasing relative humidity, and the results are presented in Fig. 35.16 [35.25]. It shows that for Si(100) and Z-15 film, the friction force increases with a relative humidity increase up to relative humidity (RH) 45%, and then it shows a slight decrease with further increase in relative humidity. Z-DOL (fully bonded) has a smaller friction force than Si(100) and Z-15 in the whole testing range, and its friction force shows a relative apparent increase when the relative humidity is higher than RH 45%. For Si(100), Z-15, and Z-DOL (fully bonded), their adhesive forces increase with relative humidity, and their coefficients of friction increase with a relative humidity up to RH 45%, after which they decrease with a further increase of relative humidity. It is also observed that the humidity effect on Si(100) really depends on the history of the Si(100) sample. As the surface of Si(100) wafer readily adsorbs water in air, without any pretreatment the Si(100) used in our study almost reaches its saturated stage of adsorbing water, and is responsible for a smaller effect during increasing relative humidity. However, once the Si(100) wafer was thermally treated by baking at 150 °C for 1 h, a larger effect was observed.

The schematic in Fig. 35.17 shows that Si(100), because of its high free surface energy, can adsorb more water molecules with an increase in the relative humidity. As discussed earlier, for Z-15 film in a humid environment, the condensed water from the humid environment competes with the lubricant film present on the sample surface. Obviously, more water molecules also can be adsorbed on a Z-15 surface while increasing relative humidity. The more adsorbed water molecules in the case of Si(100), along with lubricant molecules in the Z-15 film case, form a larger water meniscus, which leads to an increase of friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 with humidity. However, at a very high humidity of RH 70%, large quantities of adsorbed water can form a continuous water layer that separates the tip and sample surface and acts as a kind of lubricant, which causes a decrease in the friction force and coefficient of friction. For Z-DOL (fully bonded) films, because of their hydrophobic surface properties, water molecules can be adsorbed and cause an increase in the adhesive force and friction force only at high humidity (≥ RH 45%).

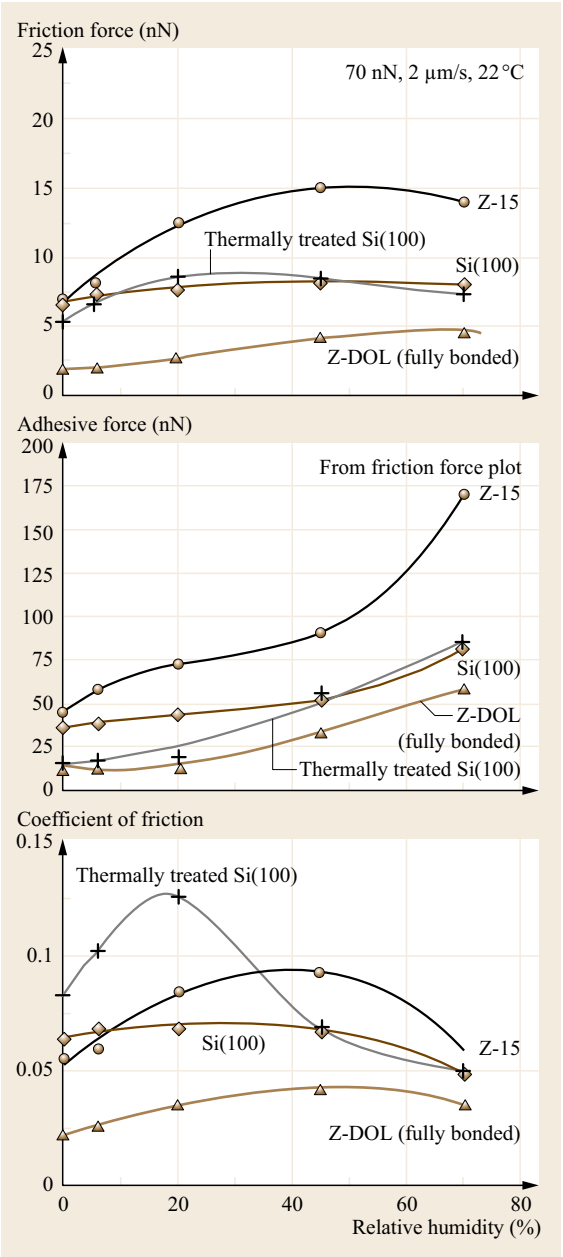

Fig. 35.16 The influence of relative humidity (RH) on the friction force, adhesive force, and coefficient of friction of Si(100), 2.8 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) film at 70 nN, 2 μm/s, and in 22 °C air.

The effect of temperature on friction and adhesion was studied using a thermal stage attached to the AFM.

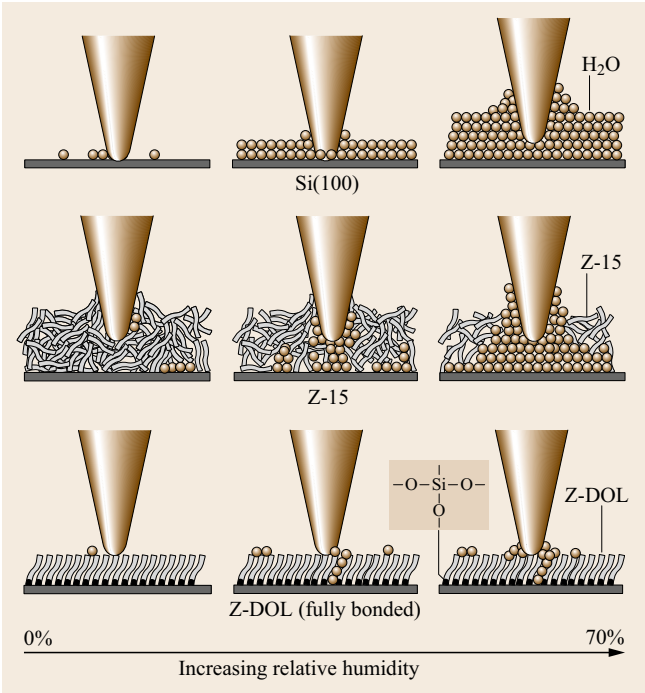

Fig. 35.17 Schematic shows the change of meniscus while increasing the relative humidity. In this figure, the thermally treated Si(100) represents the Si(100) wafer that was baked at 150 °C for 1 h in an oven (in order to remove the adsorbed water) just before it was placed in the 0% RH chamber (after [35.25])

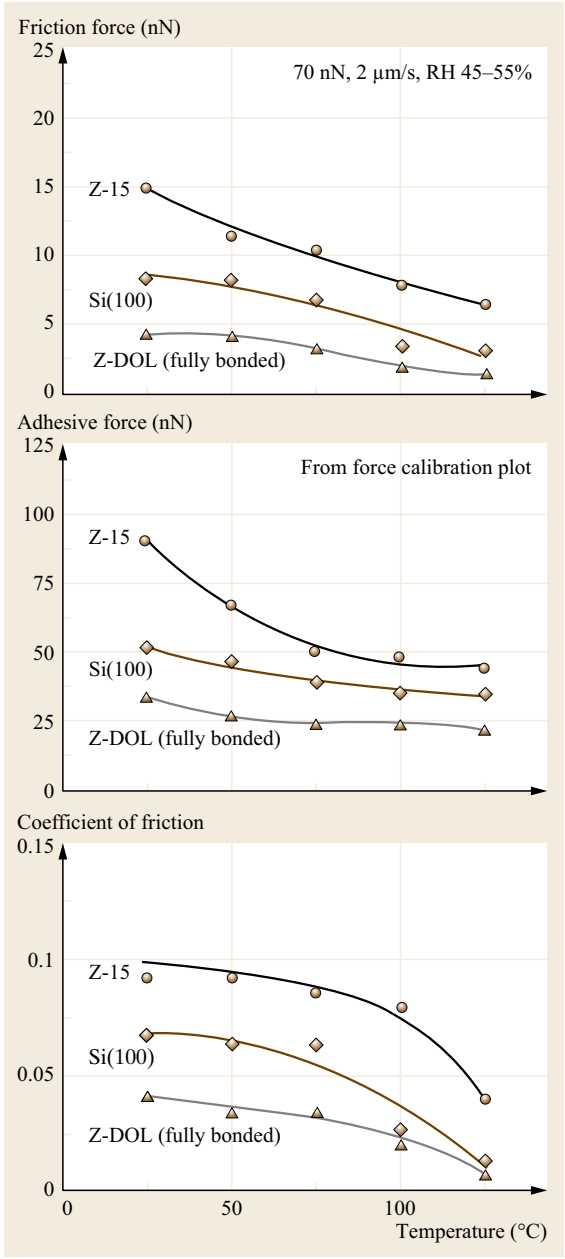

Fig. 35.18 The influence of temperature on the friction force, adhesive force, and coefficient of friction of Si(100), 2.8 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) film at 70 nN, at 2 μm/s, and in RH 40–50% air

The friction force was measured by making measurements at increasing temperature from 22 to 125 °C. The results are presented in Fig. 35.18 [35.25]. It shows that the increasing temperature causes a decrease of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (fully bonded). The schematic in Fig. 35.19 indicates that at high temperature, desorption of water leads to a decrease of friction force, adhesive force and coefficient of friction for all of the samples. Besides that, the reduction of the surface tension of water also has a contribution to the decrease of friction and adhesion. For Z-15 film, the reduction of viscosity at high temperature has an additional contribution to the decrease of friction. In the case of Z-DOL (fully bonded) film, molecules are easier to orient at high temperature, which may also be responsible for the low friction.

Using a surface force apparatus, *Yoshizawa* and *Israelachvili* [35.56, 57] have shown that a change in the velocity or temperature induces phase transformations (from crystalline solid-like to amorphous, then to liquid-like) in surfactant monolayers, which are responsible for the observed changes in the friction force. Stick slip is observed in the low velocity regime of a few μm/s, and adhesion and friction first increase followed by a decrease in the temperature range of 0–50 °C. Stick slip at low velocity and adhesion and friction curves peaking at some particular temperature (observed in their study) have not been observed in the AFM study. This suggests that the phase transforma-

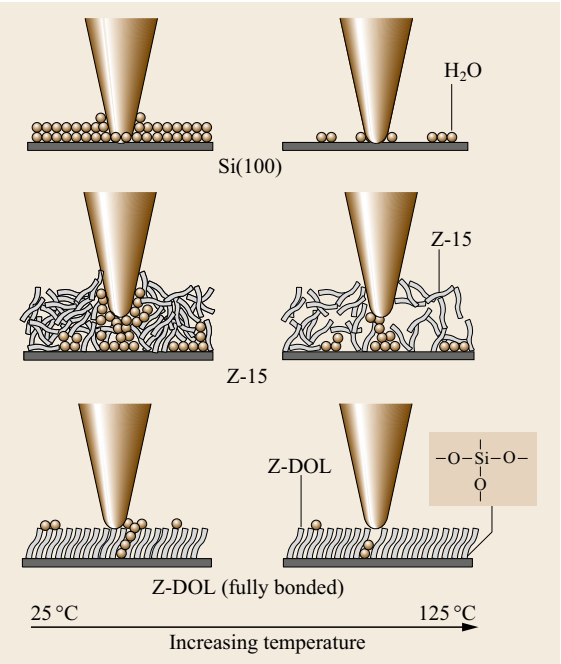

Fig. 35.19 The schematic shows that at high temperature, desorption of water decreases the adhesive forces. The reduced viscosity of Z-15 leads to the decrease of the coefficient of friction. High temperature facilitates orientation of molecules in Z-DOL (fully bonded) film, which results in a lower coefficient of friction (after [35.25])

tions may not happen in this study. This is because PFPEs generally have very good thermal stability [35.3, 4].

As a brief summary, the influence of velocity, relative humidity, and temperature on the friction force of Z-15 film is presented in Fig. 35.20. The changing trends are also addressed in this figure.

Tip Radius Effect

The tip radius and relative humidity affect adhesion and friction for unlubricated and lubricated surfaces [35.42, 43]. Figure 35.21a shows the variation of single-point adhesive force measurements as a function of tip radius on a Si(100) sample for several humidities. The adhesive force data are also plotted as a function of relative humidity for various tip radii. Figure 35.21a indicates that the tip radius has little effect on the adhesive forces at low humidities, but the adhesive force increases with tip radius at high humidity. Adhesive force also increases with an increase in humidity for all tips. The trend in adhesive forces as a function of tip radii and relative humidity, in Fig. 35.21a, can be explained by the presence of meniscus forces, which arise from the capillary condensation of water vapor from the environment.

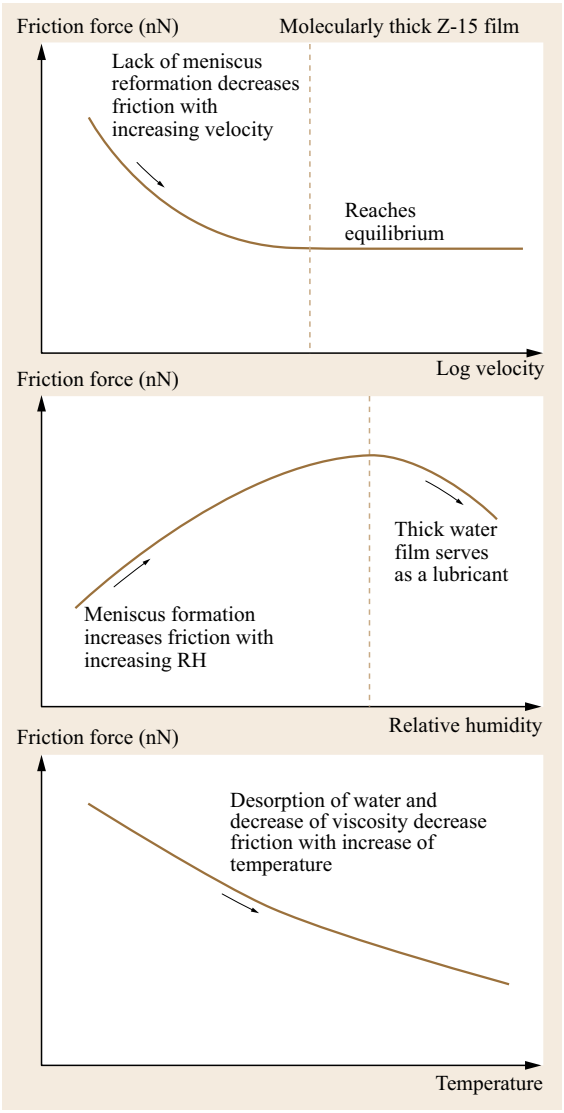

Fig. 35.20 Schematic showing the change of friction force of molecularly thick Z-15 films with log velocity, relative humidity, and temperature (after [35.25])

If enough liquid is present to form a meniscus bridge, the meniscus force should increase with an increase in tip radius based on (35.2). This observation suggests that the thickness of the liquid film at low humidities is insufficient to form continuous meniscus bridges and to affect adhesive forces in the case of all tips.

Figure 35.21a also shows the variation in coefficient of friction as a function of tip radius at a given humidity and as a function of relative humidity for a given tip radius on the Si(100) sample. It can be observed that for RH 0%, the coefficient of friction is about the same for the tip radii except for the largest tip, which shows

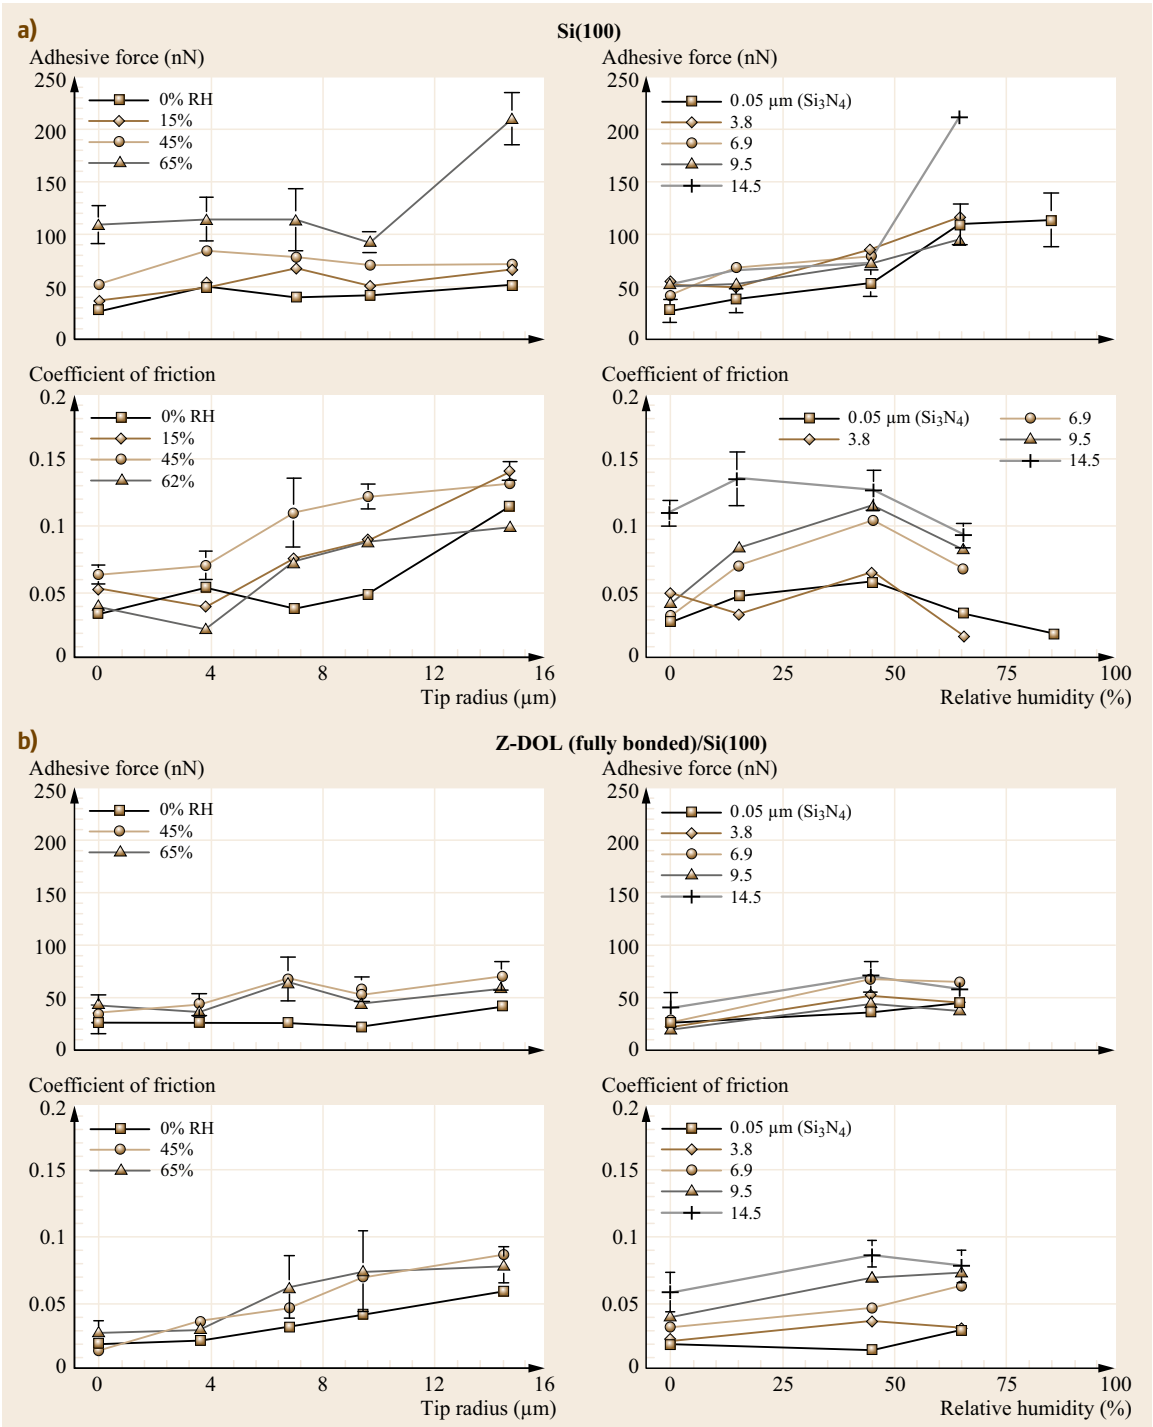

Fig. 35.21 Adhesive force and coefficient of friction as a function of tip radius at several humidities and as a function of relative humidity at several tip radii on **(a)** Si(100), and **(b)** 0.5 nm Z-DOL (fully bonded) films (after [35.42])

a higher value. At all other humidities, the trend consistently shows that the coefficient of friction increases with tip radius. An increase in friction with tip radius at low to moderate humidities arises from increased contact area (i. e., higher van der Waals forces) and higher values of shear forces required for larger contact area. At high humidities, similar to adhesive force data, an increase with tip radius occurs because of both contact area and meniscus effects. It can be seen that for all tips, the coefficient of friction increases with humidity to about RH 45%, beyond which it starts to decrease. This is attributed to the fact that at higher humidities, the adsorbed water film on the surface acts as a lubricant between the two surfaces [35.25]. Thus the interface is changed at higher humidities, resulting in lower shear strength and hence lower friction force and coefficient of friction.

Figure 35.21b shows adhesive forces as a function of tip radius and relative humidity on Si(100) coated with a 0.5 nm-thick Z-DOL (fully bonded) film. Adhesive forces for all the tips with the Z-DOL (fully bonded) lubricated sample are much lower than those experienced on unlubricated Si(100) shown in Fig. 35.21a. The data also show that even at a monolayer thickness of the lubricant, there is very little variation in adhesive forces with tip radius at a given humidity. For a given tip radius, the variation in adhesive forces with relative humidity indicates that these forces slightly increase from RH 0 to RH 45%, but remain more or less the same with a further increase in humidity. This is seen even with the largest tip, which indicates that the lubricant is indeed hydrophobic; there is some meniscus formation at humidities higher than RH 0%, but the formation is very minimal and does not increase appreciably even up to RH 65%. Figure 35.21b also shows the coefficient of friction for various tips at different humidities for the Z-DOL (fully bonded) lubricated sample. Again, all the values obtained with the lubricated sample are much lower than the values obtained on unlubricated Si(100) shown in Fig. 35.21a. The coefficient of friction increases with tip radius for all humidities as was seen on unlubricated Si(100) due to an increase in the contact area. Similar to the adhesive forces, there is an increase in friction from RH 0 to RH 45% due to a contribution from an increased number of menisci bridges. However, there is very little additional water film forming due to the hydrophobicity of the Z-DOL (fully bonded) layer thereafter, and consequently, the coefficient of friction does not change appreciably, even with the largest tip. These findings show that even a monolayer of Z-DOL (fully bonded) offers good hydrophobic performance of the surface.

Wear

To study the durability of lubricant films at the nanoscale, the friction of Si(100), Z-15, and Z-DOL (fully bonded) as a function of the number of scanning cycles was measured (Fig. 35.22) [35.25]. As observed earlier, the friction force of Z-15 is higher than that of Si(100), and Z-DOL (fully bonded) has the lowest value. During cycling, the friction force of Si(100) shows a slight variation during the initial few cycles then remains constant. This is related to the removal of the top adsorbed layer. In the case of Z-15 film, the friction force shows an increase during the initial few cycles and then approaches higher and stable values. This is believed to be caused by the attachment of the Z-15 molecules onto the tip. The molecular interaction between these attached molecules to the tip and molecules on the film surface is responsible for an increase in the friction. However, after several scans, this molecular interaction

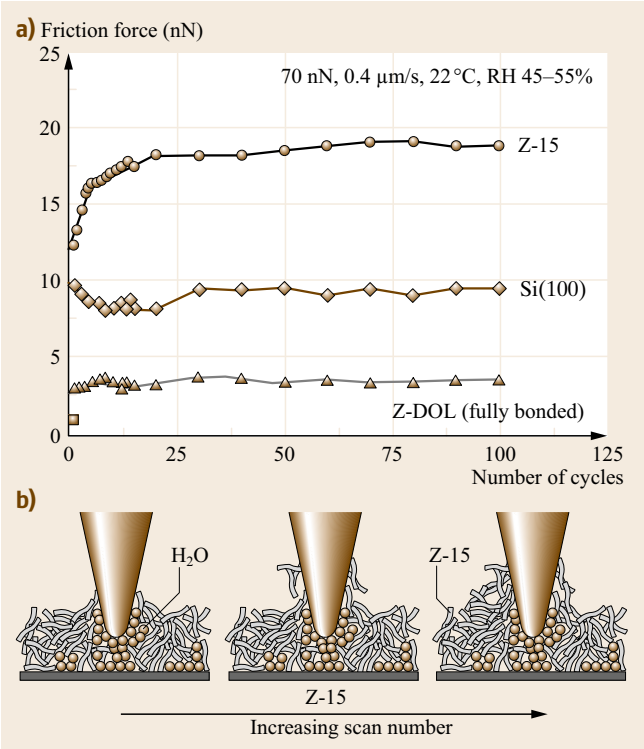

Fig. 35.22 Friction force versus number of sliding cycles for Si(100), 2.8 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) film at 70 nN, 0.8 µm/s, and in ambient air. Schematic (*bottom*) shows that some liquid Z-15 molecules can be attached to the tip. The molecular interaction between the molecules attached to the tip with the Z-15 molecules in the film results in an increase of the friction force with multiscanning (after [35.25])

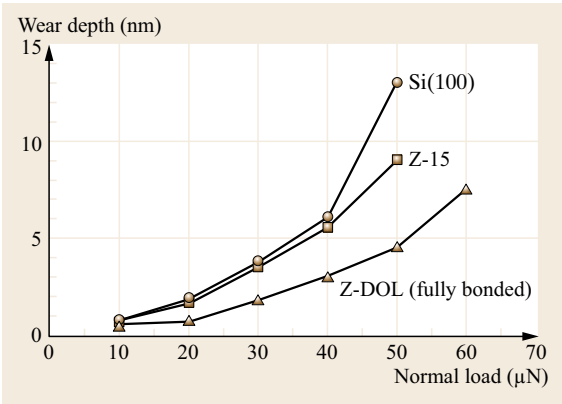

Fig. 35.23 Wear depth as a function of normal load using a diamond tip for Si(100), 2.9 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) after one cycle (after [35.28])

reaches equilibrium, and after that the friction force and coefficient of friction remain constant. In the case of Z-DOL (fully bonded) film, the friction force starts out low and remains low during the entire test for 100 cycles. It suggests that Z-DOL (fully bonded) molecules do not get attached or displaced as readily as in Z-15.

Koinkar and *Bhushan* [35.28, 41] conducted wear studies using a diamond tip at high loads. Figure 35.23 shows the plots of wear depth as a function of normal force, and Fig. 35.24 shows the wear profiles of the worn samples at 40 μN normal load. The 2.3 nm-thick Z-DOL (fully bonded) lubricated sample exhibits better wear resistance than unlubricated and 2.9 nm-thick Z-15 lubricated silicon samples. Wear resistance of the Z-15 lubricated sample is little better than that of the unlubricated sample. The Z-15 lubricated sample shows debris inside the wear track. Since Z-15 is a liquid lubricant, the debris generated is held by the lubricant, and it becomes sticky, which moves inside the wear track and does damage (Fig. 35.23). These results suggest that Z-DOL (fully bonded) exhibits higher wear resistance of the substrate as compared to that for Z-15.

To study the effect of the degree of chemical bonding, durability tests were conducted on both fully bonded and partially bonded Z-DOL films. Durability results for Z-DOL (fully bonded) and Z-DOL bonded and unwashed Z-DOL (partially bonded) (which is a partially bonded film, and contains both bonded and mobile phase lubricants) with different film thicknesses are shown in Fig. 35.25 [35.41]. Thicker films, such as Z-DOL (partially bonded) with a thickness of 4.0 nm (bonded/mobile = 2.3 nm/1.7 nm) exhibit behavior similar to 2.3 nm-thick Z-DOL (fully bonded) film. Figure 35.25 also indicates that Z-DOL (fully bonded) and Z-DOL (partially bonded) films with a thinner film thickness exhibit a higher friction value. Compar-

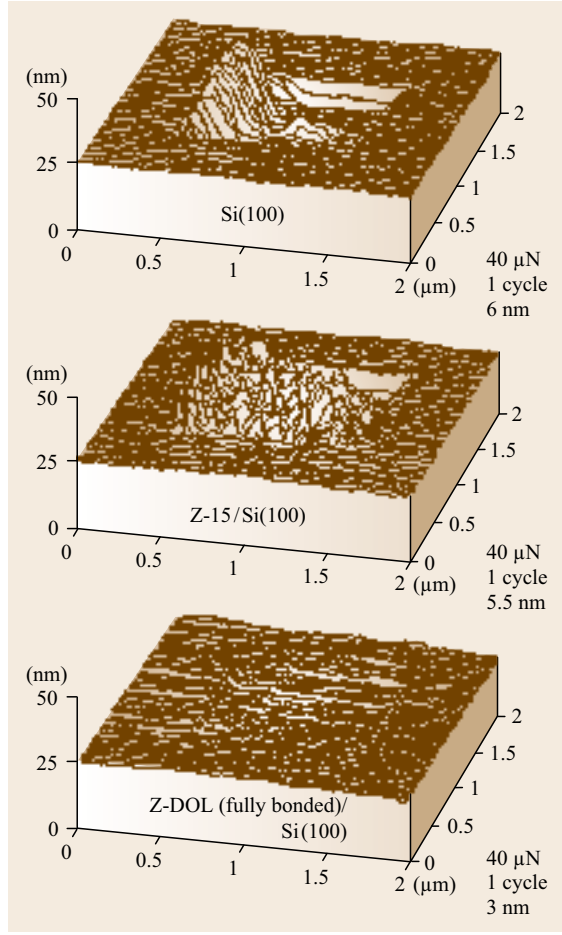

Fig. 35.24 Wear profiles for Si(100), 2.9 nm-thick Z-15 film, and 2.3 nm-thick Z-DOL (fully bonded) film after wear studies using a diamond tip. Normal force used and wear depths are listed in the figure (after [35.28])

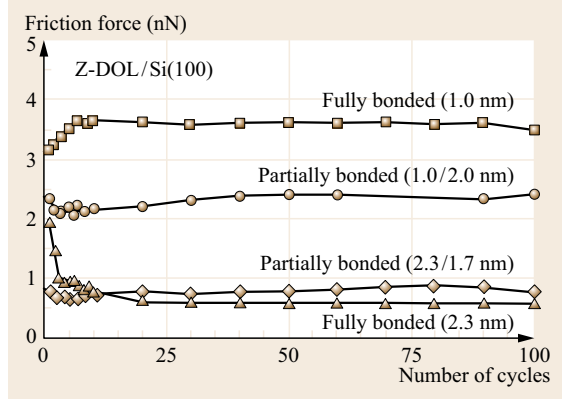

Fig. 35.25 Friction force as a function of number of cycles using a Si_3N_4 tip at a normal load of 300 nN for Z-DOL (fully bonded) and Z-DOL (partially bonded) films with different film thicknesses (after [35.41])

ing 1.0 nm-thick Z-DOL (fully bonded) with 3.0 nm (bonded/mobile = 1.0 nm/2.0 nm)-thick Z-DOL (partially bonded), the Z-DOL (partially bonded) film exhibits lower and stable friction values. This is because the mobile phase on a surface acts as a source of lubricant replenishment. Similar conclusions have also been reported by *Ruhe* et al. [35.58], *Bhushan* and *Zhao* [35.13], and *Eapen* et al. [35.59]. All of them indicate that using partially bonded Z-DOL films can dramatically reduce friction and improve the wear life.

35.2 Nanotribological, Electrical, and Chemical Degradations Studies and Environmental Effects in Novel PFPE Lubricant Films

Electrical properties of lubricant films are of interest in various MEMS/NEMS applications. Changes in the surface potential and electrical resistance can be measured during sliding using an AFM [35.20, 24, 44, 45, 60–62]. These techniques are also useful for wear detection and for studying the initiation of wear [35.15, 19, 60]. *Palacio* and *Bhushan* [35.44, 45, 61] carried out nanotribological studies on various novel PFPE lubricant films and monitored the electrical properties as well. Chemical degradation studies and environmental effects on various PFPE lubricant films on a Si(100) wafer and amorphous carbon-coated (diamond-like carbon) magnetic tapes were carried out in a macroscale configuration by *Tao* and *Bhushan* [35.63], *Bhushan* and *Tao* [35.64], and *Bhushan* et al. [35.65].

The structure and properties of several novel PFPE lubricants commonly used in the lubrication of magnetic rigid disks – Z-TETRAOL 2000 and A20H-2000 – are presented in Table 35.2 [35.63]. Z-DOL 2000 is also included for comparison. Z-TETRAOL (Solvay Solexis Inc.) is a derivate of PFPE. The backbone of Z-TETRAOL is the same as the conventional PFPE lubricant Z-DOL (Solvay Solexis Inc.) as described earlier. The difference between Z-TETRAOL and Z-DOL is that Z-TETRAOL has two hydroxyl groups at each end while Z-DOL has one hydroxyl group at each end. It is believed that two hydroxyl bonds are expected to lead to stronger interaction with the substrate. However, the Z-TETRAOL lubricant film is less mobile because of larger viscosity, which may lead to shorter durability. A20H (Moresco, Japan) is a PFPE lubricant with a cyclotriphosphazene at one end and a hydroxyl at the other end. The backbone of A20H is also the same as that of Z-DOL. Phosphazene lubricants (such as X1-P) have been used as additives in the data storage industry because they exhibit better durability in high-humidity environments [35.5, 13]. It is believed that X1-P coats the mating surface and makes it hydrophobic and minimizes stiction and improves durability. Studies have shown that A20H exhibits less thinning or reduced mobility during drive rotation [35.63]. The durability of these less mobile lubricants could be less than that of the highly mobile Z-DOL + X1-P systems. A mixture of Z-DOL and A20H is known to provide longer durability and good performance at high humidity.

The lubricants were applied on single-crystal Si(100) with a native oxide layer on the surface using the dip coating technique by *Tao* and *Bhushan* [35.63] and *Palacio* and *Bhushan* [35.44]. The wafer was ultrasonicated in acetone followed by methanol for 10 min each. This was then followed by soaking in the solvent HFE 7100 (3M, St. Paul, MN), which consists of isomers of methoxynonafluorobutane ($C_4F_9OCH_3$). The cleaned wafer was vertically submerged into a beaker containing a dilute solution of the lubricant in HFE 7100 for 10 min and then pulled off. The lubricated sample used without postthermal treatment is referred

Table 35.2 Chemical structures and selected properties of several PFPE lubricants (data obtained from manufacturers' data sheets)

Lubricant	End group (X[a])	Molecular weight (amu)	Density (10^3 kg/m^3 at 20 °C)	Kinematic viscosity (mm^2/s)	Surface tension (mJ/m^2)	Vapor pressure (Torr)	
						20 °C	100 °C
Z-DOL 2000[b]	$-CF_2-CH_2-OH$	2000	1.81	85	24	2×10^{-5}	6×10^{-4}

to as untreated. Partially bonded samples were prepared by heating at 150 °C for 30 min after dip coating, while the fully bonded samples were heated at 150 °C for 30 min and washed in the HFE 7100 solvent to remove the mobile fraction. The lubricant-coated silicon samples were then measured with an ellipsometer and the coating thickness was found to be about 1, 3, and 7 nm for the fully bonded, partially bonded and untreated samples respectively. A schematic of the bonding of the Z-DOL, Z-TETRAOL, and A20H end groups to the silicon substrate is shown in Fig. 35.26.

35.2.1 Nanotribological Studies

Adhesive force and coefficient of friction measurements were made using an AFM and the results are presented in Fig. 35.27 [35.44]. The lubricant-coated samples reduce adhesion compared to the uncoated silicon. The adhesive forces measured on the partially bonded lubricant films are higher than the data from their fully bonded counterparts. As discussed earlier, the mobile fraction on the surface of the partially bonded sample facilitates the formation of a meniscus, which increases the tip-surface adhesion. All of the lubricant-coated samples exhibit a reduction in the coefficient of friction relative to the uncoated silicon. The partially bonded samples have a lower coefficient of friction compared to the fully bonded samples, implying that the mobile lubricant molecules in the former facilitate sliding of the tip on the surface. This will be analyzed in more detail in the following subsection in the context of wear, which was monitored using surface potential and resistance measurements.

Palacio and *Bhushan* [35.45] studied the effect of relative humidity and temperature on the friction and adhesion of novel PFPE films deposited on amorphous carbon-coated (diamond-like carbon) magnetic tapes. The trends were similar to those as reported earlier in Sect. 35.1.2, *Relative Humidity and Temperature Effect*.

35.2.2 Wear Detection by Surface Potential Measurements

Wear experiments were performed on the lubricated surfaces using a diamond tip over a $5 \times 5\,\mu m^2$ region at a load of 10 μN for 20 cycles. Figure 35.28a shows the surface height and surface potential images for the fully bonded and partially bonded lubricants [35.44]. The corresponding images for the uncoated silicon substrate are shown for comparison. It can be seen from the images that debris is generated around the wear region for all coatings tested. More wear debris is observed in

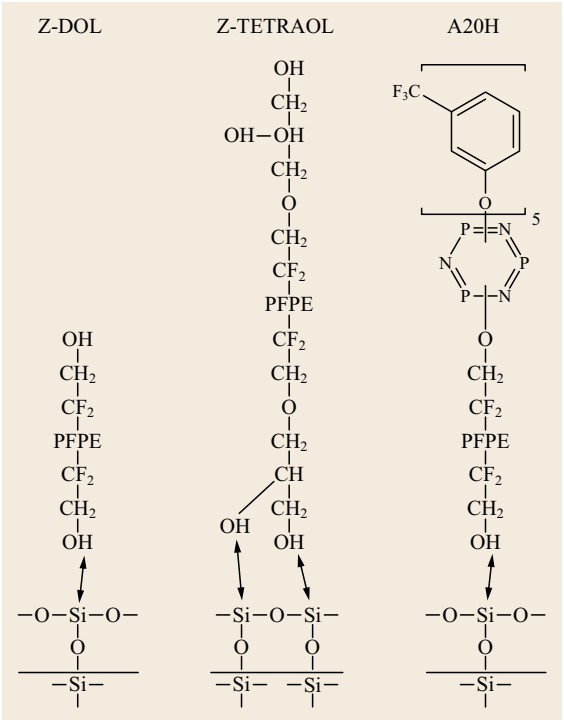

Fig. 35.26 Schematics of Z-DOL, Z-TETRAOL, and A20H molecules bonded on Si substrates

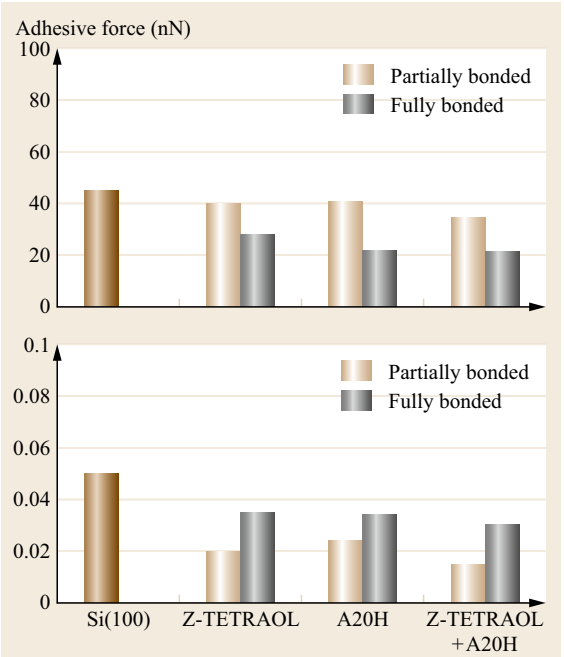

Fig. 35.27 Summary of the adhesive force and coefficient of friction of Si(100), Z-TETRAOL, A20H and Z-TETRAOL+A20H films at room temperature (22 °C) and in ambient air (45–55% RH) (after [35.44])

the fully bonded samples than in the partially bonded samples. Samples with the fully bonded lubricant have limited wear protection compared to those with partially bonded lubricants because the former has only immobile molecules, while the latter has both immobile and mobile molecules. The mobile fraction of the lubricant can replenish the surface, i. e., it can move to the worn area and protect it after the immobile lubricant molecules have been displaced from the surface following repeated rubbing. Since the partially bonded films are thicker than the fully bonded films, additional wear protection is attributed to a thickness effect.

Figure 35.28b presents a bar chart showing surface potential changes for various samples. The surface potential of the area subjected to the wear test increased, which is more prominent in the fully bonded samples. The partially bonded samples exhibited a smaller change in surface potential, indicating less wear. These findings should be correlated with the result of the wear test on the uncoated silicon sample, where the increase in surface potential is well understood. The Kelvin probe method measures the surface potential difference between the tip and sample, which pertains to differences in the work functions between these two materials. For conducting and semiconducting materials, the mechanism is as follows. The surface potential is altered during physical wear because the Fermi energy level is altered. This is the energy required to

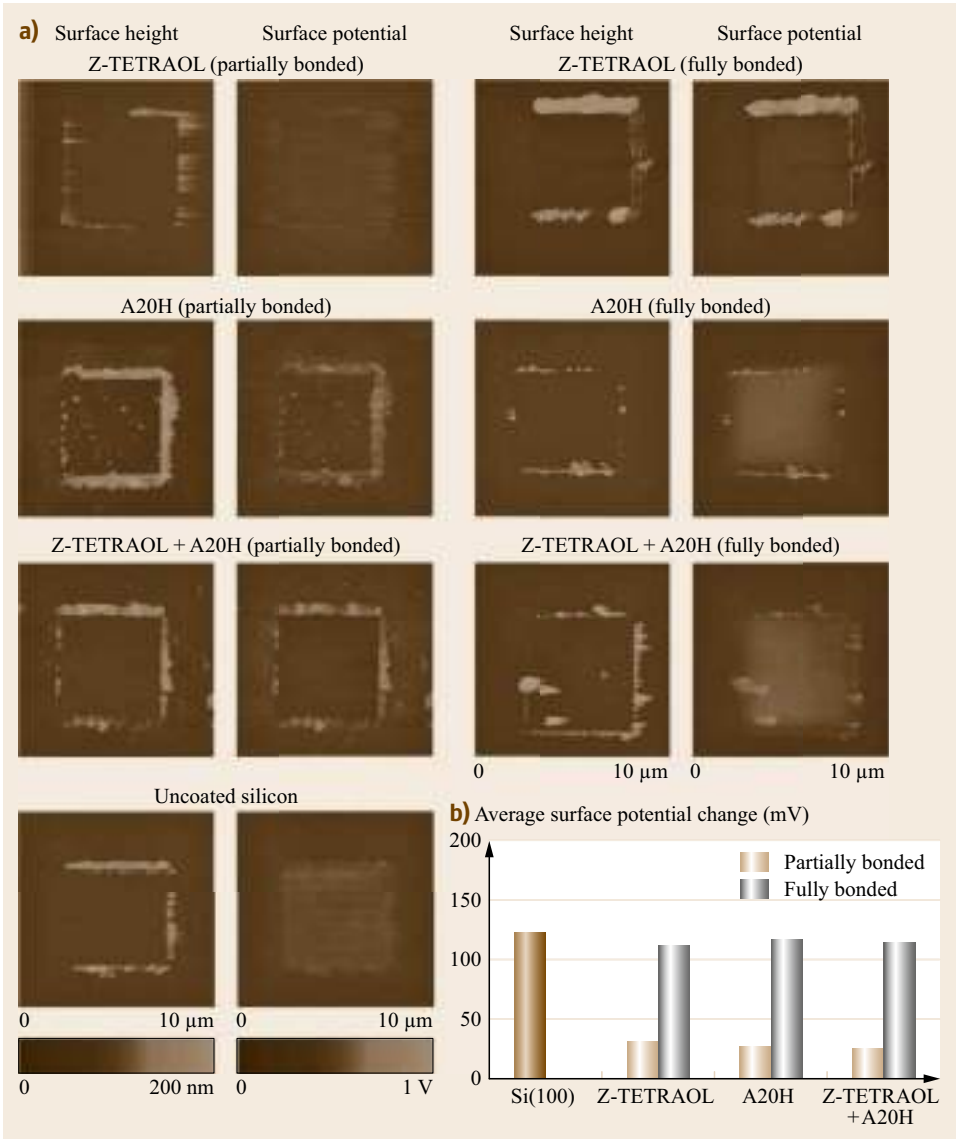

Fig. 35.28 (a) Surface height and surface potential maps of the coatings under investigation after wear testing. Brighter areas correspond to higher values of both the height and surface potential change. (b) Bar chart showing surface potential change (after [35.44])

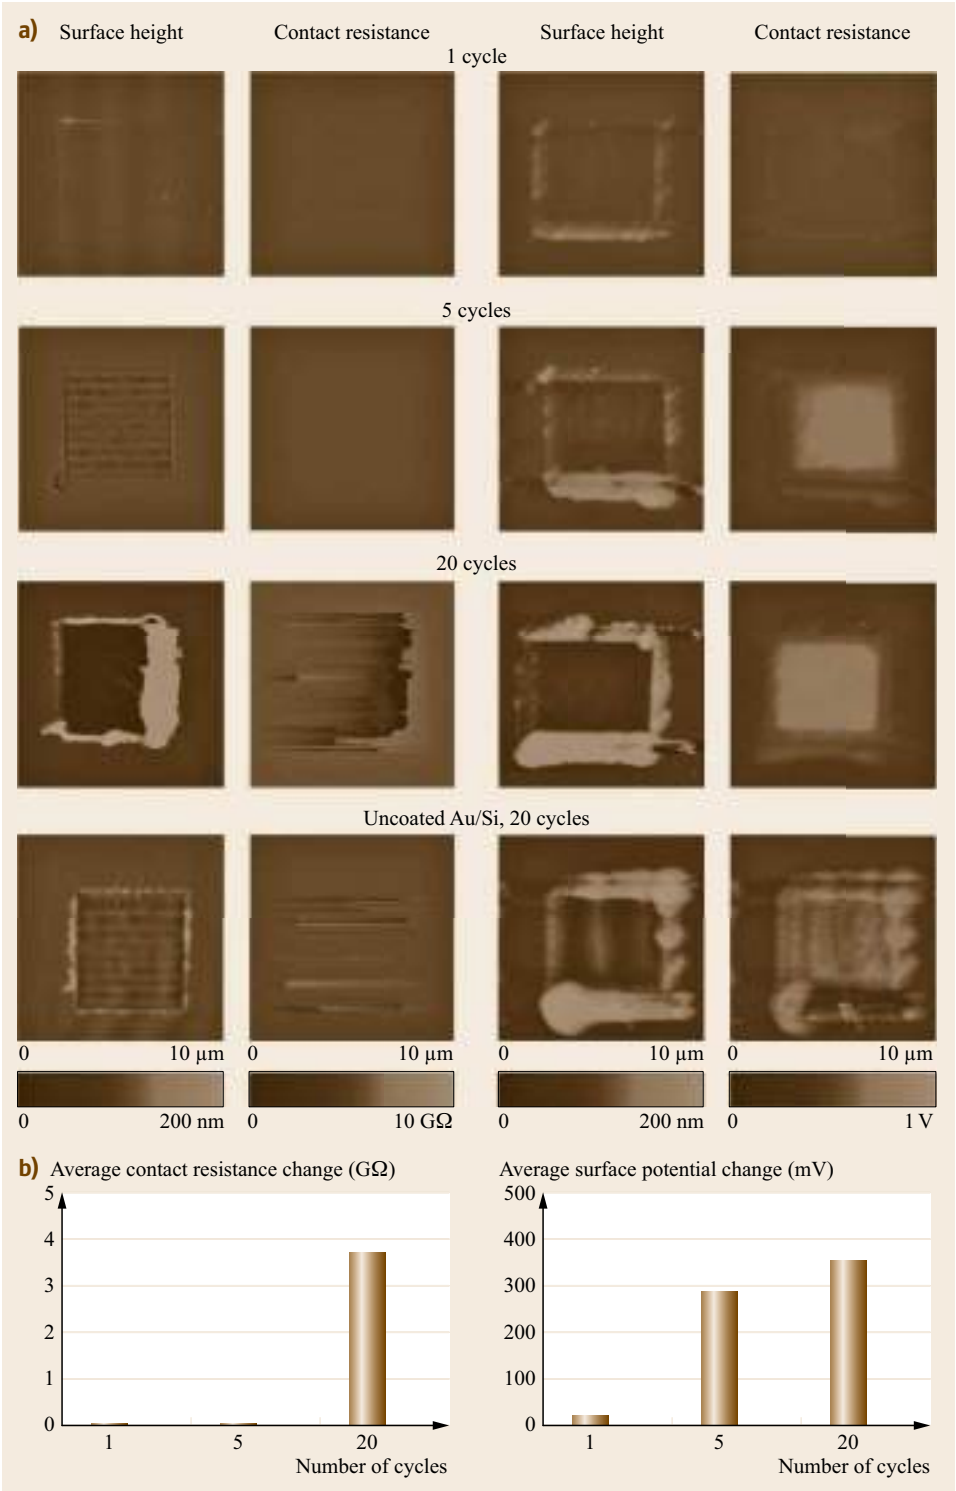

Fig. 35.29 **(a)** Surface height, contact resistance and surface potential maps of fully bonded Z-TETRAOL coating on Au as a function of the number of wear cycles, and **(b)** bar chart showing contact resistance and surface potential change (after [35.44])

remove an electron to a point just outside the material surface. Thermodynamic equilibrium is disrupted with a change in the Fermi level, and can only be restored by the flow of electrons either into or from the area subjected to wear. This mechanism does not apply to materials such as SiO_2 (naturally present as a thin layer) and the lubricants, which are both insulators. Physical wear on these materials would not cause a change in the surface potential because charge dissipation is poor. Therefore, a considerable surface potential change would be observed only when:

1. The lubricant has been fully removed from the substrate.
2. The native SiO_2 layer has been abraded from the surface.
3. Wear has caused subsurface structural changes.

However, for insulators such as the lubricant, electrostatic charges are introduced as they come into contact with a material with a dissimilar electron affinity (the diamond tip) during the wear test. The charges on the insulating lubricant surface have low mobility and would eventually dissipate into the ambient environment. In the presence of debris, the electrostatic charges become localized and may get trapped (as debris particles are mostly isolated), causing an increase in the surface potential of the debris that formed around the worn area.

35.2.3 Wear Detection by Electrical Resistance Measurements of Z-TETRAOL and the Effect of Cycling

For electrical resistance measurements, lubricant films were applied on evaporated Au film deposited on a Si substrate. The silicon wafer used in the experiments is lightly doped, and it was coated with Au so that a metal-metal contact would be attained once the lubricant was removed. PFPE is insulating. Figure 35.29 presents surface height and resistance images for a fully bonded Z-TETRAOL coating on Au by using a scanning spreading resistance microscopy (SSRM) attachment in AFM. For comparison, another set of tests was conducted on the same sample, and the postwear surface potential images were obtained as shown in the same figure. The Au surface is expected to have a low resistance (corresponding to darker areas in the resistance map), while the lubricant should have high resistance (lighter areas) as it is an insulator. The surface height images show a small amount of wear after one and five cycles. In both cases, the resistance images are featureless, which implies that the lubricant is still present, and the Au is not yet exposed. A surface potential increase is observed, which is attributed to electrostatic charge buildup, but this does not imply full lubricant removal since the resistance of the test area has remained unchanged to this point. After 20 cycles, the contact resistance in the tested area has suddenly decreased, which indicates exposure of the underlying Au. The wear debris has the same resistance compared to

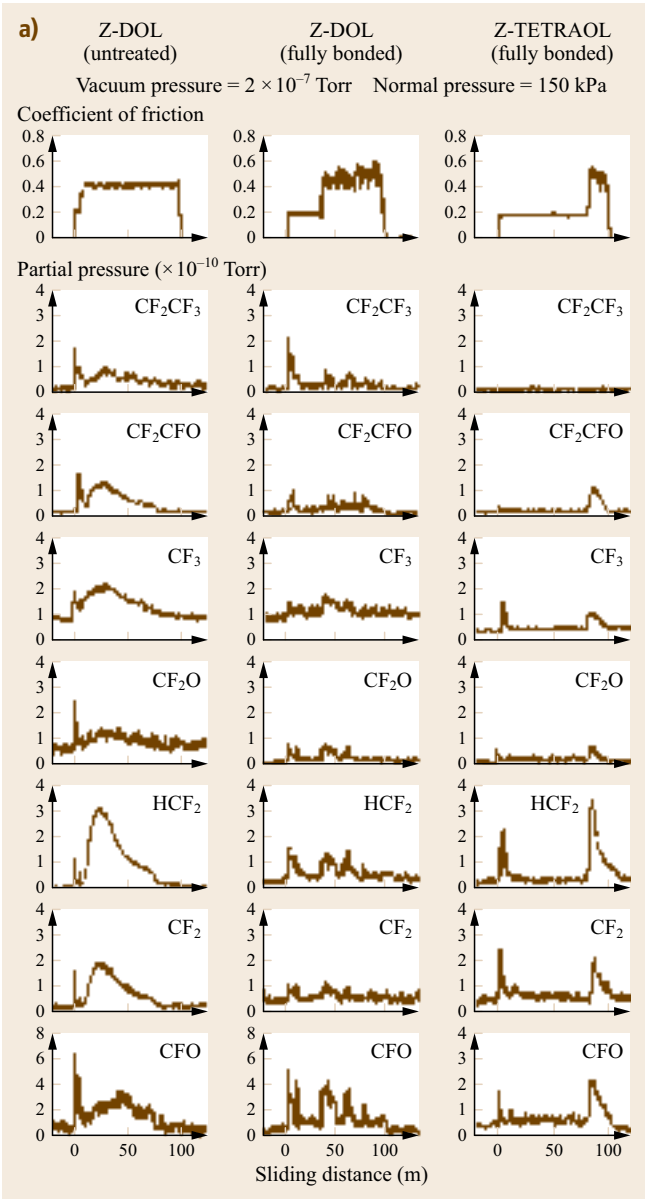

Fig. 35.30 Coefficients of friction and mass spectra data on **(a)** untreated (2.2 nm) and fully bonded (2.3 nm) Z-DOL, fully bonded Z-TETRAOL (2.6 nm), **(b)** fully bonded (0.9 nm) and partially bonded (2.3 nm) A20H, and Z-DOL+A20H (2.4 nm) in high vacuum and under 150 kPa normal pressure, **(c)** partially bonded A20H in high vacuum and under 200 kPa normal pressure (after [35.63])

the unworn lubricant, indicating that the current flow is influenced by the inherent difference in conductivity between the probe tip and the material it is in contact with.

During the scan of the area subjected to the wear test, the current measured by the SSRM sensor corresponds to the contact resistance that exists between the metal-coated tip and the sample. The spreading resistance of the electric current flowing within the semiconductor sample is not measured because this is only present when there is direct contact between the metal-coated tip and a highly doped semiconductor sample.

Because the lubricant is very soft, some signal instability could occur. This comes from possible tip contamination by the lubricant as well as plowing of wear debris during the scan. Since this AFM-based resistance measurement is a contact technique, contamination and plowing are more likely to occur compared to the surface potential measurement, which is a tapping technique. However, this technique is of interest because it provides complementary information to the Kelvin probe method in measuring the extent of wear of conducting films and lubricants, which are materials that can potentially be used in MEMS/NEMS devices.

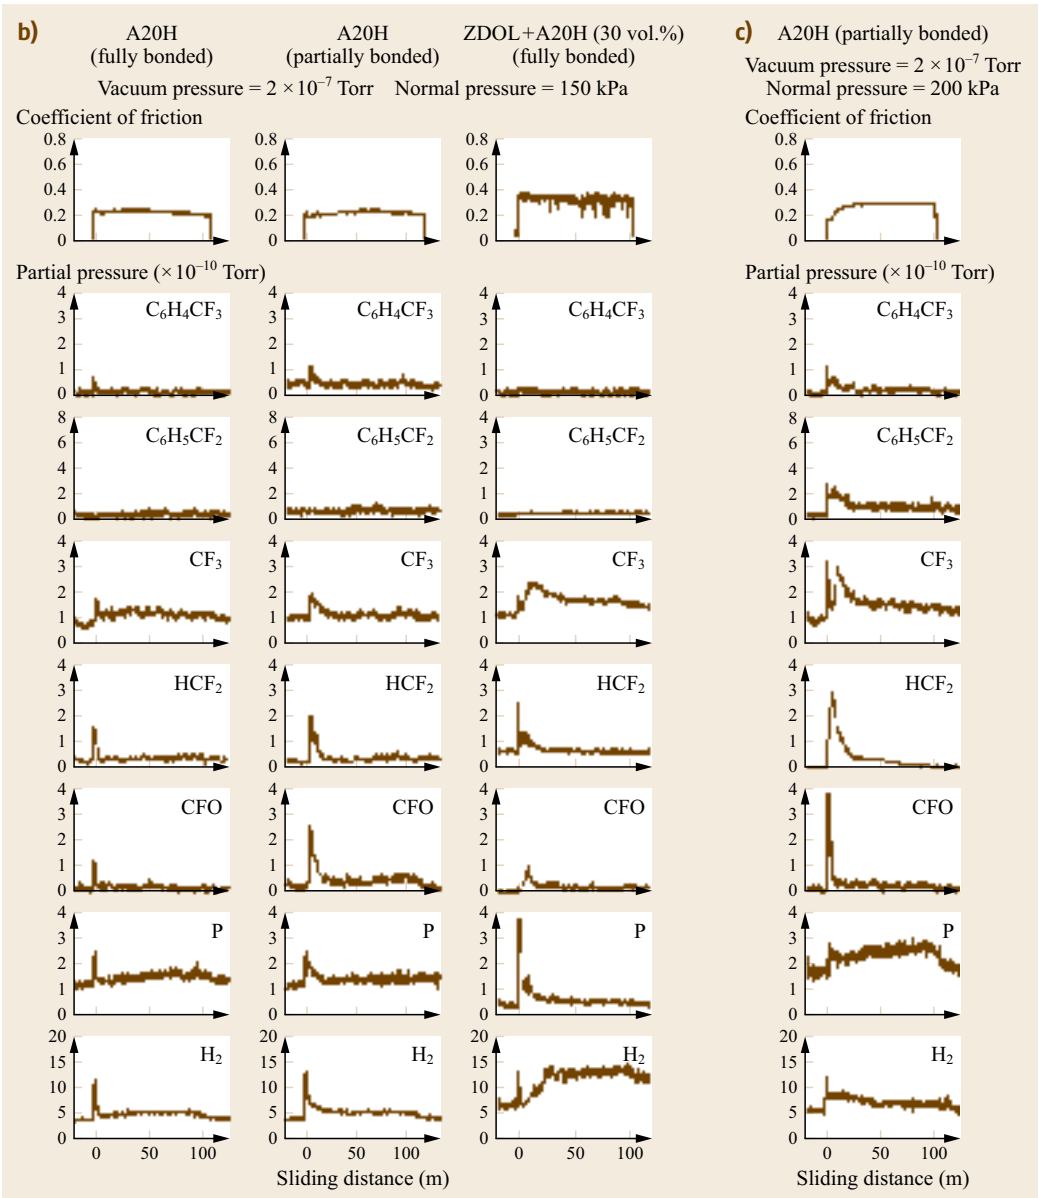

Fig. 35.30 (continued)

35.2.4 Chemical Degradation and Environmental Studies

Tao and *Bhushan* [35.63] carried out chemical degradation studies in a high-vacuum tribotest apparatus [35.40, 66]. In this apparatus, a lubricated wafer mounted on a flexible cantilever beam was slid against an uncoated Si(100) wafer in a macroscale configuration. The system was equipped with a mass spectrometer so that gaseous emissions from the interface could be monitored in situ during the sliding in high vacuum and other controlled environments. The normal load and friction force at the contacting interface were measured using resistive-type strain gage transducers. For the sliding tests, the lubricated Si(100) sample was glued onto a flat surface at the end of a rotating shaft. The sample was slid against a Si(100) wafer mounted on the flat surface of a slider integrated with a flexible cantilever used in magnetic rigid disk drives. The sliding speed was 0.3 m/s and applied pressure was 150 kPa. The environmental effects were investigated in high vacuum (2×10^{-7} Torr), argon, dry air (less than 2% RH), ambient air (30% RH) and high-humidity air (70% RH).

Chemical Degradation Studies

The coefficient of friction and partial pressure of the gaseous products for fully bonded Z-DOL, Z-TETRAOL, A20H, Z-DOL+A20H (30 vol.%), and partially bonded A20H during sliding in high vacuum are shown in Fig. 35.30a–c. The result for untreated Z-DOL is also shown in the figure as a comparison.

In the tests, the sharp increase of friction indicates the failure of the lubricant film. Therefore, the durability of the lubricant film can be obtained from the friction curve. Under the normal pressure of 150 kPa, the untreated Z-DOL failed immediately after sliding. The fully bonded Z-DOL began to fail after sliding of about 40 m. The fully bonded Z-TETRAOL, began to fail at about 80 m. Fully bonded and partially bonded A20H, however, did not fail during the 100 m sliding. The fully bonded Z-DOL+A20H (30 vol.%) failed immediately after sliding. The results show that fully bonded Z-TETRAOL and A20H are more durable than fully bonded Z-DOL, while the untreated Z-DOL is less durable than the bonded films. The PFPE lubricants can be bonded to the applied surface through the hydroxyl group. Z-TETRAOL, with two hydroxyl groups at each end of the molecular chain, can be bonded more tightly on the silicon surface than Z-DOL. The high durability of A20H, however, is beyond expectation. To further confirm the result, the normal pressure of 200 kPa was applied on partially bonded A20H. At the normal pressure of 200 kPa, the coefficient of friction was found to increase. At the same time, gaseous products were detected (Fig. 35.30c). The final coefficient of friction was about 0.3, which is lower than the values (about 0.4) of the other films after failure. This could indicate that the A20H film was only partially worn. The reason for lower durability of Z-DOL+A20H (30 vol.%) in high vacuum is not clear.

In the tests on Z-DOL and Z-TETRAOL films, CF_2CF_3, CF_2CFO, CF_3, CF_2O, HCF_2, CF_2, and CFO were found to increase when friction increased. In the test of A20H films, $C_6H_4CF_3$, $C_6H_5CF_2$, CF_3, HCF_2, CFO, P, and H_2 were detected. For Z-DOL+A20H (30 vol.%), $C_6H_4CF_3$, $C_6H_5CF_2$, CF_3, HCF_2, CFO, P, and H_2 were also detected during sliding. Degradation mechanisms for Z-DOL and various model lubricants have been studied by *Zhao* and *Bhushan* [35.67–69]. Based on their work, Z-DOL starts to decompose above 350 °C. In the sliding conditions used here, it is not likely that the frictional heat can generate such a high temperature. The possibility of catalytic degradation is very low because of the small contact area. Triboelectrical reaction and mechanical scission are considered to be the dominant mechanisms during the sliding of Si on PFPE films. Electron emission is known to

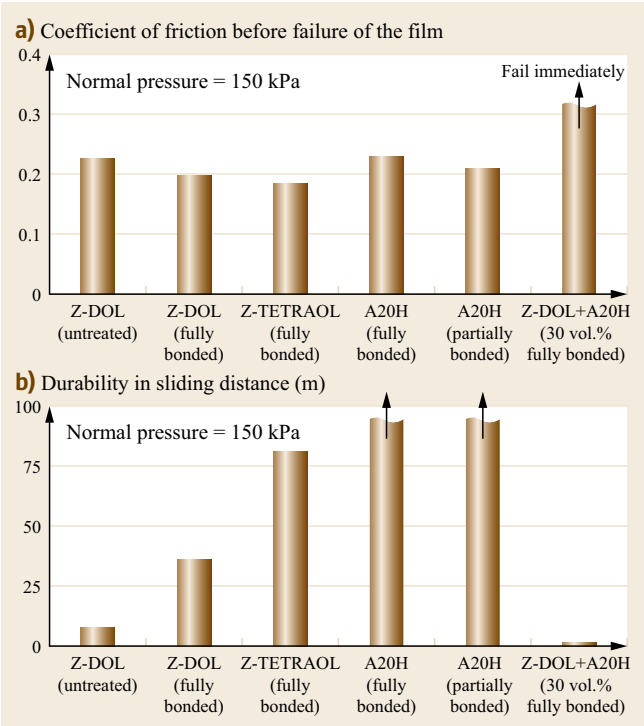

Fig. 35.31 Coefficient of friction and durability comparison of Z-DOL, Z-TETRAOL, A20H, and Z-DOL+A20H in high vacuum (after [35.63])

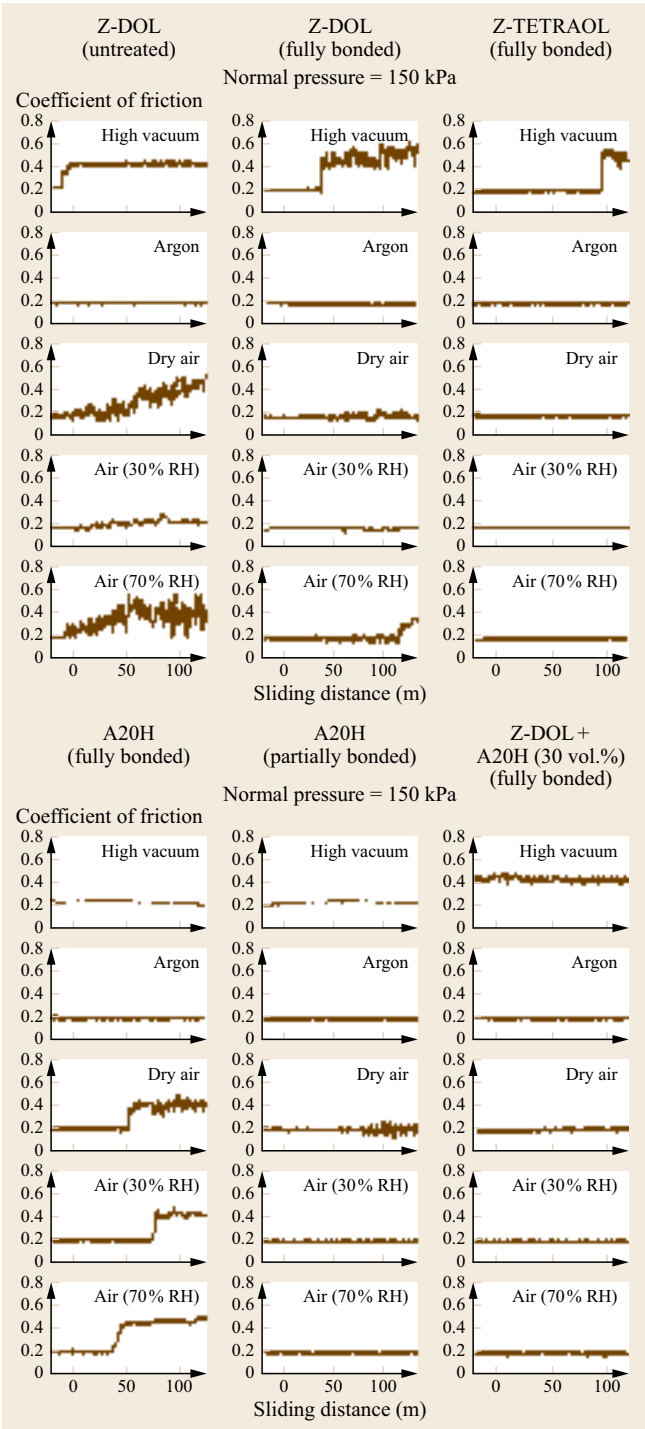

Fig. 35.32a,b Coefficient of friction data in high vacuum, argon, and air with different humidity levels of untreated (2.2 nm) and fully bonded (2.3 nm) Z-DOL, fully bonded Z-TETRAOL (2.6 nm), fully bonded (0.9 nm) and partially bonded (2.3 nm) A20H, and Z-DOL+A20H (2.4 nm) (after [35.63])

occur during sliding for both metal and nonmetal surfaces. The interaction of electrons with PFPE molecules could create various radicals such as $^{\bullet}CF_2{-}O{-}CF_2{-}$, $^{\bullet}CF_2{-}CF_2{-}O{-}CF_2{-}$, and/or $^{\bullet}CF_2{-}CF_3$. These radicals can decompose or react with each other and/or the remaining PFPE molecules. A detailed description of triboelectrical reactions can be found in *Zhao* et al. [35.69] and *Zhao* and *Bhushan* [35.68].

Mechanical scission is another mechanism capable of causing the degradation of PFPE films. The PFPE molecule has a long linear chain structure. The C−C and C−O bonds in the molecular chain are easily subjected to cleaving by the microasperities on the rubbing surfaces, which results in decomposition of the lubricant in the sliding process.

A summary of the coefficients of friction and durability for tested lubricants in high vacuum is shown in Fig. 35.31. The coefficients of friction of fully bonded Z-DOL and Z-TETRAOL are lower than untreated Z-DOL and A20H in high vacuum. Z-TETRAOL shows higher durability than Z-DOL, while A20H (both fully bonded and partially bonded) even shows high durability in high vacuum.

Environmental Studies

The wear tests were conducted in high vacuum, argon, dry air (less than 2% RH), air with 30% RH, and air with 70% RH [35.63]. The applied normal pressure was 150 kPa for all tested films, which was the same as in the degradation tests. Test results are presented in Fig. 35.32. The coefficients of friction show that friction and durability vary with the environment. Z-DOL films fail more rapidly in high vacuum than in other environments. As described in the previous section, there are very few foreign molecules on the contacting surfaces in high vacuum. This enables an intimate contact between the lubricant film and the counterpart surface. A tendency towards chemical bonding occurs between the lubricant film and the counterpart surface. In argon, the Z-DOL films exhibited lower friction and higher durability than in dry air. The chemical effects of oxygen can influence the friction and durability of the lubricant films [35.66]. The water molecules at a moderate humidity level (ambient air) can act as a lubricant between the contacting surfaces. However, in a high humidity environment, the water molecules can penetrate the Z-DOL film and result in a nonuniform distribution of the Z-DOL molecules. The fully bonded Z-DOL film is less influenced by environment than untreated Z-DOL. The reason is that the untreated Z-DOL has more free hydroxyl end groups. The water molecules in the environment can interact with the hydroxyl group of Z-DOL via hydrogen bonds.

Z-TETRAOL is more durable than Z-DOL. In particular, a high-humidity environment does not seem to have negative effects on Z-TETRAOL, although it has one more hydroxyl end group than Z-DOL and may attract more water molecules in high humidity. This could be because the two-hydroxyl end group provides better attachment than Z-DOL on the surface. The tight bonding reduces the probability of nonuniform distribution of the film. The coefficient of friction of fully bonded Z-TETRAOL is very close to fully bonded Z-DOL in argon and air with various humidity levels. In high vacuum, Z-TETRAOL shows a lower coefficient of friction than Z-DOL.

Both fully bonded and partially bonded A20H were very durable in high vacuum. In argon, fully bonded and partially bonded A20H did not fail during the 100 m sliding. In air with various humidity levels, however, the fully bonded A20H failed. The durability is lower compared to Z-DOL. The low durability can be from the low thickness of the film, which is only 0.9 nm. For the 2.3 nm thick partially bonded A20H film, the durability in air with various humidity levels is apparently improved. In particular, at high-humidity levels, partially bonded A20H exhibits high durability. A20H consists of a phosphazene group that is large in size and protects the surface. Phosphazene lubricant has been used as an additive and is known to have high durability in a high-humidity environment. The coefficient of friction of A20H, however, is higher (in the range of 5–15%) than that of Z-DOL in various environments.

Z-DOL+A20H (30 vol.%) shows low durability in high vacuum. In argon and air with various humidity levels, however, the film did not fail during the 100 m sliding. The durability of the mixture is higher than fully bonded Z-DOL. The coefficient of friction of the mixture is higher than that of Z-DOL while lower than that of A20H.

A summary of the coefficients of friction before the failure of the lubricant films in various environments is presented in Fig. 35.33. To summarize the highlights, Z-TETRAOL exhibits higher durability than Z-DOL. A20H exhibits high durability in high vacuum, in argon, and in air with various humidity levels. The mixture of Z-DOL+A20H (30 vol.%) shows low durability in high

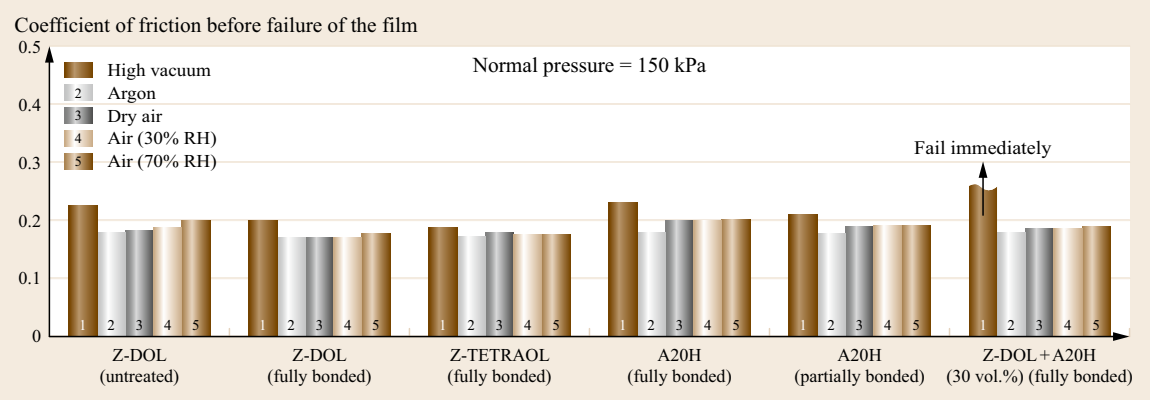

Fig. 35.33a–c Comparison of coefficient of friction data for Z-DOL, Z-TETRAOL, A20H, and Z-DOL+A20H in high vacuum, argon, and air with different humidity levels (after [35.63])

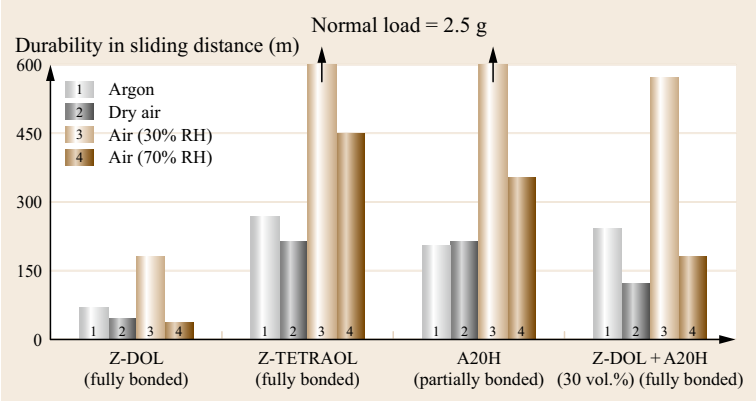

Fig. 35.34 Durability comparison for Z-DOL, Z-TETRAOL, A20H, and Z-DOL+A20H in argon and air with different humidity levels. A single crystal Si(100) ball (1 mm in diameter) was used as a slider on the films (after [35.63])

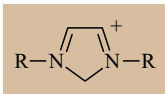
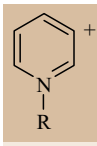
vacuum while it shows high durability in argon and air with various humidity levels.

In order to further investigate the durability of the lubricant films, a single-crystal Si(100) ball (1 mm in diameter, 5×10^{-7} atoms/cm^3 boron doped) was used as a slider on the films to accelerate wear. Tests were performed in argon, dry air, ambient air, and high-humidity air. The applied load on the silicon ball was 2.5 g, and the sliding speed was 0.3 m/s. The sliding distance was up to 600 m. The results are shown in Fig. 35.34. From Fig. 35.34, in all environments, Z-TETRAOL exhibits higher durability than the other films. The durability of A20H is slightly lower than that of Z-TETRAOL except in ambient air, where both are comparable. Tests on Z-TETRAOL and A20H were terminated at 600 m. Z-DOL+A20H shows higher durability than Z-DOL.

35.3 Nanotribological and Electrical Studies of Ionic Liquid Films

An ionic liquid (IL) is a synthetic salt with a melting point below 100 °C. A room-temperature ionic liquid is a synthetic molten salt with a melting point at or below room temperature. One or both of the ions are an organic species. At least one ion has a delocalized charge such that the formation of a stable crystal lattice is prevented, and the ions are held together by strong electrostatic forces. As a result of the poor coordination of the ions, these compounds are liquid below 100 °C or even at room temperature [35.20, 62].





The number of combinations of anions and cations that can be used to produce ionic liquids is in the range of one million. Typical cations include imidazolium, pyridinium, ammonium, phosphonium and sulfonium as shown below, where R stands for an organic group (Table 35.3).

Typical anions are tetrafluoroborate, BF_4^-, hexafluorophosphate, PF_6^-, bis(trifluorosulfonyl) imide, $(CF_3SO_2)_2N$ (*triflamide*) and toluene-4-sulfonate, $C_7H_7O_3S$ (*tosylate*) [35.70]. Dependent upon the substrate wettability and other functional requirements, a set of cations and anions can be combined. The ionic liquids were initially developed for use as electrolytes in batteries and for electrodeposition. Recent applications have geared these compounds as environmentally friendly solvents for chemical synthesis (*green chemistry*) where these liquids are used as substitutes for conventional organic solvents.

Ionic liquids are considered as potential lubricants. Their strong electrostatic bonding, compared to covalently bonded fluids, leads to very desirable lubrication properties. They also possess desirable properties such as negligible volatility, nonflammability, high thermal stability or high decomposition temperature, efficient heat transfer properties, low melting point, as well as compatibility with lubricant additives. Unlike conventional lubricants that are electrically insulating, ionic liquids can minimize the contact resistance between sliding surfaces because they are conducting, and conducting lubricants are needed for various electrical applications [35.22–24]. These liquids can also be used to mitigate arcing, which is a cause of electrical breakdown in sliding electrical contacts. In addition, ILs have high thermal conductivity, which helps to dissipate heat during sliding. The use of ionic liquids instead of hydrocarbon base oils (such as highly reformed mineral oils) has the potential to dramatically reduce air emissions. Perfluoropolyethers (PFPEs) are used in magnetic rigid disk and vacuum grease applications due to their high thermal stability and extremely low vapor pressure. However, from the commercial standpoint, ionic liquids are cheaper than PFPEs by a factor of two or so, providing the motivation for comparing the tribological properties of the former with the latter. ILs are being considered for MEMS/NEMS applications because of their high temperature stability, electrical conductivity, and desirable lubrication properties.

Bhushan et al. [35.62] evaluated ionic liquids with the hexafluorophosphate anion deposited on Si(100) wafers, and these were found to exhibit improved friction and wear properties compared to conventional lubricants. The films were evaluated as untreated, partially bonded (by heating at 150 °C for 30 min after dip coating), and fully bonded (thermal treated and washed). The ionic liquid containing the octyl sulfate anion has also been developed and is of interest due to

Table 35.3 The number of combinations of anions and cations to produce ionic liquids

		NR_4^+	PR_4^+	SR_3^+
Imidazalium	Pyridinium	Ammonium	Phosphonium	Sulfonium

its resistance to hydrolysis. Based on experience, anions are observed to affect tribological performance. Table 35.4 lists the physical and thermal properties of a selected ionic liquid and its properties are compared to the PFPE lubricant Z-TETRAOL.

The durability of ionic liquid films on various metal and ceramic substrates has been investigated from the standpoint of film formation (wettability) and film removal (friction and wear), where it was found that certain cations and anions exhibit better wetting, friction reduction, and wear resistance properties [35.62]. In general, ionic liquids exhibit better wettability on noble metal and ceramic surfaces than on nonnoble metal surfaces [35.70]. The flat imidazolium cation shows poorer wettability compared to bulkier cations such as ammonium and sulfonium. Among salts with the imidazolium cation, the presence of longer organic side chains lead to a reduction of the coefficient of friction. An anion effect is also observed, where oxygen-rich anions show better substrate wettability and lower wear compared to other imidazolium salts. Based on these findings, the ionic liquids of interest are 1-butyl-3-methylimidazolium hexafluorophosphate (BMIM-PF_6) and 1-butyl-3-methylimidazolium octyl sulfate (BMIM-$OctSO_4$). These were studied by *Bhushan* et al. [35.62], and the former was found to be superior in tribological performance. The chemical structures of BMIM-PF_6 and Z-TETRAOL for comparison are shown in Fig. 35.35, and a summary of their properties is presented in Table 35.4.

Some dicationic ILs are thermally stable up to 400 °C [35.75]. The adhesion and friction properties of two dicationic IL films on Si(100) substrate, based on the imidazolium cation and the bis(trifluoromethanesulfonyl)imide (or *triflamide*) anion, were studied by *Palacio* and *Bhushan* [35.21] and compared to the monocationic IL 1-butyl-3-methyl-1 *H*-imidazolium hexafluorophosphate (BMIM-PF_6). AFM experiments were also performed at various humidity and temperature conditions in order to investigate the effect of the environment on the nanolubrication properties of these ILs. Microscale friction and wear experiments using the ball-on-flat tribometer and wear at ultralow loads using an AFM were carried out. Fourier transform

infrared (FTIR) spectroscopy and x-ray photoelectron spectroscopy (XPS) were used to determine the chemical species that affect intermolecular bonding and also to elucidate the effect of the environment on the IL film surface in the case of FTIR data (Table 35.4).

The dicationic ionic liquids used in this study were 1,1′-(Pentane-1,5-diyl)bis(3-hydroxyethyl-1*H*-imidazolium-1-yl) di[bis(trifluoromethanesulfonyl)imide)] (abbreviated as BHPT) and 1,1′-(3,6,9,12,15-Pentaoxapentadecane-1,15-diyl)bis(3-hydroxyethyl-1*H*-imidazolium-1-yl) di[bis(trifluoromethanesulfonyl)imide)] (abbreviated as BHPET) [35.76] deposited on Si(100) wafers. The common name *triflamide* will be used here when referring to the anion. The properties of these dicationic ILs were compared with the conventional monocationic ionic liquid 1-Butyl-3-methyl-1*H*-imidazolium hexafluorophosphate, abbreviated as BMIM-PF_6 (Merck, Germany). Their chemical structures are shown in Fig. 35.35b. These compounds have been applied on single-crystal Si(100) (phosphorus doped) with a native oxide layer on the surface using the dip coating technique. The method and the apparatus used have been described earlier in Sect. 35.1.2. The films were heat-treated at 150 °C for 30 min after dip coating, such that they were partially bonded [35.62].

35.3.1 Monocationic Liquid Films

In this section, nanotribological data on BMIM-PF_6 and Z-TETRAOL are presented [35.20, 24, 45, 62].

Nanotribological Studies

In Fig. 35.36a, the surface height images for the untreated sample (air dried) are compared with the two chemically bonded samples (partially bonded and fully bonded). Aggregates of varying sizes are observed on the untreated Z-TETRAOL and on the ionic liquid coating. These aggregates could have formed initially during preparation of the dilute solution. For Z-TETRAOL, the long PFPE chains can orient in various configurations (such as coils), leading to aggregate formation [35.62]. In ionic liquids containing the 1-butyl-3-methylimidazolium cation, it is believed that aggregate formation in solvents that are less polar compared to water aids in minimizing the charge density (charge delocalization) within the ions. These aggregates are subsequently deposited on the silicon surface during the dip coating procedure. It is observed that the untreated lubricant surface has more prominent aggregates compared to the two chemically bonded samples, implying that the heat treatment promotes bonding to the Si substrate. Without the chemical bonding procedure, the lubricant molecules are less likely to attach to the substrate and would tend to attract each other instead, such that dewetting is more likely. The immobilization of the ionic liquid, which is promoted by thermal treatment, occurs by reaction of the anion with the hydroxyl groups present on the silicon surface, as shown in Fig. 35.36b for BMIM-PF_6.

Figure 35.37a is a summary of the adhesive force and coefficient of friction measurements on the ionic

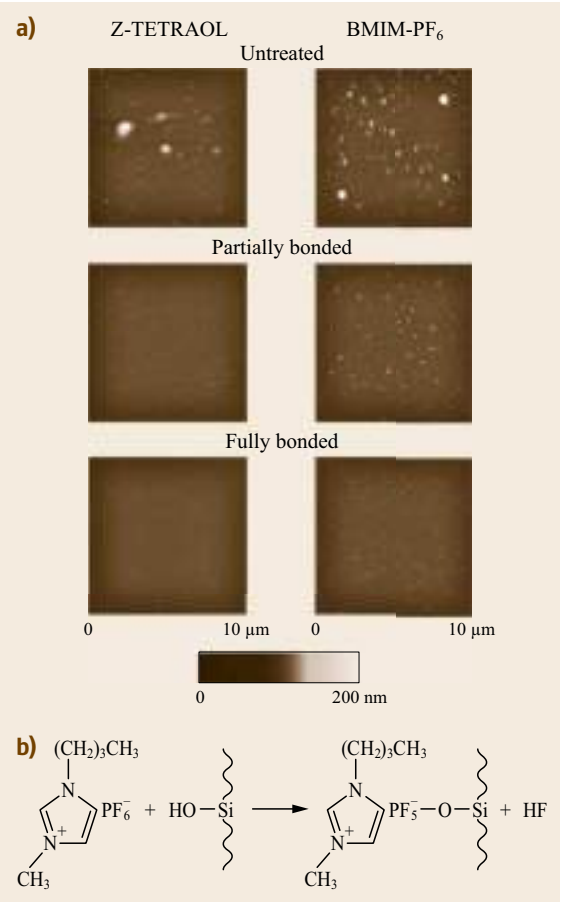

Fig. 35.36 **(a)** Surface height images for the untreated, partially bonded and fully bonded films of BMIM-PF_6 on silicon substrate, and **(b)** schematic for the attachment of BMIM-PF_6 to the silicon substrate (after [35.62])

liquid. Z-TETRAOL and Si(100) data are provided for comparison. The adhesive force has been observed to decrease in the following order: untreated > partially bonded > fully bonded. This mobile fraction on the untreated sample facilitates the formation of a meniscus, which increases the tip-sample adhesion. The adhesive force is highest in the untreated coating since it has the greatest amount of the mobile fraction among the three samples. Conversely, the sample with no mobile lubricant fraction available (fully bonded) has the lowest adhesive force.

A different trend is observed in the coefficient of friction (μ) data. Both the fully bonded and partially bonded samples have lower μ values compared to the uncoated silicon. Friction forces are lower on the latter, implying that the mobile lubricant fraction present in the partially bonded samples facilitates sliding of the tip on the surface. However, μ values for the untreated samples are higher than the data for the heat-treated coatings. Due to the lack of chemical bonding, the interaction of the lubricant to the substrate is weakened and dewetting can occur. Water and lubricant molecules are more likely to form a meniscus as the tip approaches the surface. This provides greater resistance to tip sliding, leading to higher coefficient of friction values. The lower portion of Fig. 35.37a is a schematic illustrating the role of meniscus formation in the adhesive and friction forces obtained for the uncoated Si and the untreated, partially bonded and fully bonded lubricant-coated Si surfaces.

Figure 35.37b contains plots of the coefficient of friction as a function of the number of sliding cycles at 70 nN normal load. Only a small rise in the coefficient of friction was observed for both Z-TETRAOL and the BMIM-PF_6 surfaces, indicating low surface wear. In the case of untreated Z-TETRAOL, a crossover is observed, where the coefficient of friction increases from its initial value and exceeds the μ of silicon after a certain number of cycles. This is attributed to the transfer of lubricant molecules to the AFM tip and the interaction of the transferred molecules with the lubricant still attached on the Si substrate, which will increase the friction force.

In order to compare friction and wear properties on the nanoscale with those on the microscale, conventional ball-on-flat tribometer experiments were conducted on the same samples. Images and profile traces of the wear scars are shown in Fig. 35.38a. The coefficient of friction and number of cycles to failure are summarized in Fig. 35.38b. Ionic liquid shows enhanced durability compared to both the Z-TETRAOL-coated and the uncoated Si. The nanoscale data presented in Fig. 35.37 can be compared to μ values obtained from ball-on-flat tests (Fig. 35.38b). The μ values of the untreated lubricant samples obtained by using AFM are lower than the μ obtained from the ball-on-flat tests. This is attributed to the difference in the length scales of the test techniques. An AFM tip simulates a single asperity contact while the conventional friction test involves the contact of multiple asperities present in the test system [35.1, 2]. With regards to wear, the interface contact of the AFM and ball-on-flat techniques are different from each other. In an AFM, the contact stress is very high, such that material can be displaced more easily. For a ball-on-flat test, the ball exerts a lower pressure on the surface, and the coating is in a confined geometry. As a consequence, displacement of the coating is not as easy as in AFM, leading to enhanced wear resistance.

Wear Detection by Surface Potential and Electrical Resistance Measurements

Figure 35.39a is a summary of the wear tests and the corresponding surface potential measurements on the

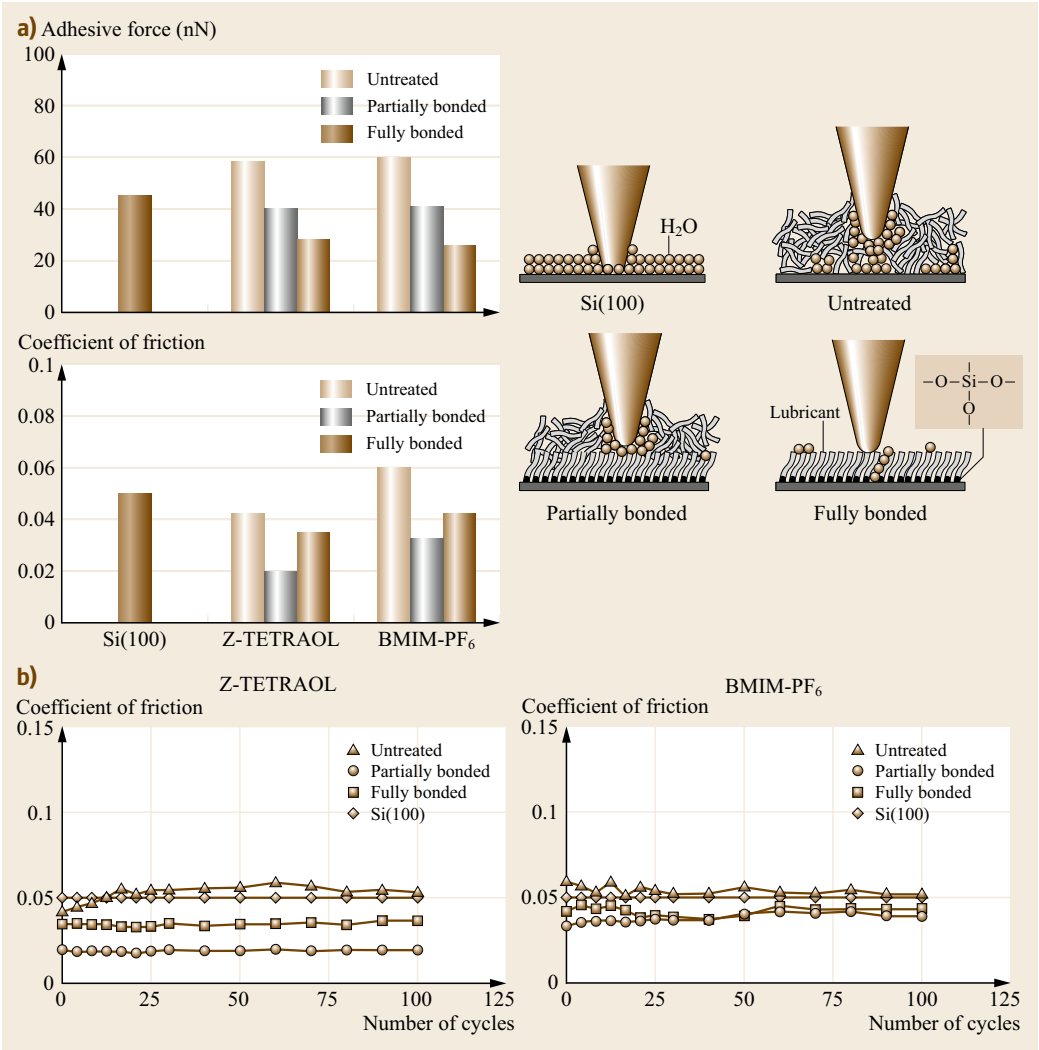

Fig. 35.37 **(a)** Summary of the adhesive force and coefficient of friction, and **(b)** durability data after 100 cycles for BMIM-PF_6 at room temperature (22 °C) and ambient air (45–55% RH). Data for the uncoated Si and Z-TETRAOL are shown for comparison. Schematic in **(a)** shows the effect of chemical bonding treatment and meniscus formation between the AFM tip and sample surface on the adhesive and friction forces (after [35.62])

ionic liquid. A bar chart summarizing the average surface potential change on the tested area is shown in Fig. 35.39b. In all cases, a smaller amount of debris was generated compared to the uncoated silicon surface, indicating that the ionic liquid provides wear protection. In general, the samples containing the mobile lubricant fraction (i. e., untreated and partially bonded surfaces) exhibit a lower surface potential change compared to the fully bonded sample, which only has immobile lubricant molecules. This is attributed to lubricant replenishment by the mobile fractions, which can occur in the untreated and partially bonded samples [35.44, 63]. From the bar chart in Fig. 35.39b, it is also observed that the change in surface potential is generally lower in the ionic liquid coating compared to the Z-TETRAOL coating and the uncoated silicon. This indicates that any built-up surface charges arising from the wear test were immediately dissipated onto the conducting ionic lubricant coating surface. In the case of Z-TETRAOL and the uncoated silicon, the charges remained trapped in the test area, since both these materials are insulators. Based on these findings, a considerable surface potential change will be observed on the wear region when:

1. The lubricant has been fully removed from the substrate.

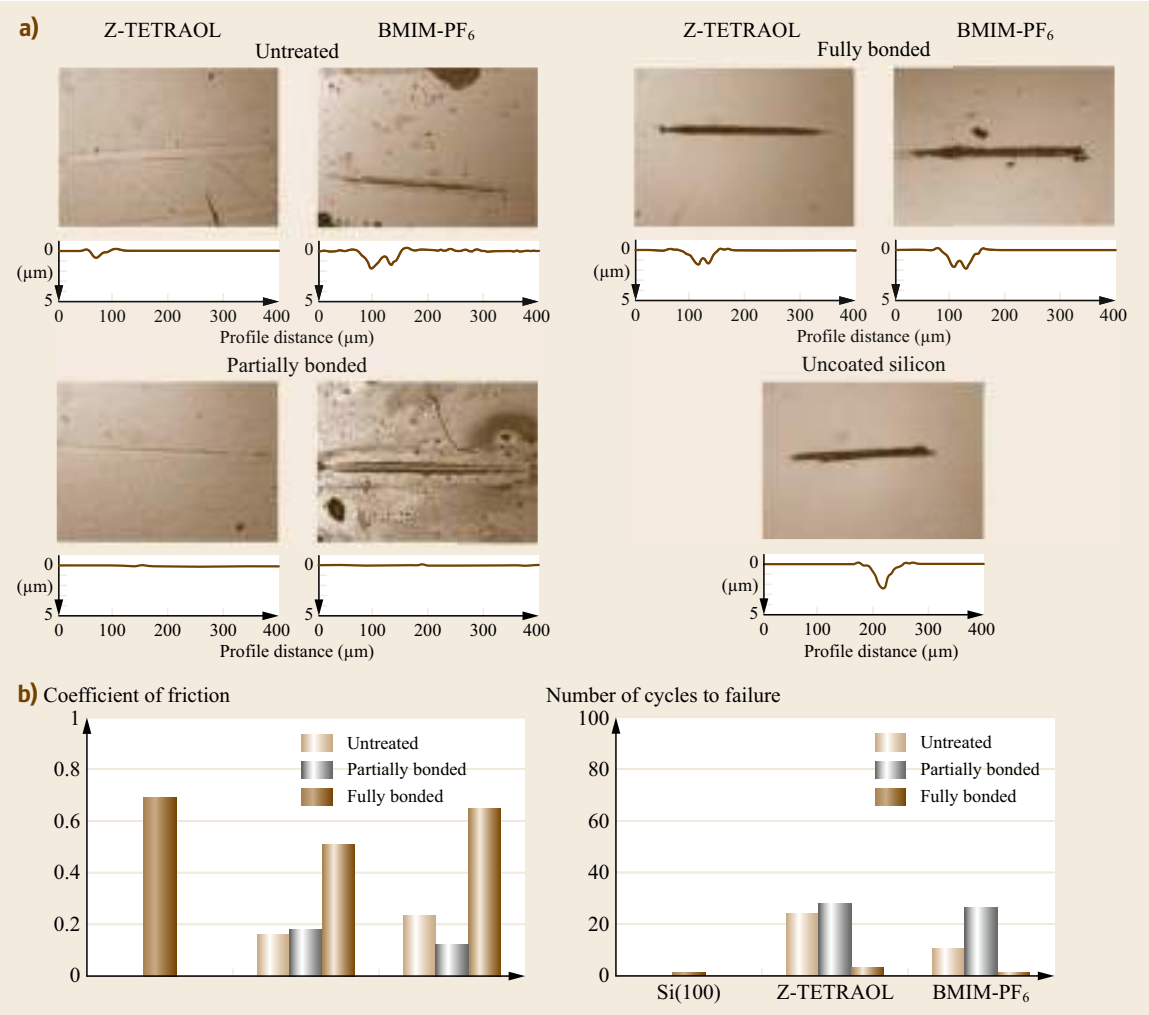

Fig. 35.38 **(a)** Optical images and height profiles taken after 20 cycles, and **(b)** summary of the coefficient of friction and number of cycles to failure from ball-on-flat tests on various BMIM-PF_6 coatings. Data for the uncoated Si and Z-TETRAOL are shown for comparison (after [35.62])

2. The native SiO_2 layer has been abraded from the surface.
3. Wear has caused subsurface structural changes.
4. Charges build up as they are unable to dissipate into the surrounding material.

Contact resistance images for the surfaces subjected to the wear tests are presented in Fig. 35.40a. The average change in the contact resistance of the wear region relative to the untested area is summarized in Fig. 35.40b. The fully bonded BMIM-PF_6 has an appreciable contact resistance increase in the wear region. Since silicon is a semiconductor, it has much higher resistance compared to the surrounding ionic liquid. The resistance increase in the worn area implies that the substrate is exposed after the wear test. Partially bonded films did not get worn out from the substrate after the test, as evidenced by the lack of contact resistance change in the tested area. The untreated Z-TETRAOL exhibited an observable resistance change, while BMIM-PF_6 did not. This can be correlated to the durability data in Fig. 35.37b, where the untreated Z-TETRAOL sample exhibited an increase in the friction force with time due to the transfer of lubricant molecules to the tip. Easier lubricant removal means that the diamond tip (in the case of Fig. 35.40) can cause substrate wear much sooner, leading to the observed resistance increase in the tested area. However, the resistance image does not provide a clear contrast between Z-TETRAOL and the newly exposed

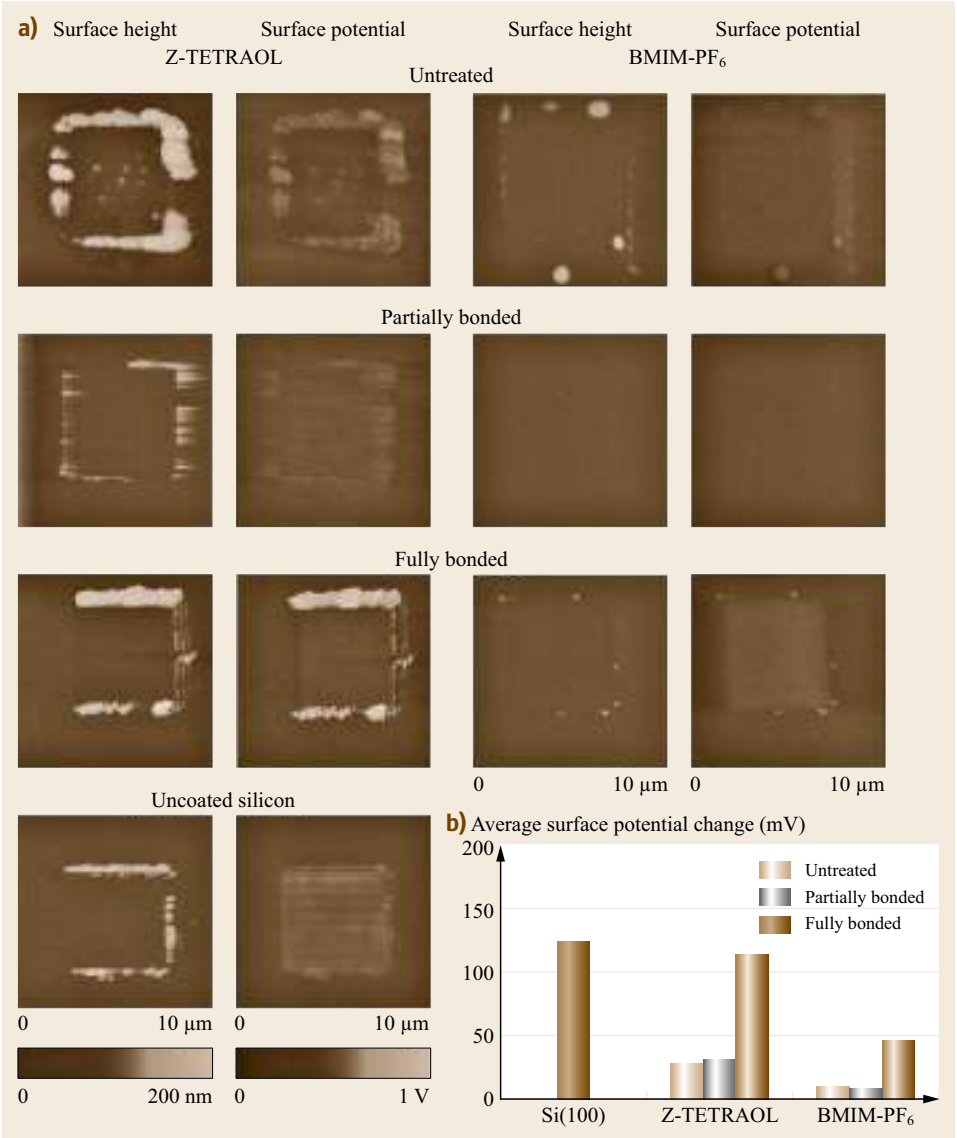

Fig. 35.39 **(a)** Surface height and surface potential maps after wear tests, and **(b)** bar chart showing surface potential change for various $BMIM\text{-}PF_6$ coatings. Data for the uncoated Si and Z-TETRAOL are shown for comparison (after [35.62])

substrate since both materials have high resistance values.

Microscale contact resistance obtained from ball-on-flat tribometer testing is shown in Fig. 35.41, along with the corresponding coefficient of friction data. For the ionic liquid films, the initial resistance is slightly lower than that of uncoated silicon, confirming their conductive nature. For the Z-TETRAOL samples, the contact resistance is about the same magnitude as the uncoated silicon. But for the conducting ionic liquid, an increase in resistance corresponds to an increase in the coefficient of friction, indicating wear of the lubricant and exposure of the silicon substrate, similar to observations in the nanoscale. These results are consistent with the adhesion, friction, and surface potential results with regards to wear detection and wear protection coming from the mobile and immobile lubricant fractions.

The durability data and trends for the ionic liquid obtained by using a steel ball are inferior to the results in Fig. 35.38, which was measured using a sapphire ball. In Fig. 35.41, the partially bonded samples still show the best durability, but in this case, Z-TETRAOL has the highest number of cycles to failure (opposite trend compared to Fig. 35.38b), as indicated by the point where the jump in the coefficient of friction is observed. This can be accounted for from the wetting properties of ionic liquids on different surfaces. It has been observed that ionic liquids have a tendency to wet

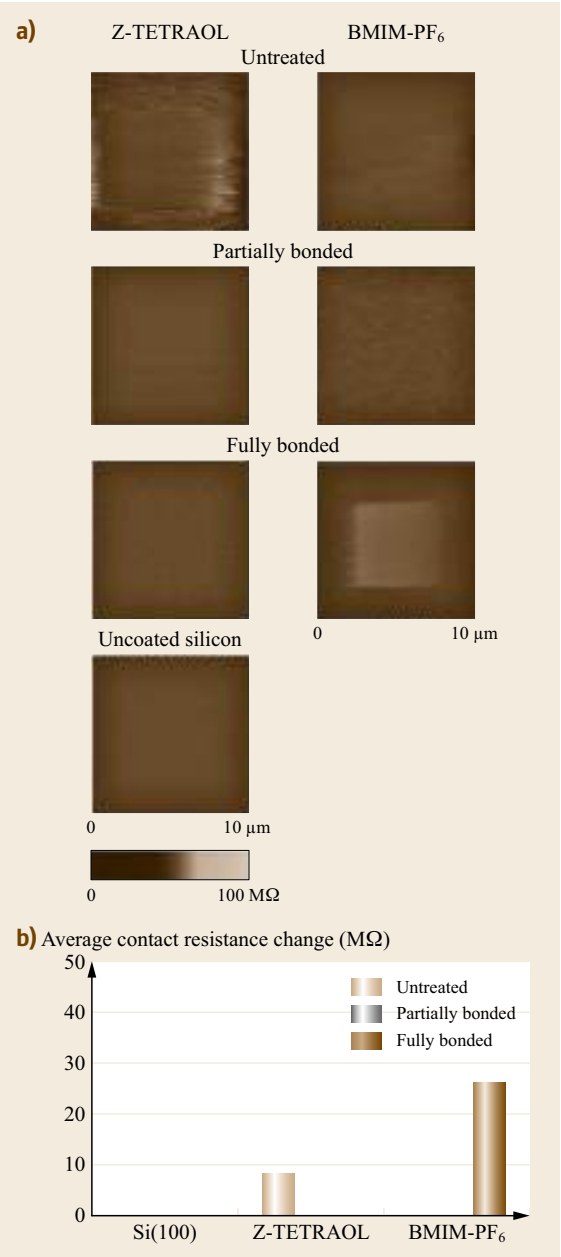

Fig. 35.40 **(a)** Nanoscale contact resistance images after wear tests and **(b)** bar chart showing contact resistance change for various BMIM-PF_6 coatings. Data for the uncoated Si and Z-TETRAOL are shown for comparison. Cases without the clear wear scar did not exhibit measurable change (after [35.62])

nonmetal surfaces (e.g., Si_3N_4, SiO_2, glass) better than conventional metal surfaces (such as 440C, M50 and 52100 steel) [35.62]. For wear tests with a steel ball, less wettability means less lubricant retention at the interface. This material wetting effect is possibly more significant for the ionic liquid than in Z-TETRAOL, but nonetheless, the durability of the partially bonded BMIM-PF_6 is still close to its Z-TETRAOL counterpart, such that ILs are still viable lubricants and comparable to PFPEs.

35.3.2 Dicationic Ionic Liquid Films

In this section, nanotribological data on BHPT and BHPET are presented. Data on BMIM-PF_6 and uncoated Si(100) are also presented for comparison [35.21].

Nanotribological Studies

Figure 35.42a is a summary of the contact angle, adhesive force, and coefficient of friction (μ) measurements for the coated and uncoated samples performed at ambient temperature and humidity conditions (22 °C and 50% RH respectively). The data shown in the bar charts are the averages of three measurements and the error bars represent $\pm 1\sigma$. BHPT is the least hydrophilic as it has the highest contact angle (81°) among the three IL coatings. This coating also exhibited the greatest reduction in the coefficient of friction relative to the uncoated surface. The high contact angle of BHPT leads to minimal meniscus formation between the tip and surface, leading to a large drop in the nanoscale friction force. In addition, BHPT has a pentyl chain that links the two imidazolium cations. This chain can orient the cation molecules on the substrate, thereby facilitating tip sliding on the film surface. In contrast, the polyether chain of BHPET is susceptible to interactions with water molecules, which can promote (instead of minimize) meniscus formation. The BMIM-PF_6 film also exhibited a reduction in the adhesive force and coefficient of friction. This comes from the combination of mobile and immobile lubricant fractions. Immobilization of this ionic liquid is possible as a result of the thermal treatment, which promotes the reaction between the hexafluorophosphate anion and the hydroxyl groups present on the silicon substrate surface [35.21, 62, 77].

Wear tests were conducted by monitoring the change in the friction force on a 2 μm line for 100 cycles. The data shown in Fig. 35.42b are representative of the three measurements made for each sample. The focus of this experiment is the wear of the lubricant film on the substrate. The μ value of the BHPT film changed minimally during the duration of the experiment, which indicates that the film was not being worn after 100 cycles. On the other hand, the BMIM-PF_6 and BHPET samples exhibited a gradual increase in μ, which means that these films could be undergoing some wear and that their interaction with the silicon substrate is weaker compared to that of BHPT.

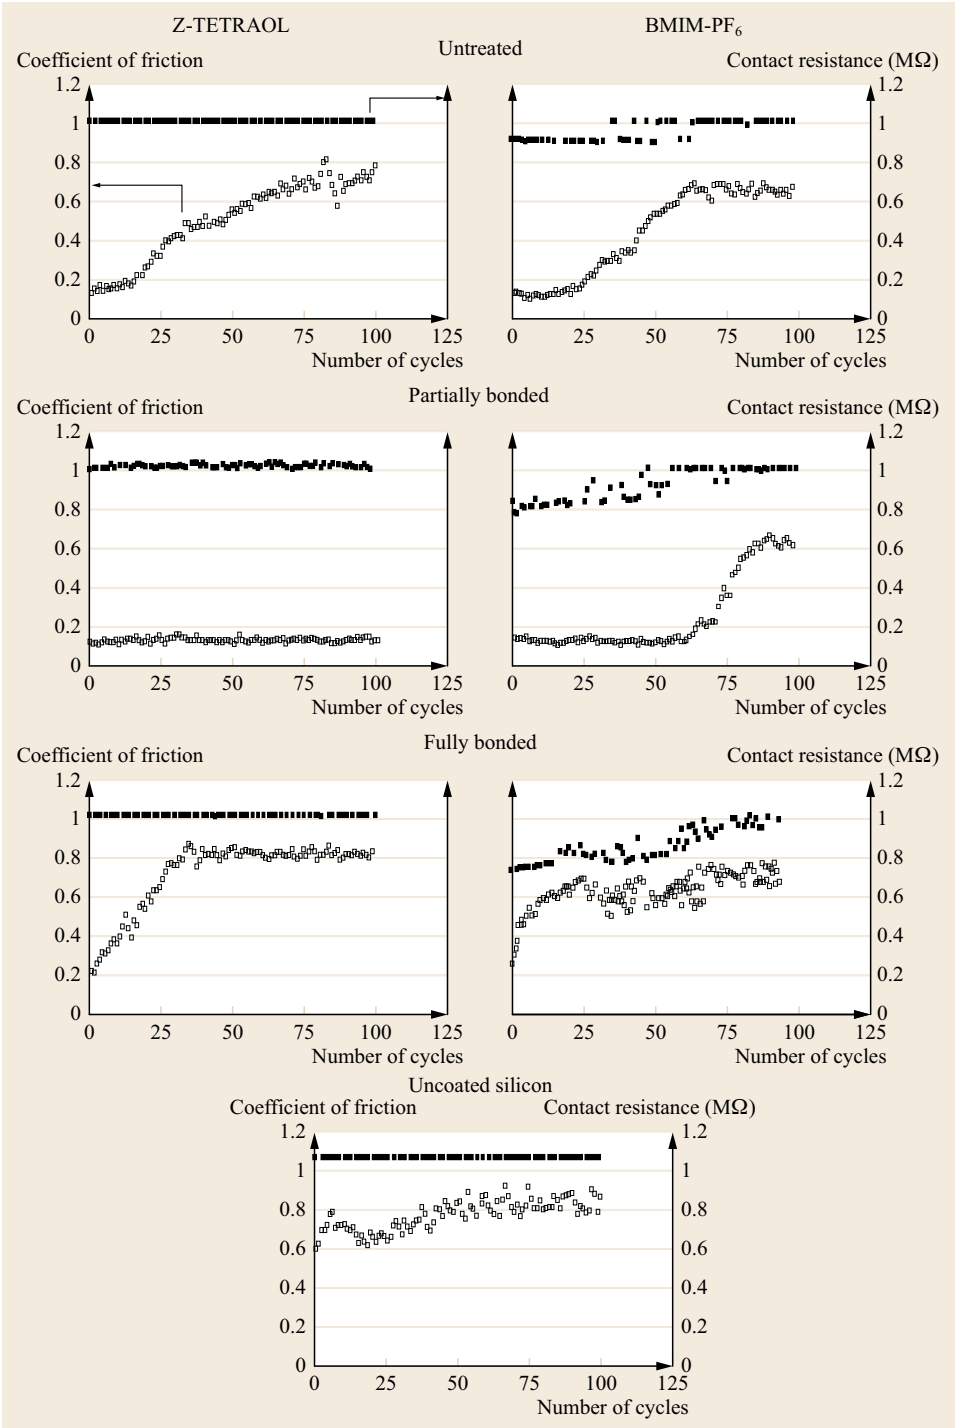

Fig. 35.41 Microscale contact resistance and coefficient of friction after ball-on-flat tests for 100 cycles on various BMIM-PF_6 coatings. Data for the uncoated Si and Z-TETRAOL are shown for comparison (after [35.62])

Figure 35.43 is a summary of the average contact potential change after the wear tests conducted by creating $5 \times 5\,\mu m^2$ wear scars with a diamond tip, where the height and surface potential maps were imaged afterwards. The data shown in the bar chart are an average of three measurements and the error bars represent $\pm 1\sigma$. A change in the surface potential in the wear region is observed when the following occur: the lubricant

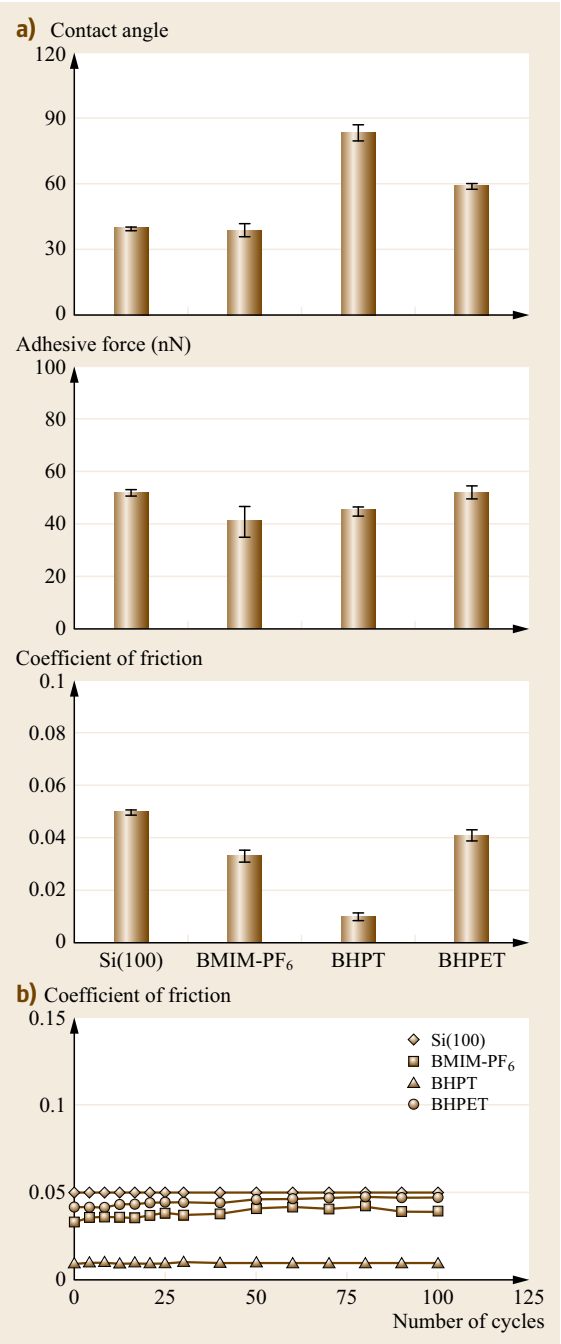

Fig. 35.42 **(a)** Summary of the contact angle, adhesive force and coefficient of friction, and **(b)** durability data after 100 cycles for BMIM-PF_6, BHPT and BHPET coatings at room temperature (22 °C) and ambient air (45–55% RH). Data for uncoated Si are shown for comparison. The error bars in **(a)** represent $\pm 1\sigma$ based on three measurements performed (after [35.21])

has been fully removed from the substrate, the native SiO_2 layer has been abraded from the surface, wear has caused subsurface structural changes, and charges build up as they are unable to dissipate into the surrounding material [35.21, 62]. As expected, the uncoated Si exhibited the greatest amount of wear (as evidenced by debris buildup around the edge of the wear test region) and highest increase in the surface potential. The surface potential image for BHPET film also showed an increase, indicating that the film was worn out after the test. This was not seen on tests with the BMIM-PF_6 and BHPT samples. The surface potential change could be absent in the test area if the lubricant was not removed completely, indicating that these two samples have a stronger interaction with the silicon substrate compared to BHPET.

Figure 35.44 shows a summary of the average contact resistance change after the wear test. As shown in Fig. 35.43, a significant change is observed in the wear region of the Si and BHPET samples. There is also a small amount of localized contact resistance increase in the BMIM-PF_6 sample. These results are consistent with the wear test presented in Fig. 35.42b, where the films are in this order of decreasing durability: BHPT > BMIM-PF_6 > BHPET.

Microscale Friction and Wear

In order to compare friction and wear properties at the microscale and the nanoscale, conventional ball-on-flat tribometer experiments were conducted on the same samples. The coefficient of friction data are summarized in Fig. 35.45. The data shown in the bar chart is an average of three measurements. All of the lubricated samples are reported to have less wear scars as a result of the ball having to displace the lubri-

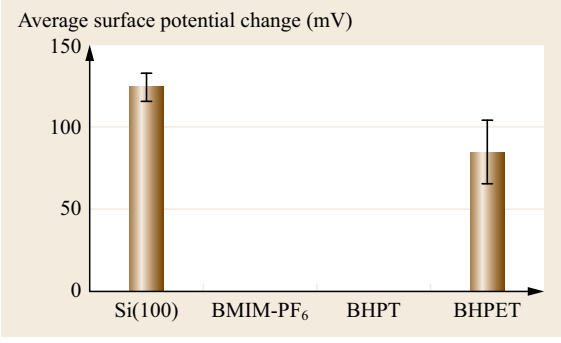

Fig. 35.43 Bar chart showing average surface potential change for BMIM-PF_6, BHPT and BHPET coatings. Data for uncoated Si are shown for comparison. The error bars represent $\pm 1\sigma$ based on three measurements performed (after [35.21])

cant before damaging the silicon surface. A reduction in the coefficient of friction arising from application of the lubricant film is observed, which is consistent with the nanoscale adhesion, friction and wear results.

The μ values of the lubricant samples obtained by using AFM are lower than the μ obtained from the ball-on-flat tests. This is attributed to the difference in the length scales of the test techniques. An AFM tip simulates a single asperity contact while the conventional friction test involves the contact of multiple asperities present in the test system. With regards to wear, the interface contact of the AFM and ball-on-flat techniques are different from each other such that one cannot expect both tests to show the same trend. On an AFM, the tip stress is very high such that material can be displaced more easily. For a ball-on-flat test, the tip exerts a lower pressure on the surface and the coating is in a confined geometry.

Relative Humidity and Temperature Effect Measurements

The influence of relative humidity on adhesion and friction is summarized in Fig. 35.46. In general, the adhesive force increases with the relative humidity. The condensed water in the humid environment facilitates meniscus formation between the tip and sample and higher adhesive forces. Since Si(100) is hydrophilic, it readily adsorbs water molecules. For the three ionic liquids, an increase in the adhesive force is also due to increased water adsorption. This comes from attractive electrostatic interactions (ion-dipole forces) between the individual ions and water molecules.

Water adsorption affects the observed coefficient of friction as a function of the relative humidity. In Si, the coefficient of friction is uniform at 10–50% RH, then decreases at 70% RH. The adsorbed water at higher humidity can lead to the formation of a continuous water layer separating the tip and sample surface, which can act as a lubricant. Although the adhesive force increases, the reduction in interfacial strength accounts for the slight decrease of the coefficient of friction at the highest range of humidity level examined. However, the presence of more water molecules at higher humidity has an opposite effect on the ionic liquid surfaces, where the coefficient of friction increases with humidity. The attractive ion-dipole forces between the ions and water are amplified at higher humidity because more water molecules are available. A greater attractive force between tip and surface leads to greater resistance to sliding and a higher coefficient of friction. This is observed on both the monocationic (BMIM-PF_6) and the dicationic (BHPT and BHPET) ionic liquid-coated surfaces. For BHPET, polar interactions between water and the oxygen atoms in the polyether (C–O–C) chain is possible and increases the water adsorption to the surface. This could account for the larger rise in the coefficient of friction in the BHPET sample from 50 to 70% RH, compared to BMIM-PF_6 and BHPT.

The effect of temperature on the adhesion and friction properties of the ILs is summarized in Fig. 35.47. The adhesive and friction forces were measured from 22 to 125 °C. As shown in Fig. 35.47, the increase in test temperature leads to a decrease in the adhesive force and the coefficient of friction. The decrease in the adhesive force at higher temperatures is observed in all the samples, while the corresponding drop in the coefficient of friction is seen only for BMIM-PF_6, BHPET and the silicon substrate. At higher temperatures, the surface water molecules are desorbed, leading to the decrease in both the adhesive and friction forces. A reduction in the viscosity at higher temperatures can also facilitate the decrease in the friction force [35.25]. In BHPT, the coefficient of friction was not adversely

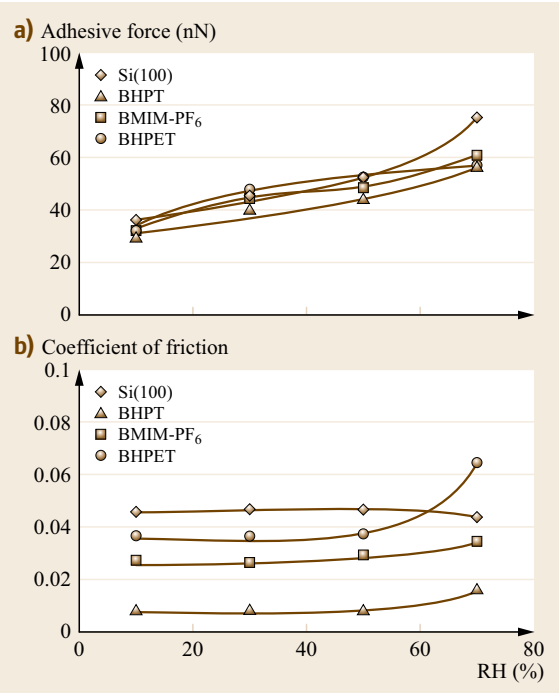

Fig. 35.46a,b Influence of the relative humidity (RH) on the adhesive force **(a)** and coefficient of friction **(b)** for unlubricated and lubricated tapes at 22 °C (after [35.21])

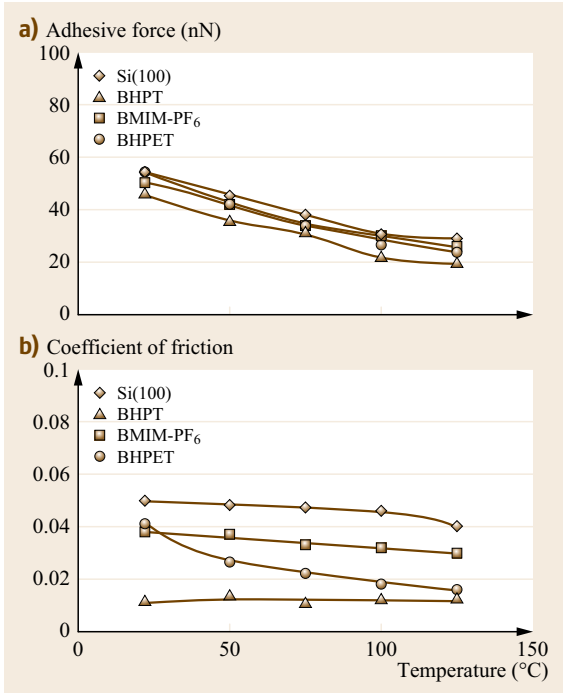

Fig. 35.47a,b Influence of temperature on the adhesive force **(a)** and coefficient of friction **(b)** for uncoated and coated Si samples at 50% RH air (after [35.21])

affected as the test temperature was increased. This implies that at ambient humidity conditions, the BHPT film does not adsorb a large amount of water molecules. Moreover, this also implies that the BHPT surface has weak interactions with surface water molecules, such that friction force during sliding is not very much affected.

Fourier Transform Infrared Spectroscopy

Figure 35.48 is a summary of the FTIR spectra obtained for the different ionic liquid-coated samples, along with the uncoated Si substrate. The observed peaks are labeled with the chemical bonds that they correspond to. In the case of the Si substrate (with a contact angle of 40°) exposed to water molecules in the ambient, no peaks are observed. C–H stretching vibrations in the coated samples are observed at the 600–800 cm^{-1} range. For BHPET, the strong peak at $\approx$ 1060 cm^{-1} is for the C–O–C vibration, which is prominent due to the presence of the polyether chain in its cation. This peak overlaps with the C–O vibration, which is present in BHPT as the terminal primary alcohol (C−OH). In BMIM-PF_6, a peak appears in this range due to rocking vibrations of the methyl (CH_3) substituent. The peak at 1500–1600 cm^{-1} comes from the C=N vibrations, which is common to all three ionic liquids since they

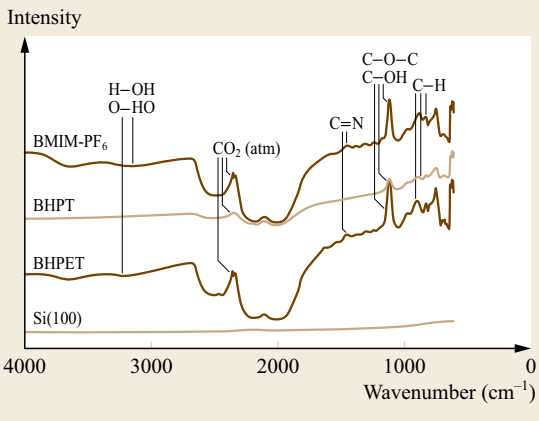

Fig. 35.48 FTIR spectra of uncoated and coated Si samples. The chemical bonds (or species) were listed above the spectra to indicate the possible bonding modes that correspond to the observed peaks (after [35.21])

are all based on the imidazolium cation. However, it is not observed in BHPT as the C=N vibrations may be weak. The wide peak at 3600–4000 cm^{-1} corresponds to hydrogen bonding, possibly due to water molecules adsorbed on the surface [35.21, 78, 79]. This is present in BMIM-PF_6 and in BHPET but not in BHPT. This

accounts for the much lower contact angle of BMIM-PF_6 and BHPET (39° and 59° respectively) compared to BHPT (81°). This implies that the surface of BHPT is more hydrophobic compared to either BMIM-PF_6 or BHPET, which is consistent with the observed low coefficient of friction for BHPT [35.21].

X-ray Photoelectron Spectroscopy

The XPS survey spectra obtained on the uncoated and coated Si samples are shown in Fig. 35.49a. In the uncoated sample, prominent peaks are observed at 99, 151 and 533 eV, corresponding to the binding energies of Si 2p, Si 2s and O 1s electrons respectively. Additional peaks are observed on the three coated samples at 285 and 689 eV, which correspond to C 1s and F 1s electrons respectively. Smaller peaks observed at approximately 1000 eV on all samples are due to Auger lines (KLL transitions) for oxygen [35.80].

The high-resolution, best-fit XPS spectra are shown in Figure 35.49b for the Si 2p, C 1s, O 1s and F 1s electrons. The peaks are labeled with the corresponding chemical bonds, which pertain to either the silicon substrate or groups found on the ionic liquid molecule. One noteworthy exception is the presence of peaks at approximately 292 eV, which confirms the presence of CF_2 on the surface. This indicates the immobilization of the BHPT and BHPET ionic liquids, which occurs by the reaction of the anion with the hydroxyl groups present on the silicon surface [35.21, 23, 62].

Relationship Between IL Structure and Adhesion, Friction and Wear Properties

Figure 35.50 is an interpretation of how the IL cations interact with the silicon substrate. For the monocationic BMIM-PF_6, only weak interactions between the imidazolium ring and the silicon surface is expected. For the dicationic ionic liquids, multiple cation attachment schemes are possible. In BHPT, the hydroxyl groups attached to the imidazolium cation at the ends of the chain provide a means for strong H-bonding interactions with active sites on the silicon surface. As shown in Figure 35.50, either one (case 1) or two (case 2) hydroxyl groups can create this bond. The second case is particularly desirable because if the two hydroxyl groups are bonded (i. e., not exposed to the surface), they are not available to interact with water molecules in the ambient, leading to a reduction in the adhesion and friction forces, as well as enhanced wear resistance [35.21].

In BHPET, these hydroxyl group attachment schemes are also applicable. However, the additional mechanism of intramolecular hydrogen bonding can also take place (case 3). This is not as desirable as

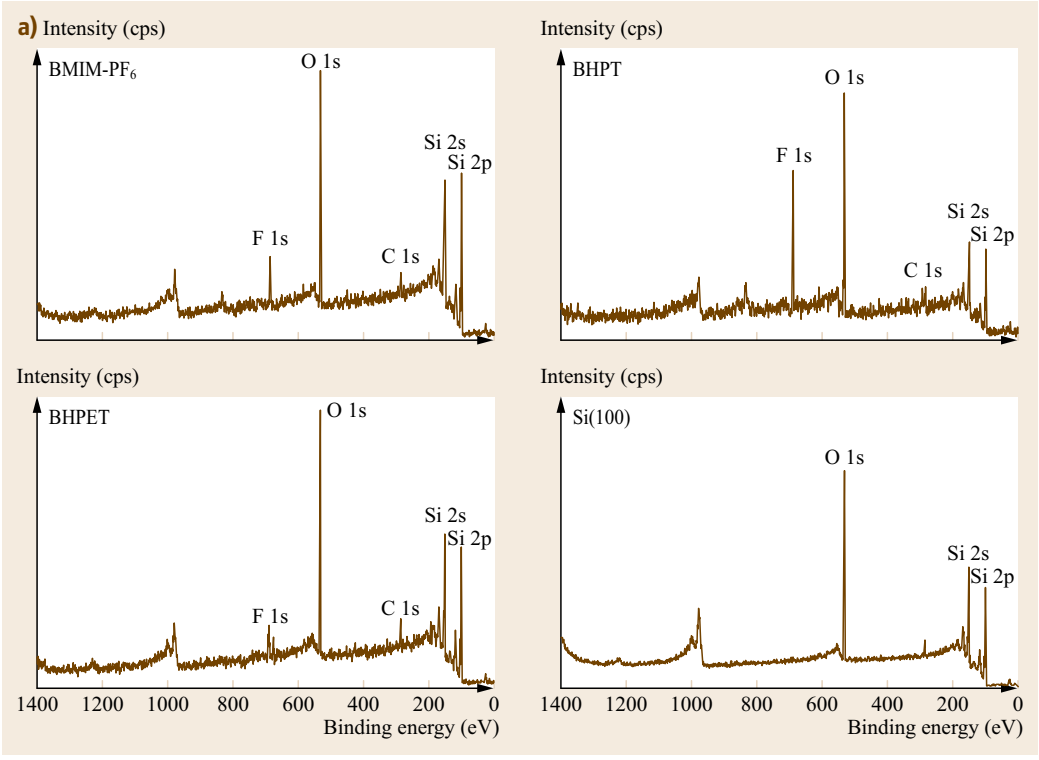

Fig. 35.49
(a) XPS spectra of uncoated and coated Si samples. Survey scan from 0–1400 eV provides the surface elemental composition. **(b)** High-resolution (deconvoluted) XPS spectra for Si 2p, C 1s, O 1s and F 1s reveals the different binding environments present on the surface (after [35.21])

the second case because it depletes the available chain ends with hydroxyl groups, which can bond to the silicon surface. The interaction of the lubricant film with the silicon substrate is weakened, and water molecules can displace the lubricant from the substrate. In addition, the polyether chain that links the two cations contains five oxygen atoms in each chain. These oxygen atoms can also form H-bonds with the water molecules in the ambient. This can account for the large difference in the friction properties between BHPET and BHPT. While the application of the BHPT film has lowered the coefficient of friction of the silicon surface, the BHPET film did not have a similar effect due to the molecular interactions described above. This interpretation of lubricant-substrate interaction is corroborated by the adhesion and friction data at varying humidities and temperatures, as well as the FTIR spectra. Both BMIM-PF_6 and BHPET have large peaks in their FTIR spectra that correspond to H-bonds of water molecules, which is consistent with the observed sensitivity of their adhesion and friction to the change in humidity and temperature. Meanwhile, BHPT does

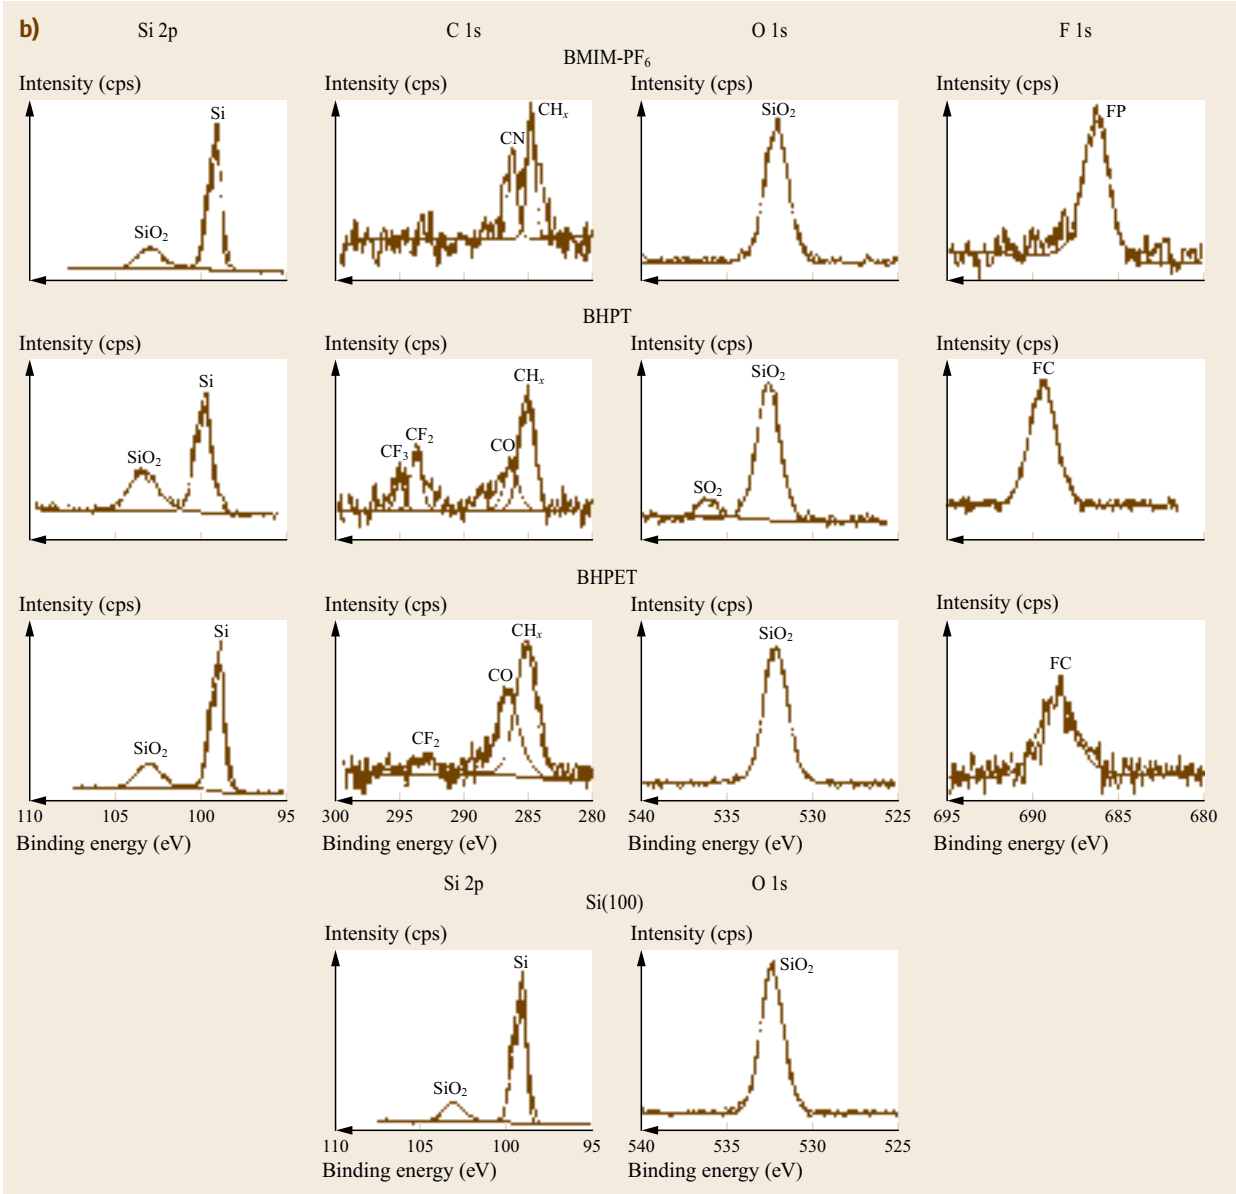

Fig. 35.49 (continued)

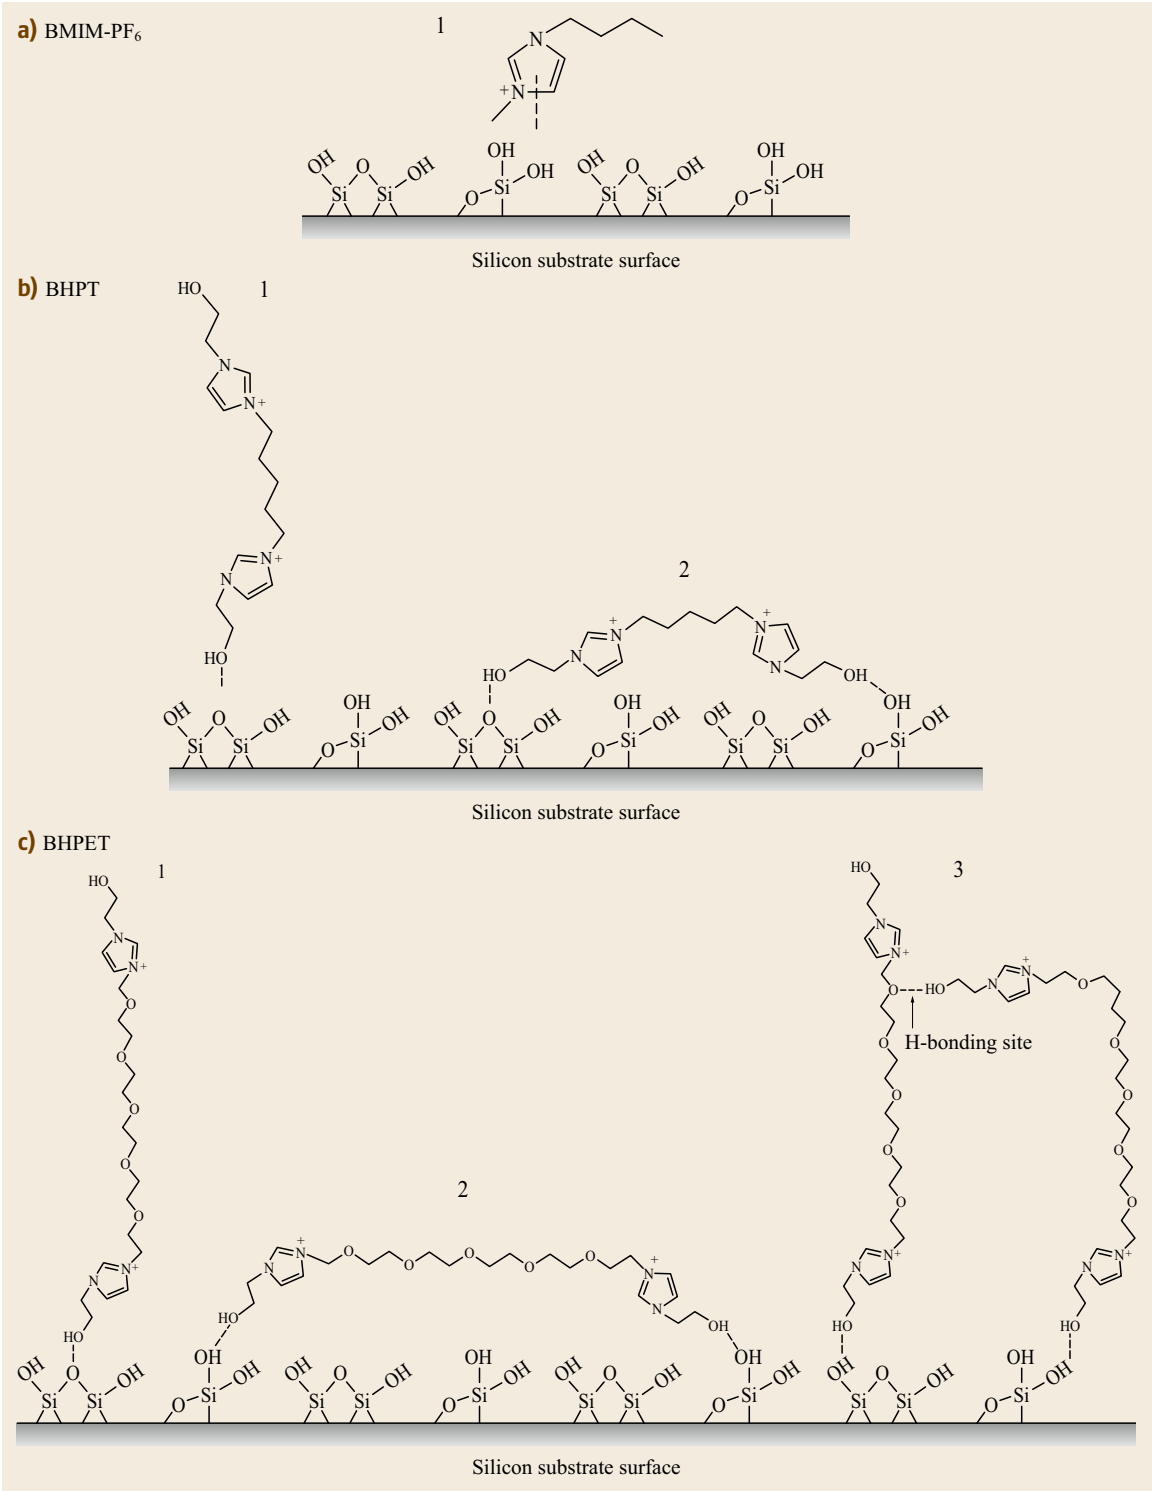

Fig. 35.50a,b Schematic for the attachment of the anions of **(a)** BMIM-PF_6, and **(b)** BHPT and BHPET to the silicon substrate (after [35.21])

not have the aforementioned peak, and its adhesion and friction properties appear to be less sensitive to water molecules compared to the other two ionic liquids [35.21].

Figure 35.51 is a schematic showing the interaction of the anions with the silicon substrate. As mentioned previously, XPS spectra indicate immobilization of the ionic liquid, which occurs through the reaction of the anion with the hydroxyl groups on the substrate surface. In BMIM-PF_6, the O attaches to P, while in BHPT and BHPET (which have the same anion), the O bonds to C. Since the reactions involve the creation of new covalent bonds, this implies that the anions of the ILs investigated are more strongly attached to the substrate compared to the cations, which are chemically adsorbed [35.21].

Based on the micro- and nanoscale friction and wear measurements, the ionic liquids show strong potential as lubricants for MEMS/NEMS because they have desirable thermal and electrical conductivities as well as desirable tribological properties.

35.4 Conclusion

Boundary films are formed by physisorption, chemisorption, and chemical reaction. A good boundary lubricant should have a high degree of interaction between its molecules and the solid surface. As a general rule, liquids are good lubricants when they are polar and thus able to grip solid surfaces (or be adsorbed). In this chapter, we presented an overview of various perfluoropolyethers (PFPEs) and ionic liquid films.

Nanodeformation studies have shown that fully bonded PFPE lubricants behave as soft polymer coatings, while the unbonded lubricants behave like liquid. AFM studies have shown that the physisorbed nonpolar molecules on a solid surface have an extended, flat conformation. The spreading property of PFPE is strongly dependent on the molecular end groups and the substrate chemistry.

Using a solid-like Z-DOL (fully bonded) film can reduce the friction and adhesion of Si(100), while using the liquid-like lubricant Z-15 showed a negative effect. Si(100) and a Z-15 film showed an apparent time effect. The friction and adhesion forces increased as a result of the growth of the meniscus up to an equilibrium time, after which they remained constant. The use of a Z-DOL (fully bonded) film can prevent rest time effects. During sliding at high velocity, the meniscus was broken and did not have enough time to rebuild, which led to a decrease of friction force and adhesive force of Z-15 and Z-DOL (fully bonded). The influence of relative humidity on friction and adhesion is dominated by the amount of adsorbed water molecules. Increasing humidity can either increase friction through increased adhesion by water menisci or reduce friction through an enhanced water-lubricating effect. Increasing temperature led to desorption of the water layer, a decrease in water surface tension, a decrease in viscosity, and easier orientation of the Z-DOL (fully bonded) molecules. These changes caused a decrease of friction force and adhesion at high temperature. During cycling tests, the molecular interaction between the attached Z-15 molecules to the tip and the Z-15 molecules on the film surface caused the initial increase in friction. Wear tests showed that Z-DOL (fully bonded) can improve the wear resistance of silicon. Partially bonded PFPE films appear to be more durable than fully bonded films. This suggests that partially/fully bonded films are good lubricants for micro/nanoscale devices operating in different environmental conditions.

The surface potential technique has been useful in detecting lubricant removal and the initiation of substrate wear. The increase in surface potential is attributed to the change in the work function of the silicon after wear and electrostatic charge buildup of debris in the lubricant. Coatings with a mobile lubricant fraction were better able to protect the silicon substrate from wear compared to the fully bonded coating. This enhanced protection is attributed to a lubricant replen-

ishment mechanism. The contact resistance technique provides complementary information to surface potential data in detecting exposure of the substrate after wear and is a promising method for studying conducting lubricants.

Degradation of novel PFPE lubricants – Z-DOL, Z-TETRAOL, A20H, and Z-DOL+A20H (30 vol.%) – was studied. The coefficient of friction of Z-TETRAOL was lower than Z-DOL and A20H in high vacuum. Fully bonded Z-TETRAOL exhibited higher durability than fully bonded Z-DOL on Si, and both were more durable than untreated Z-DOL. A20H showed very high durability in high vacuum. Environment influences the friction and durability of PFPE films. Generally, PFPE films are less durable in high vacuum than in other environments because of intimate contact between surfaces. In argon, the PFPE films showed low friction and high durability. Water molecules can act as a lubricant for PFPE films at a moderate humidity level, while at a high-humidity level they can penetrate the PFPE films and cause increased friction. The durability of fully bonded Z-TETRAOL and partially bonded A20H is higher than that of Z-DOL in tested environments. The mixture of Z-DOL+A20H (30 vol.%) showed low durability in high vacuum while it showed high durability in argon and air with various humidity levels.

The ionic liquids exhibited low adhesion, friction, and wear properties comparable to the PFPE lubricants. For example, ionic liquid BMIM-PF_6 is comparable to Z-TETRAOL. Based on the surface height, adhesion, and friction data, chemical bonding treatment facilitated attachment of the ionic liquid to the silicon substrate surface, leading to a more uniform coating and lower adhesion force and coefficient of friction. The partially bonded coatings have the lowest coefficients of friction and longest durability as they possess a desirable combination of lubricant bonded to the substrate, as well as a mobile fraction that facilitates sliding. In micro- and nanoscale experiments, the ionic liquid exhibited comparable durability with the lubricant Z-TETRAOL, which has high thermal stability and extremely low vapor pressure. The low postwear surface potential change observed on the silicon coated with ionic liquid is indicative of enhanced charge dissipation compared to the Z-TETRAOL-coated and uncoated surfaces, which are poor conductors. Contact resistance data is consistent with the surface potential data with regards to identifying the role of the mobile and immobile lubricant fractions in protecting the surface from wear.

The dicationic liquid BHPT exhibits superior nanoscale friction and wear resistance properties. This is attributed to the presence of a pentyl chain and hydroxyl groups on both chain ends, which facilitate molecular orientation, as well as bonding interactions with the substrate surface. The other dicationic liquid, BHPET, has less desirable adhesion, friction, and wear properties compared to either BHPT or BMIM-PF_6. Intermolecular hydrogen bonding in BHPET reduces the chain ordering on the substrate surface, which accounts for the observed higher adhesive force and coefficient of friction relative to the other ionic liquids investigated. From the nanoscale wear tests, surface potential, and contact resistance imaging, it was found that the films are in this order of decreasing durability: BHPT > BMIM-PF_6 > BHPET. The microscale coefficient of friction was higher than the nanoscale value due to the difference in the length scales and configurations of the two test methods.

Nanotribological experiments performed at various humidities and temperature conditions indicated that the adhesive force and coefficient of friction of the ionic liquid films, especially BMIM-PF_6 and BHPET, are highly sensitive to the amount of water molecules present on the surface. This was confirmed by FTIR spectroscopy, where the BMIM-PF_6 and BHPET films showed peaks corresponding to hydrogen bonding mainly resulting from water adsorption and partially from intermolecular interactions. The absence of this peak in BHPT indicated that a much smaller amount of water was adsorbed by this ionic liquid, which is consistent with its superior nanotribological properties. The anions are more strongly attached to the substrate compared to the cations. The anions could be covalently bonded, while the cations are chemically adsorbed. XPS analysis confirmed the immobilization of the anion to the silicon substrate.

In summary, PFPE and ionic liquids can be used for nanoscale boundary lubrication in demanding environments.

36. Plant Surfaces: Structures and Functions for Biomimetic Applications

Wilhelm Barthlott, Matthias Mail, Bharat Bhushan, Kerstin Koch

This chapter presents an overview of plant surface structures and their evolution, combines surface chemistry and architecture with their functions and refers to possible biomimetic applications.

Within some 3.5 billion years biological species evolved highly complex multifunctional surfaces for interacting with their environments, providing some 10 million living prototypes (i. e., estimated number of existing plants and animals) for engineers. The complexity of the hierarchical structures and their functionality in biological organisms surpasses all abiotic natural surfaces: even superhydrophobicity is restricted in nature to living organisms and was probably a key evolutionary step in the invasion of terrestrial habitats some 350–450 million years ago by plants and insects. Special attention should be paid to the fact that global environmental change implies a dramatic loss of species and with it many biological role models.

Plants, the dominating group of organisms on our planet, are sessile organisms with large multifunctional surfaces and thus exhibit particular intriguing features. Superhydrophilicity and superhydrophobicity are focal points in this chapter. We estimate that superhydrophobic plant leaves (e.g., grasses) comprise in total an area of around 250 million km^2, which is about 50% of the total surface of our planet.

A survey of structures and functions based on our own examinations of almost 20 000 species is provided; for further references we refer to [36.1]. A basic difference exists between aquatic nonvascular and land-living vascular plants; the latter exhibit a particularly intriguing surface chemistry and architecture. The diversity of features is described in detail according to their hierarchical structural order. The first underlying and essential feature is the polymer cuticle superimposed by epicuticular wax and the curvature of single cells up to complex multicellular structures. A descriptive terminology for this diversity is provided.

Simplified, the functions of plant surface characteristics may be grouped into six categories:

1. Mechanical properties
2. Influence on reflection and absorption of spectral radiation
3. Reduction of water loss or increase of water uptake, moisture harvesting
4. Adhesion and nonadhesion (lotus effect, insect trapping)
5. Drag and turbulence increase
6. Air retention underwater for drag reduction or gas exchange (Salvinia effect).

This list is far from complete.

A short overview of the history of bionics and the impressive spectrum of existing and anticipated biomimetic applications are provided. The major challenge for engineers and materials scientists, the durability of the fragile nanocoatings, is also discussed.

36.1 500 Million Years of Evolution for Innovative Technologies

Surfaces define the boundaries for the well-structured world of solids, and it is surfaces that define their interactions. They play crucial roles in environmental interactions. This is of particular importance for sessile organisms with large functional surfaces: plants. Green plants cover the terrestrial biomes of our planet and – not surprisingly – show a stunning diversity of hierarchical surface structures, which has been revealed with the help of scanning electron microscopy techniques (SEM) first employed in the 1970s (survey in [36.2]). It is even possible to examine the hierarchical surface structures at the macroscopic scale, as illustrated in two

Fig. 36.1a,b Hierarchical surface sculpturing of plants on the macroscopic scale. **(a)** The Saguaro (*Carnegiea gigantea*) is the largest cactus; it can grow up to 21 m tall. The stems are ribbed – even in the full sun of a desert in Arizona large areas of the plant are shaded. At the same time the ribs and elastic cuticle allow a rapid increase of the volume after sporadic rainfalls: the stems expand. Loss of water is a major problem for desert plants: the Saguaro is encrusted in a wax layer, but due to ultraviolet (UV) exposure the surfaces age and become wettable. Saguaros can live 150 years or more. **(b)** In contrast, the Giant Arum (*Amorphophallus titanum*) lives in the deepest shadows of the humid rainforest understories in Sumatra. Its flower opens for only one to two days; it reaches a height of three meters and is the largest blossom in the plant kingdom. The giant pleated *petal* (spathe) weights less than one kilogram: the largest lightweight construction amongst plants, possibly even in any organism. The riblets serve as mechanical stabilizers: when the spathe opens its surface is hydrophobic to shed rain droplets. Very unusual wax crystals occur on the unpleasant-smelling central column, which heats periodically to almost 40 °C to generate a convection flow to attract insects

of the giants in the plant kingdom; the Saguaro cactus (Fig. 36.1a) and the Titan Arum (Fig. 36.1b). On the other hand, the details of structures like wax crystals on their surface (Fig. 36.4h and Fig. 36.7) are only revealed by scanning electron microscopes.

Pollen and spores exhibit particularly refined hierarchical structures; they are distinct from all other plant surfaces like leaves. The functional properties of pollen (e.g., the pollen of *Cucurbita pepo*, Fig. 36.2a) are associated with the attachment and detachment to the pollinating insect and the stigma of the flower, and possibly temperature control under insolation. Pollen are hydrophilic, and spores are occasionally superhydrophobic, even bacterial spores. Wind-dispersed miniature *dust seeds* (e.g., the seeds of *Aeginetia* and *Triphora*, Fig. 36.3) are dispersed by air and possess a surface roughness to increase their Reynolds number for long-distance dispersal. Pollen and spores are not discussed in this chapter: palynology is a very specialized field and a vast literature exists (e.g., [36.3, 4]). Internal *noncuticular* surfaces (Fig. 36.2) like pollen or conducting vessels are also not considered in the following sections; they are multifunctional and differ very much from *outer* cuticular surfaces of plants. Strangely enough biomimetics has little interest in this particular subject, although applications are plausible.

The diversity of plant surface structures arises from the variability of cell shapes, and hierarchically superimposed micro- and nanostructures of the cell surfaces (mainly wax crystals), and by the formation of multicellular structures (Fig. 36.4) [36.2, 5, 6]. Based on these cellular and subcellular units a nearly unlimited

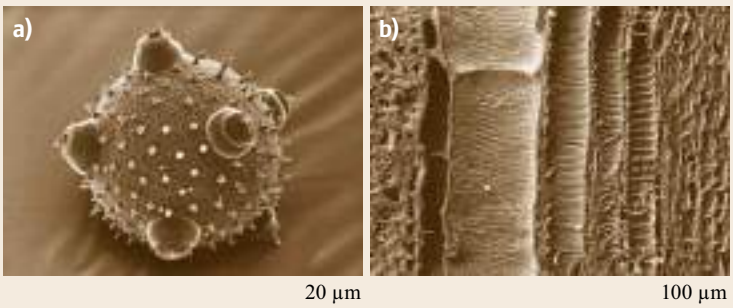

Fig. 36.2a,b Internal (*noncuticular*) functional surfaces are usually hydrophilic – two examples from a squash or pumpkin (*Cucurbita pepo*) are illustrated. **(a)** Pollen grain. Its surface functions are connected with attachment and detachment to the pollinating insect and the stigma of the pumpkin flower, and possibly temperature control under insolation. In wind-dispersed pollen these structures might also increase the Reynolds numbers. **(b)** A vessel-element of the same plant exhibiting complex spiral and perforated structures to transport water within the plant. The structural elements of internal surfaces fundamentally differ from the outer cuticular surfaces (compare e.g., Figs. 36.3, 36.7, 36.14, 36.15)

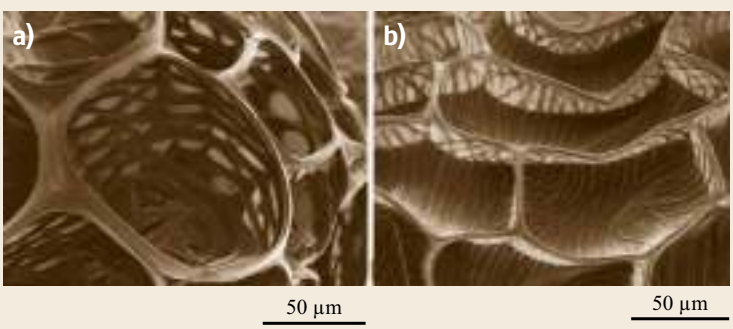

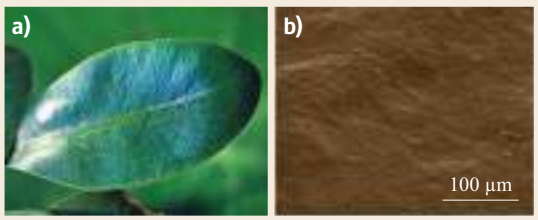

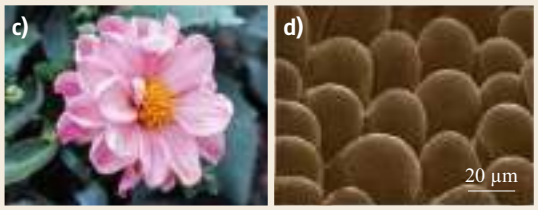

Fig. 36.3a,b SEM micrographs of two seed surfaces with concave cell sculpturing. The miniature seeds of both species **(a)** *Aeginetia indica* and **(b)** *Triphora triantophora* are optimized for seed dispersal by wind. They are hydrophobic and float for a short time in water (compare *Aeginetia* in Fig. 36.27): the concave sculpture of the nonliving cells can be interpreted as a shrinkage deformation during seed maturing and drying. The bands that form an inner network in **(a)** and the surface pattern in **(b)** are built by cellulose. All these features are lightweight constructions and generate high Reynolds numbers to prolong the floating time

Iridescent leaf of *Elaphoglossum wurdackii* with a smooth surface

Velvety leaves of a *Dahlia flower* with convex, structured cells

Hairy leaves of *Leucadendron argenteum* with straight hairs

Waxy leaves of *Eucalyptus macrocarpa* with wax threads

Fig. 36.4a–h Macroscopic optical appearance of plant surfaces and their surface microstructures. In **(a)** the leaves of *Elaphoglossum wurdackii* appear glossy because of a flat surface structure, shown in figure **(b)**. Their iridescence is caused by thin layers within the cuticle. In **(c)** the flower petals of *Dahlia* appear velvety due to the convex microstructure of the epidermis cells, shown in **(d)**. In **(e)** the silvery appearance of the *Leucadendron argenteum* leaves is caused by a dense layer of light-reflecting hairs **(f)**. In **(g)** the leaf and flower bud surfaces of *Eucalyptus macrocarpa* appear white or bluish, caused by a dense covering of thread-like wax crystals **(h)**

combination of structures leads to a high structural and functional diversity of the surfaces of the some 450 000 different species of land plants [36.1]. Superhydrophobicity is one of the most remarkable features of many plant surfaces; most families of higher plants [36.1, 7] include many species where the entirety or part (e.g., only lower side of the leaves) of the assimilating leaf surface is superhydrophobic. Grasses (Fig. 36.5a,b) with a few exceptions (e.g., maize), are superhydrophobic and are, with around 12 000 species, one of the largest plant families that dominates the largest ecosystems of our globe. As is the case in many plants, often only the young leaves are superhydrophobic (Fig. 36.5b), older ones may become wettable: superhydrophobicity is often an instable state in plant surfaces (compare also the Saguaro, Fig. 36.1a) – as is also seen in technical surfaces. Some grasses (like *Elymus arenarius* with a static contact angle of 161°) exhibit similar properties to lotus leaves [36.8]. One square meter of a meadow may exhibit a minimum of four square meters of leaf surfaces (compare e.g., [36.9]). According to UN Food and Agriculture Organization (FAO) assessments [36.10], grasslands (e.g., steppes, savannas, wheat and rice fields) cover some 52.5 million km^2. A rough calculation indicates that at least 250 million km^2 (with other plant families included, possibly much more) are superhydrophobic: this means more than half of the total surface area of our whole planet. In actuality, the dimensions are probably considerably higher and might equal the total surface of our planet.

There is a basic and obvious difference in surface structure and function between aquatic and terrestrial plants. In terrestrial (vascular) plants an epidermis is present, as the specialized outermost cell layer with a cuticle of the primary tissues of all leaves and several other organs plays an important role in environmental interactions and surface structuring. A simplified model presented in Fig. 36.6 shows a layered stratification of the outermost part of epidermis cells. Starting with the outside, one finds a highly functional thin outermost layer; the polymer cuticle with its superimposed waxes. This outermost layer covers nearly all aerial tissues of land-living plants as a continuous extracellular membrane, but is absent in roots. One of the most important attributes of the cuticle is its function as a transpiration barrier, which enables plants to overcome the physical and physiological problems connected to an ambient environment, such as desiccation.

The cuticle is basically a biopolymer made of a polyester called cutin, impregnated with integrated (intracuticular) waxes. Additionally, waxes on the cuticle surface (epicuticular waxes) play an important role in surface structuring at the subcellular scale. They occur in different morphologies, show a large variability in their chemistry and are able to self-assemble into three-dimensional crystals. Intracuticular waxes function as the main transport barrier to reduce the loss of water and small molecules such as ions from inside of the cell, and also for reducing the uptake of liquids and molecules from the outside. Epicuticular waxes form the boundary layer for many interactions with the plant's environment, like wettability or spectral

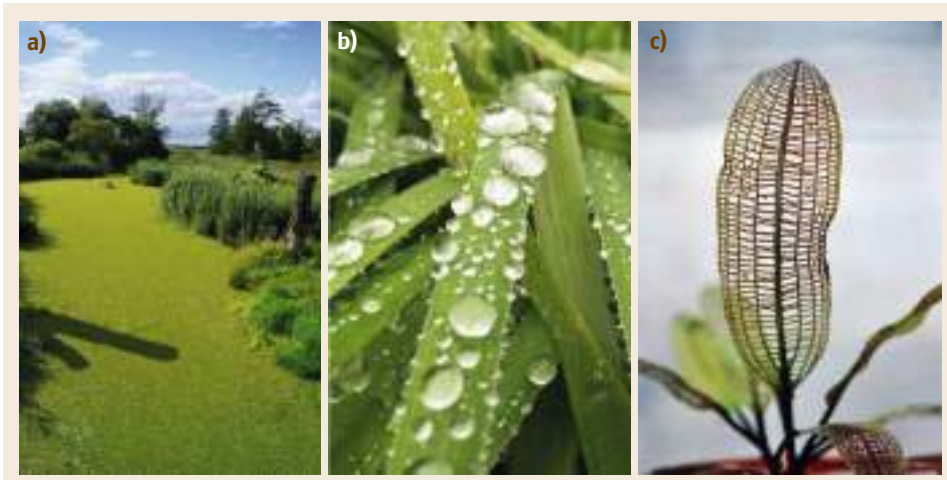

Fig. 36.5a–c Plant surfaces exposed to the air are very often superhydrophobic. Like the leaves **(a)** of the reed (*Phragmites autralis*) and the grassland in the background, or the surfaces of the floating fern (*Salvinia natans*) in the foreground-left in the Oder national park, Germany. Dew droplets in the early morning roll off of the superhydrophobic grass leaves **(b)**. Since grasslands alone form the largest terrestrial ecosystems (around 52.5 million km^2) of our planet we estimate there are at least about 250 million km^2 of superhydrophobic leaf surfaces, which equal about 50% of the Earth's total surface. But all plant roots are superhydrophilic – like the surfaces of water plants, illustrated in **(c)**: the Madagascar Laceleaf (*Aponogeton madagascariensis*) additionally exhibits a grid of a lattice-like network to reduce the flow resistance. Source: **(a)** kindly provided by Pierre Ibisch

reflection (Sect. 36.6). The next layer (Fig. 36.6) is the pectin layer. It connects the cuticle to the much thicker underlying cellulose wall, which is built by single cellulose fibrils. Pectin is not always formed as a layer, but in some species, especially during the early ontogeny of the cuticle, a layered structure has been shown by transmission electron microscopy (TEM). Additionally polysaccharides, not shown in this schematic, are integrated into the cellulose wall. The last layer shown is the plasma membrane, which separates the living, water-containing compartment cell from the outer nonliving part of the epidermis.

We focus on *superhydrophobic* and *superhydrophilic* surfaces, which are of particular importance for biomimetic applications (e.g., self-cleaning: lotus effect). *Superhydrophilicity* means that a droplet imposed on a surface *spreads* instantly and a contact angle cannot even be measured, e.g., in the leaves of *Ruellia* [36.11]. In contrast, on a *superhydrophobic* surface water remains as an almost globular droplet with a contact angle of more than 150°. The SEM micrographs presented were largely taken from our archive of almost 220 000 SEM micrographs at the University of Bonn, which has been built up as a result of over four decades of research on biological surfaces (compare [36.1]) by the first author and his collaborators.

Biomimetics and bionics (which we consider here as synonymous) are surmised to be modern scientific

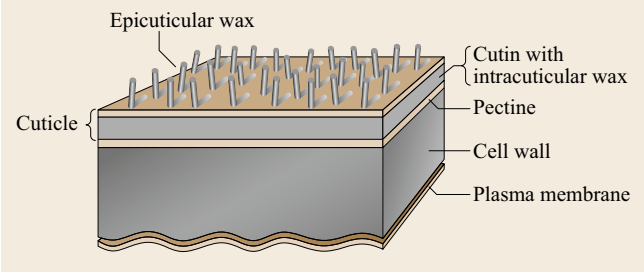

Fig. 36.6 A simplified model of the stratification of the outermost layers of a plant epidermal cell. The schematic shows the outermost wax layer in its most common form, as a composite of three-dimensional waxes with an underlying wax film. Below this layer is the cuticula, made of a cutin network and integrated waxes. The cuticula is connected with the underlying cellulose wall by a pectin layer. Below the cell wall, the plasma membrane is shown. This membrane separates the water-containing living part of the cells from the outermost nonliving outer cell wall and cuticle, as shown in the schematic

fields; despite the evidence that inspiration from living organisms is as old as mankind. The magnificent 17 000-year-old paleolithic paintings in the caves of Lasceaux are bio-inspired – like the Cadillac tail fins in the 1960s. Bio-inspiration in the sense of nonfunctional *biodecoration* is an inspiration for art and design into modern times [36.12, 13]. Early attempts to copy

mechanical functions were not particularly successful – Ovid's story of Daedalus and Icarus and Leonardo da Vinci's design of flying machines and other devices did not translate into technical success stories.

Historically, the dream of flying and the use of the strange phenomena *electricity* were the two fundamental forces for the foundation of what we call today *bionics* or *biomimetics*. The construction of an electric battery based on observations of the *Torpedo* fish (today we call it Electric Ray) by Allessandro Volta in 1800 was the first milestone [36.12] of bionics. And Icarus' dream was realized with the first well-documented, repeated, and successful flights by Otto Lilienthal from 1894 onwards; his design was based on his analysis of the flight of birds. The term *Biotechnik* (usually abbreviated in German as *Bionik*) for the new field was coined by *Raul Francé* in 1920 [36.14] and finally rediscovered under the influence of cybernetics under the names *bionics* [36.15] and *biomimetics* between 1960 and 1964; the misleading term *biomimicry* arose in 1982 (for a historical survey see [36.12]). Surfaces came surprisingly late into the focus of bionics. The Swiss engineer George de Mestral observed in 1941 the way that the burrs (*Arctium*) clung to his trousers and his dog, and, in 1958, he developed the bionic *hook and loop* fastener under the trade mark Velcro®. Starting with the discovery of hierarchically structured superhydrophobic lotus surfaces [36.2, 16, 17] and the drag-reducing shark skin [36.18, 19], biomimetic surface technologies (e.g., lotus-, shark-, gecko-, moth eye-, and Salvinia-effect) became a most important field [36.1, 7, 20, 21]. The publication of the *lotus effect* in 1997 [36.16] led to a change of paradigms in surface technologies and to an astonishing number of publications and the popularization of the term superhydrophobicity [36.1].

It is inevitable that the estimated 250 million km^2 of superhydrophobic surfaces were noticed in the early history of mankind. The remarkable abilities of self-cleaning lotus leaves are mentioned as early as the second century B.C. in the Sanskrit text of the Bhagavad Gita (e.g., book 5,10) and in Chinese poems. Even the name *lotus* (Greek λωτός) may refer to the Greek and Latin word elements for *washed*. In the first century A.D., Pliny the Elder introduces his remarkable *Naturalis Historia* with the modern statement *the world is a perfect globe* and later compares this phenomena with droplets: *everywhere one finds ... droplets forming ... perfect ... globes ... on dust or on hairy leaves ...*, thus anticipating hierarchical structuring as a precondition for superhydrophobicity. *J.W. von Goethe* (1820) [36.22] is more precise: *Raindrops remain on certain leaves as perfect spheres, which we attribute to an exsudated being ...* and continues in the same context: *The surfaces of a ripe plum ... appears blue*. This is an almost concise description of superhydrophobicity and the scattering and reflection of light caused by hierarchically structured epicuticular waxes, which in former times were called *exsudates*. Superhydrophobicity is so obvious that names of many plants refer to it: Pliny refers extensively to the superhydrophobic fern *Adiantum* (Greek: *not wetting*) with a contact angle larger than 160°. On the leaves of the well-known Lady's mantle (*Alchemilla*) dew droplets are preserved as perfect globes, which led to intense research by scientists today [36.23], but usually it is overlooked that the scientific name *Alchemilla* refers to the power attributed to droplets in medieval *Alchemia* (al-kimiya, alchemy). Even the vernacular names in most languages (*Lady´s mantle*, *Frauenmantel*, *manteau de notre Dame*) for *Alchemilla* refer to these protective superrepellent properties.

Biological role models provide an extraordinary diversity for innovative surface technologies, which are described for plants in the following sections primarily under the view of biologists.

36.2 Chemistry of Plant Surfaces

Here we consider only the surfaces of higher or vascular plants (Tracheophyta). Primary aquatic plants (from unicellular algae to seaweeds, see Sect. 36.8) lack a cuticle and have widely differing superhydrophilic surfaces. For biomimetic applications vascular plants are most important. In land or vascular plants waxes, from monomolecular layers to thick crusts or three-dimensional (3-D) crystals, form the boundary layer of the surface (Fig. 36.7). They are sometimes visible as a white or bluish coloration of leaves and fruits, as in wheat, cabbage, grapes, or plums. These colorations are caused by reflection of parts of the visible light spectrum by a dense coverage of 3-D wax structures. The fan palm *Copernicia prunifera*, the natural source of carnauba wax, has massive crusts of epicuticular wax, weighing several mg cm^{-2}. Carnauba wax is commercially used, e.g., for car and furniture polishes, medical products and candy. Even when there is not a bluish coloration visible, three-dimensional waxes are often present. In plants, three-dimensional waxes are responsible for several surface functions. Waxes are not only an essential part of the plant cuticle, but can also be found in fungi, lichens and animals. Waxes occur as filling material within the basic cutin network (intra-

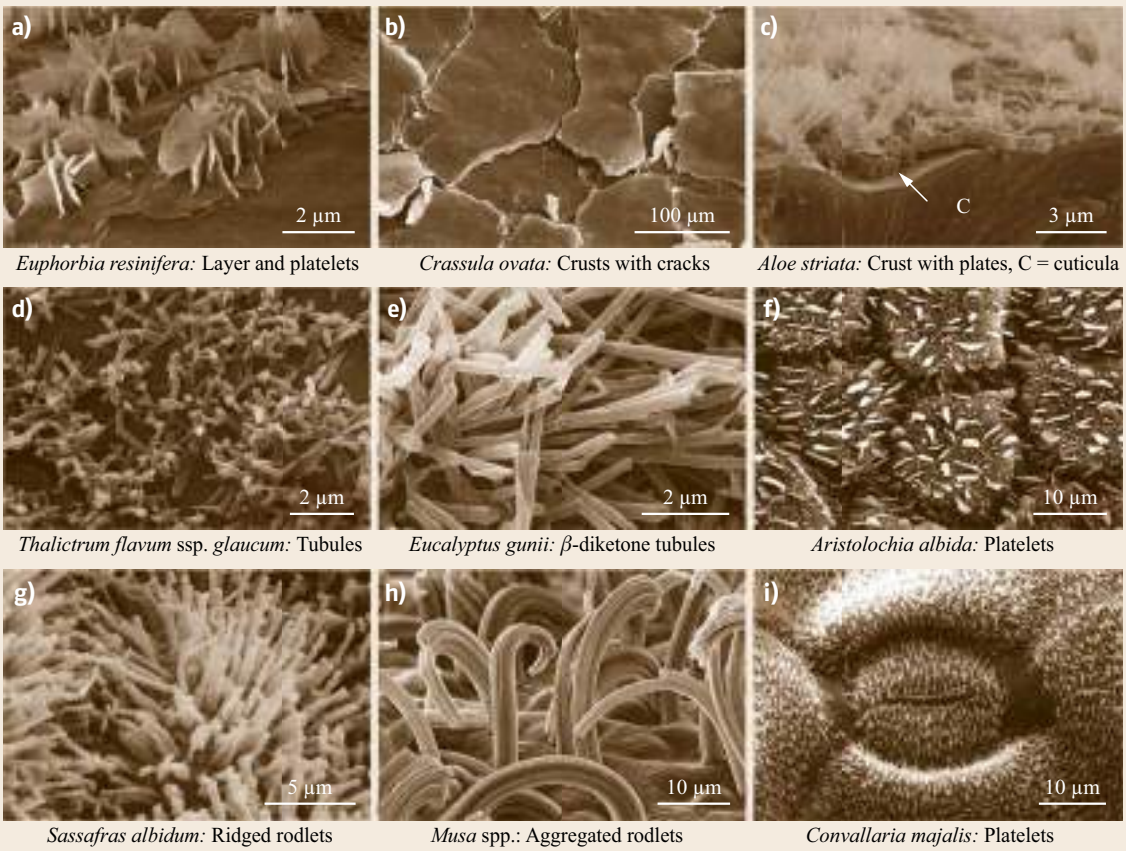

Fig. 36.7a–i SEM micrographs of epicuticular waxes. In **(a)** waxes on a leaf of *Euphorbia resinifera* have been partially removed to show the composite structure of a basal wax layer with three-dimensional wax platelets on it. In **(b)** a wax crust with fissures on a leaf of *Crassula ovata* is shown. A cross-section through the periclinal wall of *Aloe striata* in **(c)** shows the cuticle (indicated by C) and a wax layer (indicated by an *arrow*) with wax platelets on top. In **(d)** nonacosan-ol tubules on *Thalictrum flavum* spp. *glaucum* leaves and in **(e)** β-diketone wax tubules on *Eucalyptus gunnii* leaves are shown. In **(f)** wax platelets on *Aristolochis albida* leaf and in **(g)** transversely ridged rodlets on a leaf of *Sassafras albidum* are shown. In **(h)** longitudinally aggregated wax threads form large aggregated rodlets on the lower side of the leaves of *Musa* species (spp.). In *Convallaria majalis* leaves, shown in **(i)**, wax platelets are arranged in a pattern, similar to magnetic field lines, around the stomata. Thin wax films are not visible in SEM, but are present below and between the three-dimensional waxes shown here

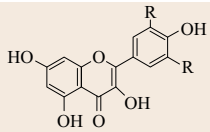
cuticular), but are also found on top of the cuticle (epicuticular). The epicuticular waxes occur in widely differing morphologies, all of which are crystalline and thus self-assembling (Fig. 36.7) (survey in [36.24]). However, waxes of different plants, and also waxes of different parts of a plant, vary in their morphology and chemical composition – they are absent in roots. In general, plant waxes are mixtures of long-chain hydrocarbons and their derivatives, and in some species they also contain cyclic compounds. Because of the strong correlation between the wax crystal morphology and their chemical composition, some waxes, such as the nonacosan-10-ol tubules of the lotus leaves and many other plants, have been named after their main wax constitution [36.25].

36.2.1 Chemical Composition of Wax



The term *wax* is used for a variety of biogenic products that contain fatty materials of various kinds. Well-known examples are beeswax, paraffin and carnauba wax from wax palms (*Copernicia prunifera*). Plant waxes are mixtures of aliphatic hydrocarbons and their derivatives, with carbon chain lengths between 20 and 40, and in the case of esters (two connected chains) about 60 atoms. Several reviews have addressed the

chemical composition of plant waxes [36.26–28]. The chemical composition of plant waxes is highly variable amongst different plant species, or within the organs of one species (e.g., upper or lower side of leaves) and even during organ development [36.29]. The main component classes are primary and secondary alcohols, ketones, fatty acids, and aldehydes. Alkanes are very common in plant waxes, but usually occur in low concentrations. Other compounds are more rarely found in plant waxes, but in those waxes where they occur, they may be the dominant compound. The most common wax compounds and their typical chain lengths are shown in Table 36.1. Examples of commonly found waxes and their major compounds are presented in Table 36.2. For some of those waxes, it has been shown that their dominant compounds crystallize in the same morphology as the complete wax mixture. Examples are the primary alcohols and the β-diketone waxes found on different parts of wheat plants [36.30]. However, an increasing number of publications report the discovery of new wax components and a long list of rare and uncommon ingredients, such as methyl-branched aliphatics [36.31]. Environmental factors, such as temperature or light intensity, influence the quantity of waxes and their chemical composition [36.32–34].

Many or even most plant *waxes* do not match the chemical definition of true waxes and they are usually complex mixtures of differing compounds. For example, triterpenoids are cyclic hydrocarbons, which occur in high concentrations in the epicuticular coatings of grapes (*Vitis vinifera*) [36.32]. Other plant waxes contain polymeric components such as polymerized aldehydes, which are only slightly soluble in chloroform [36.35, 36]. It should be noted that nearly all the existing data of the chemical composition of plant waxes is based on solvent-extracted waxes. These are mixtures of epicuticular and intracuticular waxes, which may be chemically different, as shown for the waxes of *Prunus laurocerasus* by *Jetter* and *Schäffer* [36.29] and by *Wen* et al. [36.37], for *Taxus baccata*. The development of more selective methods of wax sampling allows selective removal of the epicuticular waxes and their analysis separately from the intracuticular wax fractions [36.29, 38].

Epicuticular wax structures usually occur in the size range from 0.2 to 100 µm (Fig. 36.7); thus, the appropriate microscopic techniques for investigation of their morphology are SEM and low pressure- or environmental SEM. Several SEM investigations showed that most of the epicuticular waxes form three-dimensional structures, with great variations of their morphologies. Comprehensive overviews of the terminology and micromorphology of epicuticular waxes are given by *Barthlott* et al. [36.24], *Jeffree* [36.28], and in [36.40]. The comprehensive classification of *Barthlott* et al. [36.24], which we follow here, includes 23 different wax types. It is based on chemical and morphological features and also considers orientation

Table 36.1 The most common chemical compounds in plant waxes and their spectrum of chain length. Further examples of occurrence are given in Table 36.2

1. Aliphatic compounds **1.1 In waxes frequently existing, but mostly as minor compounds**		**Chain length**
Alkanes	CH_3–$(CH_2)n$–CH_3	Odd C_{19}–C_{37}
Primary alcohols[a]	CH_3–$(CH_2)n$–CH_2-OH	Even C_{12}–C_{36}
Esters	CH_3–$(CH2)n$–C0–0–$(CH_2)m$–CH_3	Even C_{30}–C_{60}
Fatty acids	CH_3–$(CH2)n$–COOH	Even C_{12}–C_{36}
Aldehydes	CH_3–$(CH2)n$–CHO	Even C_{14}–C_{34}
1.2 In waxes rarely existing, but if, than as major wax compounds		
Ketones e.g., palmitones	CH_3–$(CH_2)n$–CO–$(CH_2)m$–CH_3	Odd C_{25}–C_{33}
β-Diketones	CH_3–$(CH_2)n$–CO-CH_2-CO-$(CH_2)m$–CH_3	Odd C_{27}–C_{35}
Secondary alcohols (e.g., nonacosan-10-ol)	CH_3–$(CH_2)n$–CH_2OH–$(CH_2)m$–CH_3	Odd C_{21}–C_{33}
2. Cyclic compounds		
Flavonoids	e.g., Quercetin 	
Triterpene	e.g., β-Amyrin	

[a] Primary alcohols are common minor constitutions in waxes, but can occur as major compounds in the wax, e.g., of grasses, eucalypts, clover and other legumes, etc. (after [36.28])

Table 36.2 Common wax types in plant species and their major chemical compounds. With exception of the fruit surface of *Benincasa hispida*, data represent the waxes on the leaves of the species. All references for the chemical data are listed in [36.39] and examples of the wax types listed here are shown in Fig. 36.7

Wax type	Species	Dominating chemical compound(s)
Films	*Hedera helix*	Primary alcohols, aldehydes
Films	*Magnolia grandiflora*	Fatty acids C_{24}–C_{30}, primary alcohols C_{24}-C_{28}
Films	*Prunus laurocerasus*	Alkanes C_{29}, C_{31}
Crust	*Crassula ovata*	Aldehydes C_{30}, C_{32}, alkane C_{31}
Di-ketone tubules	*Eucalyptus globulus*	β-Diketones C_{33}
Di-ketone tubules	*Leymus arenarius*	β-Diketone C_{31}, hydroxy-β-diketone C_{31}
Nonacosanol tubules	*Ginkgo biloba*	Secondary alcohol C_{29}
Nonacosanol tubules	*Nelumbo nucifera*	Secondary alkane-diols C_{29}
Nonacosanol tubules	*Thalictrum flavum* ssp. *glaucum*	Secondary alcohol C_{29}
Nonacosanol tubules	*Tropaeolum majus*	Secondary alcohol C_{29}
Nonacosanol tubules	*Tulipa gesneriana*	Secondary alcohol C_{29}
Platelets	*Convallaria majalis*	Primary alcohol C_{26}, C_{28}, aldehydes
Platelets	*Euphorbia myrsinites*	Primary alcohol C_{26}, aldehydes
Platelets	*Galanthus nivalis*	Primary alcohol C_{26}
Platelets	*Iris germanica*	Primary alcohols C_{26}
Platelets	*Triticum aestivum*	Primary alcohol C_{28}
Transversely ridged rodlets	*Aristolochia tomentosa*	Ketones
Transversely ridged rodlets	*Gypsophila acutifolia*	Alkanes C_{31}
Transversely ridged rodlets	*Liriodendron chinense*	Ketones
Longitudinal ridged rodlets	*Benincasa hispida*	Triterpenol acetates

of single crystals on the surface and the orientation of the waxes to each other (pattern formation). In this classification, the wax morphologies include thin films and several three-dimensional structures such as crusts, platelets, filaments, rods and tubules, which have a hollow center. Morphological subtypes are, for example, entire and nonentire wax platelets. A further subclassification is based on the arrangement of the crystals, e.g., whether they are randomly distributed, in clusters, in parallel orientation, or in specific arrangements around stomata, as in the *Convallaria* type (Fig. 36.7h). The most common wax morphologies are introduced in the following section and shown in Table 36.2.

Probably all terrestrial plant surfaces are covered by thin (in the extreme monomolecular) wax films; the three-dimensional wax crystals appear on underlying wax films as shown in Fig. 36.7a for the waxes of *Euphorbia resinifera* and has been reported for several species [36.24, 41–44]. Wax films are often incorrectly referred to as *amorphous* [36.39]. On several plant surfaces wax films are limited to a few molecular layers that are hardly visible in SEM. By mechanical isolation of the epicuticular 3-D waxes, e.g., freezing in glycerol, the waxes can be removed from the cuticle, and transferred onto a smooth artificial substrate for microscopic investigations [36.38]. With this method, the remnants of the wax film can be detected, and the film thicknesses can be determined. Wax film formation has been investigated on a living plant surface by atomic force microscopy (AFM, Fig. 36.8) [36.43, 45]. Such investigations show that wax films are composed of several monomolecular layers, with thicknesses up to several hundred nanometers. In the following, these relatively thin wax films ($< 0.5\,\mu m$) are called two-dimensional (2-D) waxes, and the thicker wax layers ($0.5-1\,\mu m$)

Fig. 36.8 AFM experimental setup for long-term investigations of wax crystallization on a living plant surface. The tip of the leaf of a snowdrop (*Galanthus nivalis)* has been fixed on the specimen holder with a drop of two-compound glue. Existing waxes have been removed and the rebuilding (self-healing) of the wax was studied over several hours. Appropriate scan conditions for living plant surfaces are given in the text, and the method of wax removal is described in detail in [36.43]

and wax crusts (> 1 μm) are called three-dimensional (3-D) waxes. Wax crusts are often found in succulent plants, as on the leaves of *Crassula ovata*, shown in Fig. 36.7b. Such a multilayered assembly of waxes is detectable by a cross-section through the epidermis, as shown in Fig. 36.7c for *Aloe striata*.

Three-dimensional waxes occur in different morphologies. Most common are tubules, platelets, rodlets and longitudinally aggregated rodlets shown in Fig. 36.7d–i.

Wax tubules are hollow structures, which can be distinguished chemically and morphologically. The first type, called nonacosanol tubules, contains large amounts of asymmetrical secondary alcohols, predominantly nonacosan-10-ol and its homologues and to a certain degree also asymmetrical diols [36.25, 46, 47]. Nonacosan-10-ol is the most common *waxy* coating of all major vascular plant groups and was evolved with the conquest of land some 450 million years ago (a phylogenetic tree is provided by [36.1]). The nonacosanol tubules are usually 0.3−1.1 μm long and 0.1−0.2 μm wide. The second type of tubules contains high amounts of β-diketones, such as hentriacontan-14,16-dione [36.48]. This particular kind of wax tubule is characteristic for many grasses (Poaceae) but also occurs in various other groups [36.49]. Fig. 36.7e shows that the β-diketone tubules are two to five times longer than the nonacosanol tubules shown in Fig. 36.7d. Their length reaches from 2 to 5 μm, and diameters vary between 0.2 and 0.3 μm.

Platelets, as shown in Fig. 36.7f, are very common wax structures found in all major groups of plants. Following the terminology of *Barthlott* et al. [36.24], waxes are termed platelets when flat crystals are connected with their narrow side to the surface. Platelets can be further differentiated by their outline into, e.g., entire or undulated ones. Platelets vary considerably in shape, chemical composition and spatial pattern. For platelets, only limited information about the connection between morphology and chemical composition is available. In some species, wax platelets are dominated by high amounts of a single chemical compound, which can be primary alcohols, alkanes, aldehydes, esters, secondary alcohols or flavonoids [36.28]. In contrast to platelets, plates are polygonal crystalloids with distinct edges and are attached to the surface at varying angles.

The morphology of three-dimensional wax structures is not necessarily determined by the dominating chemical compound or compound class. One example of wax crystals determined by a minor component of a complex mixture is the transversely ridged rodlets, shown in Fig. 36.7g, which contain high amounts of hentriacontan-16-one (palmitone) [36.50]. Wax rodlets are massive sculptures that are irregular, polygonal, triangular or circular in their cross-sections. They have a distinct longitudinal axis, with a length : width ratio usually not exceeding 50 : 1. In addition, rodlets may have a variable diameter along the length of their axis. More complex structures are the longitudinally ridged rodlets, such as those found on banana leaves (*Musa* species), shown in Fig. 36.7h. These waxes consist exclusively of aliphatic compounds, with high amounts of wax esters and less of hydrocarbons, aldehydes, primary alcohols, and fatty acids. The origin of these wax aggregates is still not clear, and so far all attempts to recrystallize these wax types have failed. As a consequence of that, it is assumed that their origin is connected to structural properties of the underlying plant cuticle.

Brassica oleracea is known to have a very complex wax crystal morphology: several cultivars form several different wax types, and several different wax morphologies can occur on the same cell surface [36.32]. Why the different three-dimensional wax morphologies coexist on the surface of a single cell is unknown, as is whether these different morphologies are built up by phase separation of different compounds or if they are formed by the same compound.

The last example in Fig. 36.7i represents plant surfaces on which waxes are arranged in a specific pattern. Examples are parallel rows of longitudinally aligned platelets, with the orientation extending over several cells (e.g., in *Convallaria majalis*, Fig. 36.7i), or rosettes, in which the arrangements of platelets is more or less in radially assembled clusters. In particular, the parallel orientation of platelets on the leaves of several plant species leads to the question of how the orientation is controlled by the plant. It is assumed that the cutin network functions as a template for the growth of the three-dimensional wax crystals, but there is still a lack of information about the molecular structure of the cuticle, so this question is still unanswered.

Certain surface wax morphologies and their orientation patterns are characteristic for certain groups of plants; thus, patterns and the morphology of plant waxes have been used in plant systematics. *Barthlott* et al. [36.49] provide an overview of the existence of the most important wax types in plants, based on SEM analysis of at least 13 000 species, representing all major groups of vascular plants.

36.2.2 Chemical Heterogeneities

Surfaces of a particular plant species may exhibit chemical heterogeneities in the classical sense; the best example are the superhydrophilic pinning anchor cells on top of each superhydrophobic trichome of *Salvinia molesta* (Fig. 36.28): In a broader sense, all organism

have chemically heterogeneous surfaces: root surfaces differ dramatically from leaf surfaces. And within one leaf the upper side differs from the underside. In leaves of *Quercus robur*, contact angles range from 30° to 130° depending on the part of the leaf where wettability was determined [36.8].

The aquatic watermilfoil *Myriophyllum brasiliense* is – like all submersed water plants – superhydrophilic, so a contact angle of the leaves cannot be determined. However, as soon a flowering shoot approaches the water level wax crystals are generated and the new leaves outside of the water exhibit a contact angle of 162° like in a lotus leaf [36.8].

36.2.3 Crystallinity

All aliphatic plant surface waxes have a crystalline order. The classical definition for crystals implies a periodic structure in three dimensions, but with the increasing importance of liquid crystals and the detection of quasicrystals it has become necessary to extend the definition, so that certain less periodic and helical structures, as found for some waxes, were included [36.51].

The crystal structure of the epicuticular waxes can be examined by electron diffraction (ED), nuclear mass resonance (NMR) spectroscopy and x-ray powder diffraction (XRD). Electron diffraction with the transmission electron microscope provides the structure information of single wax crystals of less than 1 µm size, as shown in Fig. 36.9a,b, for a single wax platelet. However, even with a low-intensity imaging system, the crystal structure is rapidly destroyed by the electron beam intensity. Therefore, XRD is useful for determining the crystal symmetry, as well as providing information about different types of disorder. Very thin mono- or bimolecular layers of waxes, as shown in Fig. 36.9c,d, are of course not periodic in three dimensions, but form two-dimensional crystals at the molecular level. As mentioned before, in addition the planar wax structures, such as films and platelets, many natural plant waxes develop irregular three-dimensional morphologies, or structures such as threads and tubules with a large extension in one direction. These morphologically different waxes were found to occur in three different crystal structures. The majority of waxes exhibit an orthorhombic structure, which is most common for pure aliphatic compounds. Tubules containing mainly secondary alcohols show diffraction reflections of a triclinic phase, with a relatively large disorder, and β-diketone tubules show a hexagonal structure [36.39].

Self-assembly of waxes is an inherent result of the crystalline nature. That different wax morphologies on plant surfaces originate by self-assembly of the wax molecules has been shown by the recrystallization of waxes, which were isolated from plant surfaces [36.30, 43, 47, 52–54]. In these studies, most waxes recrystallized in their original morphology, as found on the plant surfaces.

Self-assembly processes resulting in nano- and microstructures are found in nature, as well as in engineering. They are the basis for highly efficient ways of structuring surfaces down to the molecular level. Self-assembly is a general process of structuring in which atoms, molecules, particles or other building units interact and self-organize to form well-defined structures. The processes of self-assembly in molecular systems are determined by five characteristics: the components, interactions, reversibility, environment and mass transport with agitation [36.55]. The most important driving forces are weak and noncovalent in-

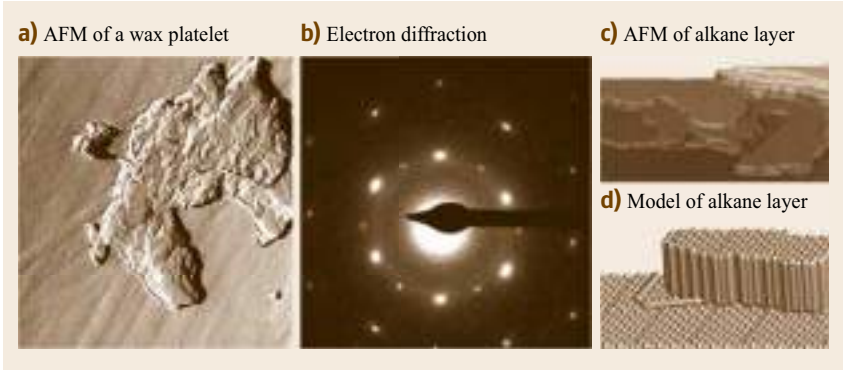


Fig. 36.9a–d The layered and crystalline structure of alkane waxes is demonstrated by an AFM map of a single wax platelet **(a)** and the corresponding electron diffraction pattern, shown in **(b)**. In **(a)** the steps visible on the crystal surface are caused by a perpendicular orientation of the molecules. Such steps can be monomolecular e.g., for alkanes, or in some waxes bilayers are formed by polar molecules of primary alcohols. The AFM map of recrystallized alkanes **(c)** and the model shown in **(d)** demonstrate the layered orthorhombic wax structure

termolecular interactions, such as Van der Waals and Coulomb interactions, hydrophobic interactions and hydrogen bonds. During self-assembly, their interactions start from a less-ordered state, e.g., dissolved waxes in a solution, to a final more-ordered state, i. e., a crystal [36.56, 57]. Environmental factors such as temperature, solvent and substrate might influence the self-assembly process, and in the case of waxes, their morphology.

The most suitable microscopy technique for studying the self-assembly process of waxes under environmental conditions is atomic force microscopy (AFM) because it combines sufficient resolving power to image nanostructures with the ability to work at STP (standard temperature and pressure) with living plant material (Fig. 36.8). Self-assembly of waxes has been studied directly on plant surfaces, as well as the recrystallization of waxes and single wax compounds on artificial surfaces. However, AFM is not suitable for all plant surfaces. Within a leaf surface large structures such as hairs with dimensions of several tens of micrometers can emerge out of the epidermis and pose a barrier against the surface scanning probe. Additionally, high-aspect-ratio structures caused by cell surface structures might cause artifacts in the resulting images. Species with smooth or slightly convex cell-surface sculptures are most appropriate for AFM investigations. The process of wax regeneration occurs over several hours; thus the loss of water from inside the plant has to be minimized to reduce the specimen drift by material shrinking during investigation. This precondition limits the range of specimens for AFMs with a small specimen chamber, because the sizes and shapes of the leaves must allow them to be mounted in the AFM without cutting them. An experimental setup where the complete plant is placed close to the AFM and a leaf is fixed on the AFM specimen holder is shown in Fig. 36.8. The leaf was fixed at its lower side to the specimen holder with a drop of a two-compound glue, and waxes on the upper leaf side were removed by embedding them into a drop of water-soluble glue. After hardening, the glue and the embedded waxes were removed from the leaf surface and the process of wax regeneration was studied. Temperature increase in long-term investigations, caused by the laser beam on top of the cantilever, induces expansion of the water in the leaf, resulting in a drift of the specimen. To minimize this, reflective cantilevers must be used, and the laser beam intensity should be reduced by integrating an attenuation filter above the cantilever [36.43]. However, the waxes themselves are fragile; thus appropriate scan conditions at scan sizes of 3–20 µm are tapping mode and scan rates of 0.7–2 Hz, encompassing 256 lines per image and a set point near the upper limit to minimize the interaction between tip and sample. Figure 36.10 shows the regeneration of a wax film on a leaf of snowdrop (*Galanthus nivalis*) by formation of a multilayered wax film and the growth of three-dimensional wax platelets. This and further investigations show that the growth of the three-dimensional wax crystals occurs by apical ac-

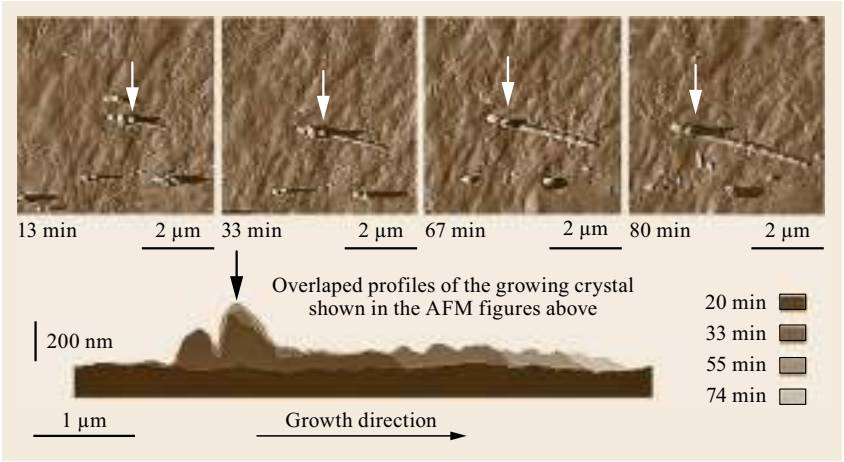

Fig. 36.10 AFM maps and a series of profile lines, taken from repeated scans during the crystal growth on a leaf of snowdrop (*Galanthus nivalis*). The first AFM map represents the wax regeneration within 13 min; the last map was taken after 80 min after wax removal. The *white arrows* mark the same position of the crystal as the *black arrow* marks in the profile figure. In the profile lines below the maps, outlines of the growing crystal have been overlapped to demonstrate that the extension is occurring at the distal end of the growing crystal and that at this time the growth in height is limited to a few nanometers. Outlines have been taken from four AFM scans: 20, 33, 55 and 74 min after the wax regeneration process began. The experimental setup is shown in Fig. 36.8

cumulation of new wax molecules on only one side of the crystal. The regeneration of the wax film results in a multilayered crystalline coverage on the plant cuticle. The time needed to regenerate waxes shows large variations depending on the species, with some species never regenerating the wax that was removed. In these plants, wax synthesis seems to be inactive when leaves are mature [36.58].

Alternatively, self-assembly of plant waxes can be studied by recrystallization of the waxes on artificial substrates (Fig. 36.11). Based on those studies, the formation of wax tubules and platelets has been described in detail. Wax platelets, characteristic for wheat leaves (*Triticum aestivum*), are constructed from the primary alcohol octacosan-1-ol [36.30]. Crystallization of the wax mixture isolated from the leaves and of pure octacosan-1-ol on different artificial substrates showed a substrate-dependent growth. On a nonpolar, crystalline substrate (highly ordered pyrolytic graphite, HOPG) platelets grow with a vertical orientation to the substrates, whereas on a polar surface, such as mica, crystals grow horizontally to the substrate surface. On amorphous polar glass only amorphous wax layers grow. This substrate dependence demonstrates epitaxial control of crystal growth depending on the orientation and order of the first layers of molecules adhering on the substrate surface. Octacosan-1-ol forms ordered bilayer structures on the substrate. In these, the first layers of molecules lie flat on nonpolar substrates, but stand upright (perpendicular) on crystalline polar surfaces. The grown platelet morphology results from an anisotropic crystal growth, caused by a faster parallel assembly of the molecules at the length side of already-existing molecules than at the ends of the molecules [36.59]. AFM micrographs in Fig. 36.12 and schematics of the molecule orientation demonstrate the differences of growth on polar and nonpolar substrates for octacosan-1-ol molecules. In both cases, flat crystals with different orientation grow. Crystals grown horizontal to the substrate surface are called plates (Fig. 36.12a,b) and those grown perpendicular to the substrate surface are termed platelets (Fig. 36.12c,d). The substrates on which the crystals grow influence the crystal morphology and their orientation. This fact can be used to create different kinds of nano- and micropatterns on technical surfaces [36.30, 54, 60, 61]. In summary, substrates can have a direct influence on the self-assembly processes of wax crystals, and can function as a template on the molecular level. In this case, the substrate organizes the assembly of the molecules in a specific spatial arrangement [36.62, 63]. Such a template effect was reported for wax platelets formed by primary alcohols [36.30]. On HOPG substrate, the spatial pattern of the re-

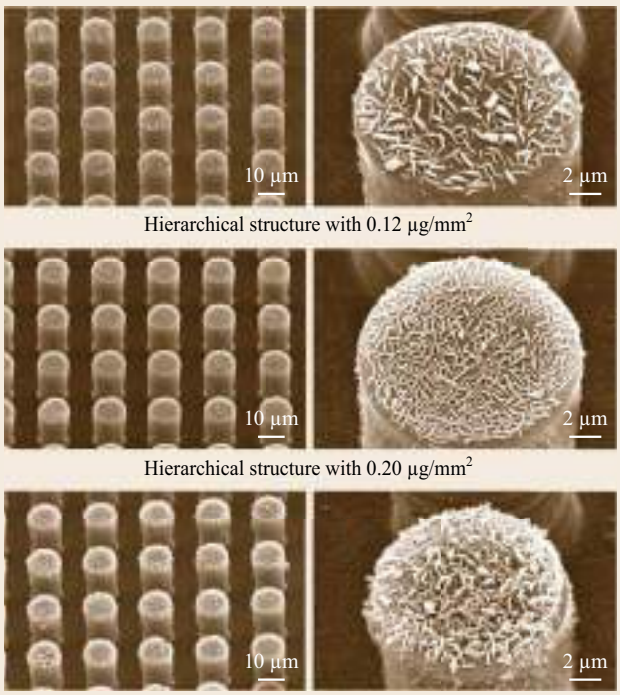

Fig. 36.11 Biomimetic superhydrophobic hierarchical structured technical surfaces. The silicon replica with pillars of 14 µm in diameter and 30 µm in height with 23 µm pitch is covered by self-assembled alkanes (hexatriacontane). From *top to bottom* an increase in crystal density is shown. Highest water repellence and lowest hysteresis has been found for the structures given in the *middle line*, where 20 µg cm^{-2} hexatriacontane was applied on the surfaces. These surfaces have been used for detailed study of wetting and adhesion (after [36.61])

assembled wax platelets strictly followed the hexagonal symmetry of the crystalline substrate. However, the cutin matrix of the cuticle, which acts as a substrate in plant surfaces, is assumed to be amorphous, and an epitaxial growth on an amorphous substrate seems paradoxical.

An example of wax crystals composed of more than one compound are the transversely ridged rodlets. These waxes can be recrystallized from the total wax mixture, but not from individual compounds such as alkanes or palmitones. For these waxes, it is assumed that their morphology is also formed by a self-assembly-based crystallization process, but the presence of minor amounts of other compounds is required as an additive for crystal growth [36.50].

The origin of wax tubules, shown schematically in Fig. 36.13a and in SEM micrographs in Fig. 36.13b, has been debated for a long time. Several observa-

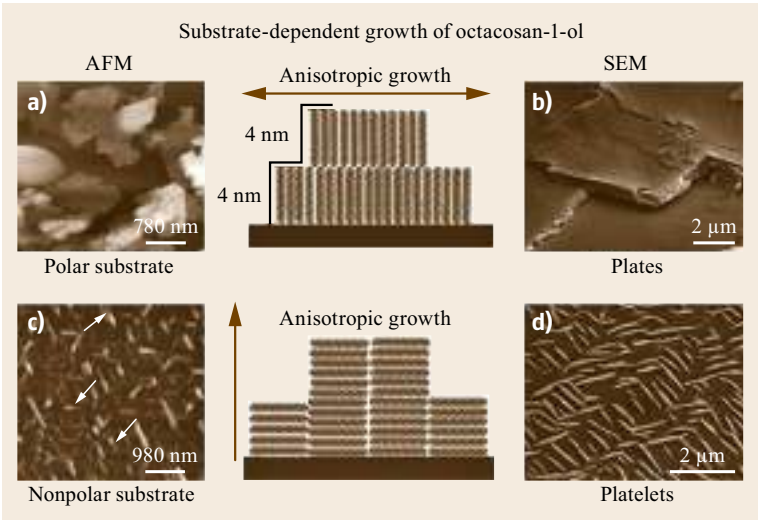

Fig. 36.12a–d AFM maps and schematics of the molecular orientation demonstrate the differences of growth on polar and nonpolar substrates for octacosan-1-ol molecules. AFM figures **(a,c)** show growing crystals, whereas the SEM figures **(b,d)** show the final crystal morphology. On both substrates flat crystals with different orientations were grown. Crystals grown parallel to the substrate surface, as shown in **(a,b)**, are called plates; crystals grown perpendicular to the substrate surface are called platelets **(c,d)**. The principle of anisotropic crystal growth is shown schematically for both preferred growth directions and described in the text

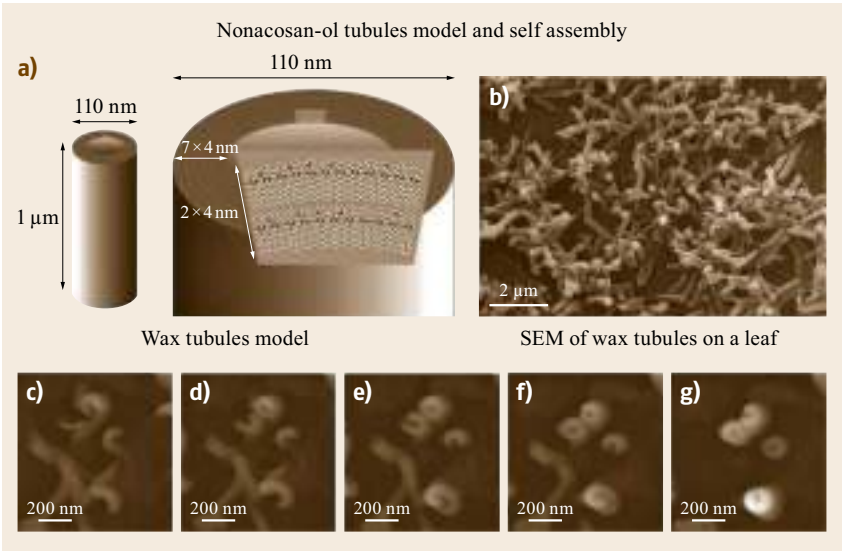

Fig. 36.13a–g A model and SEM micrograph of the molecular order of nonacosan-10-ol tubules and AFM analysis of their self-assembly. Based on SEM characterization, chemical analysis, single-compound crystallization and crystallographic data, a model of the nonacosanol tubules has been developed **(a)**. Original nonacosan-10-ol tubules are shown in the SEM micrograph **(b)** for *Thalictrum flavum* ssp. *glaucum* leaves. Consecutive AFM figures of tubule formation (nonacosan-10-ol wax from *Tropaeolum majus*) were made after applying a wax solution on HOPG. After 65 min the waxes mainly formed curved rodlets, which were arranged horizontal to the substrate **(c)**. The same area of the HOPG substrate shows that waxes start to form circles **(d–f)** and after 223 min the rodlets initially observed were dissolved and short tubules were formed **(g)**

tions, such as spiral lines on the surfaces of some nonacosanol tubules [36.53], led to the assumption that tubules arise from a twisting or folding of a platelet-like precursor form. Recrystallization experiments with nonacosan-10-ol waxes showed that these tubules grow perpendicular to the substrate surface when recrystallized on HOPG. This vertical orientation of the tubules allows a detailed study of the growth process by AFM and showed that the building of nonacosan-10-ol tubules from lotus (*Nelumbo nucifera*) and nasturtium (*Tropaeolum majus*) leaves is based on a continuous growth of a small circular precursor structure by supplementation of the wax on top of it [36.54]. The AFM micrographs shown in Fig. 36.13c–g, are con-

secutive AFM images of growing tubules, made during the tubule formation process. The terminal ends of growing tubules are asymmetric in height. This asymmetry seems to be caused by an accumulation of new wax molecules at edges found at the terminal end of the tubules and indicates a helical growth mechanism for the tubules. The pure nonacosan-10-ol alcohol, the dominating compound of wax tubules, can crystallize in different forms [36.42, 47, 53]. Here, *Jetter* and *Riederer* [36.47] show that a range of alkanediols, present in the waxes of many secondary alcohol tube-forming species, also have tube-forming capability.

Chemical analysis of the leaf waxes of lotus and nasturtium *(Tropaeolum majus)* show that waxes of both species are composed of a mixture of aliphatic compounds, with nonacosan-10-ol (a secondary alcohol) and nonacosandiols (an C_{29} alkane with two alcohol groups) as their main components [36.54]. These compounds have been separated from the rest of the wax compounds and used for recrystallization experiments. It could be shown with mixtures of nonacosan-10-ol and nonacosandiols components that a minimum amount of two percent of nonacosandiols supports tubule formation [36.25].

Analysis of wax chemistry, crystalline order, and their self-assembly has led to a better understanding of the molecular architecture of three-dimensional waxes [36.64]. Based on these data, a model of nonacosan-10-ol tubule structure has been developed, as shown in Fig. 36.13a. Here it is assumed that the lateral oxygen atoms at the side of the straight molecules hinder the formation of the normal, densely packed, orthorhombic structure and require additional space, causing a local disorder between the molecules and cause a spiral growth, leading to the tubule form.

Glands or glandular trichomes may produce very particular substances, and they can be found on approximately 30% of all vascular plants [36.65]. Multicellular glands include salt glands, nectaries, or the adhesive-secreting glands of some carnivorous plants [36.66]. Secretion and accumulation of toxic compounds at the plant surface allows direct contact with insects, pathogens and herbivores, and might therefore be an effective defense strategy [36.66]. The exudates of glands are, for example, terpenoids, nicotine, alkaloids or flavonoids. The exudates of some ferns and angiosperms, in particular several members of the *Primulaceae*, are composed of flavonoids [36.67, 68]. These flavonoid exudates or *farina* are morphologically similar to waxes, but are chemically distinct from plant waxes. Other glandular trichomes, such as the glands of the carnivorous plants of the genera *Drosera* (sundew) and *Pinguicula* (butterworts) secrete adhesives and enzymes to trap and digest small insects like mosquitoes and fruit flies.

Chemical heterogeneities are implied by the presence of other glands. The definition of this phenomenon depends on the scale: all biological surfaces show chemical heterogeneities, the most common case are leaves with a hydrophilic upper side and a superhydrophobic lower side. On a much smaller scale the trichomes of certain Salvinia species are most remarkable for hydrophilic islands within a superhydrophobic surface; the so-called Salvinia paradox (Fig. 36.28) [36.1, 69].

36.3 Structuring of Plant Surfaces: Hierarchical Architecture Between Nano- and Macrostructures

36.3.1 The Cuticle

Primary water plants (from unicellular algae to giant seaweeds) lack a cuticle; this particular polymer layer is restricted to higher plants (Sect. 36.8).

The cuticle covers leaves, flowers, stems, fruits and seeds and serves as a protective continuous layer covering the primary organs of all vascular plants and mosses. But in roots and secondary structures (e.g., bark) a cuticle is not present. The cuticle is a hydrophobic composite material, composed of a polymer called cutin and integrated and superimposed lipids called *waxes* (Sect. 36.2). The cuticle network is formed by cutin, a polyester-like biopolymer composed of hydroxyl and hydroxyepoxy fatty acids, and sometimes also by cutan, which is built by polymethylene chains. Nonlipid compounds of the cuticle are cellulose, pectin, phenols and proteins. Large differences in the chemical composition and microstructure of the cuticle have been found by comparing different species and different developmental stages. Chemical composition, microstructure and biosynthesis of the cuticle have been reviewed by several authors [36.28, 70–77].

36.3.2 Hierarchical Sculpturing

The cuticle and molecular wax films are the foundation of the surface. Additional levels of *hierarchical sculpturing* (or less-precise *structuring*) are formed by wax crystals (Fig. 36.7), the form of single cells (Fig. 36.18), composed sculptures like simple or multicellular hairs (Fig. 36.14), the form and curvature of whole organs

likes leaves (Fig. 36.27b,c) up to the gross morphological levels visible from larger distances like the riblets of the Titan arum flower (*Amorphophallus*, Fig. 36.1). The concept of hierarchical sculpturing of plant surfaces and a coherent terminology were introduced by [36.2] and used in many publications (e.g., [36.5, 78]). Based on the comprehensive survey by [36.1] we have revised this concept starting with a *flat* surface as first level, followed by a sequence of four or more superimposed *micro-architectural* hierarchical levels. The term *sculpture* (*architecture*) or sculptural seems more appropriate for three-dimensional features (discussed previously in [36.2]). The terms *structure* or *structural* also include chemistry and chemical heterogeneities, thus we prefer to use the term *sculpture* for the micro-architectural elements within the following four levels.

36.3.3 First Sculptural Level

This level comprises flat surfaces defined by their hydrophilic or hydrophobic chemistry on the scale of the resolution of a scanning electron microscope (SEM).

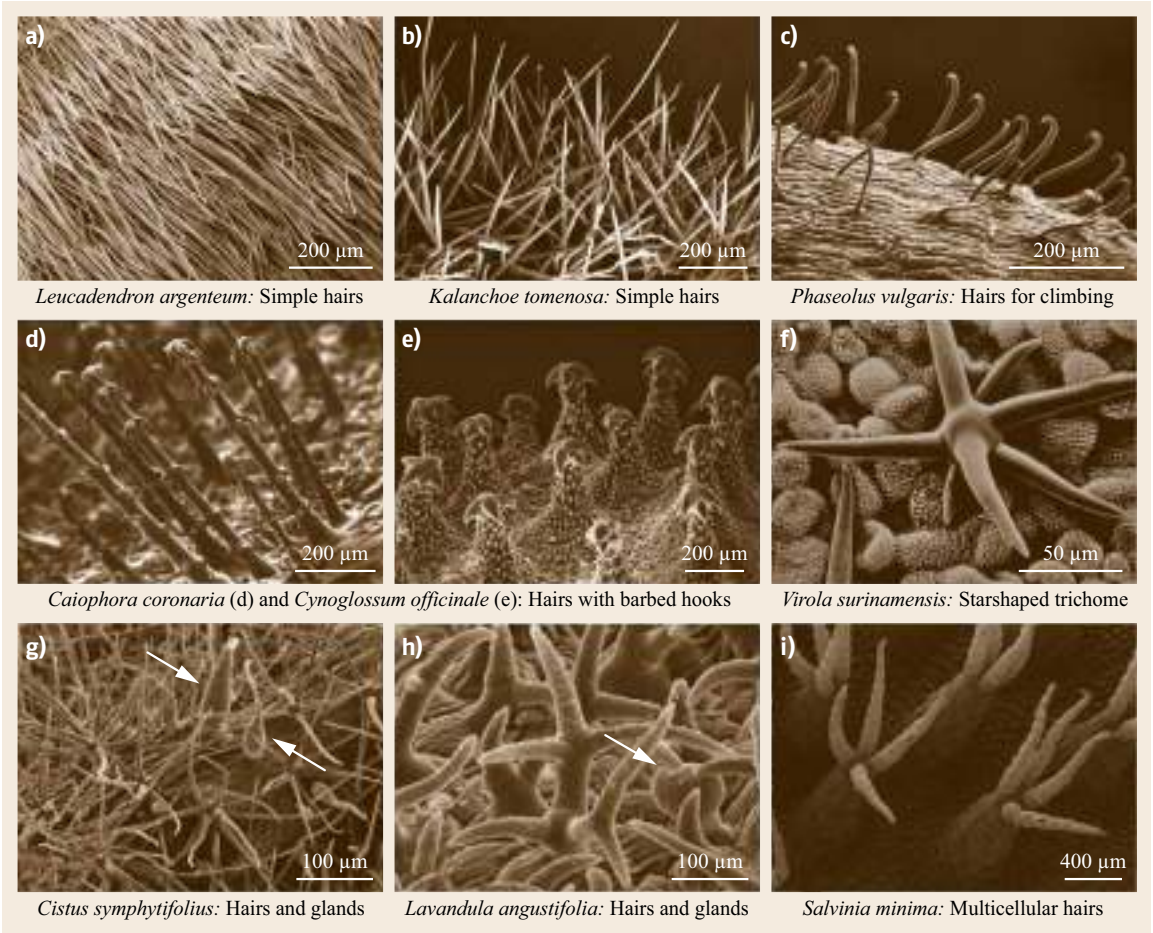

Fig. 36.14a–i SEM micrographs of hairs and glands on plant surfaces. A dense layer of straight, unbranched hairs almost orientated parallel to the leaf surface on *Leucadendron argenteum* **(a)**. The unbranched hairs of *Kalanchoe tomentosa* shown in **(b)** are orientated upright. The shoot surface of a bean shoot *Phaseolus vulgaris* with terminal hooks to facilitate climbing is shown in **(c)**. Single hairs on a leaf of *Caiophora coronaria* **(d)** and those on the seed surface of *Cynoglossum officinale* are characterized by terminal and lateral barbed hooks **(e)**. The star-like trichome on the leaf of *Virola surinamenis* **(f)** has a flat surface in contrast to the convex epidermal cells with epicuticular wax crystalloids. Simple branched star-like hairs and two morphological different glands (*arrows*) on the leaf of *Cistus symphytifolius* **(g)**, and multiple ramified hairs and short stalked glands (*arrow*) on a leaf of *Lavandula angustifolia* are shown in **(h)**. The four trichomes of *Salvinia minima* originate from a common base **(i)**, and in contrast to *S. molesta* (Fig. 36.28) the tips are free and do not show the eggbeater shape

Flat is a relative category that depends on the scale. Here, we limit the definition of flat to surfaces that feature structures of usually less than 10 nm in height. Flat surfaces are rarely found in plants and animals, but are seen for example in the leaves of rubber figs (*Ficus elastic*).

36.3.4 Second Sculptural Level

The second level comprises cell surfaces covered with structures between 50 nm and 20 µm. Structures at this level on plants are usually formed by epicuticular wax crystals (e.g., Fig. 36.7), which may exhibit a large spectrum of shapes like rodlets, platelets or tubules. They may exceed 200 µm in height (e.g., *Strelitzia*, *Copernicia*, *Benincasa*).

The main elements of the second sculptural level in plants are (a) *epicuticular wax crystals* (the diversity of waxes was discussed in the preceding sections on the chemistry of surfaces), (b) *cuticular folds* (Fig. 36.15), and (c) *subcuticular inclusions* (Fig. 36.16). Functionally, a superimposition of cuticular folds and wax crystals is not necessary: structuring on a specific level

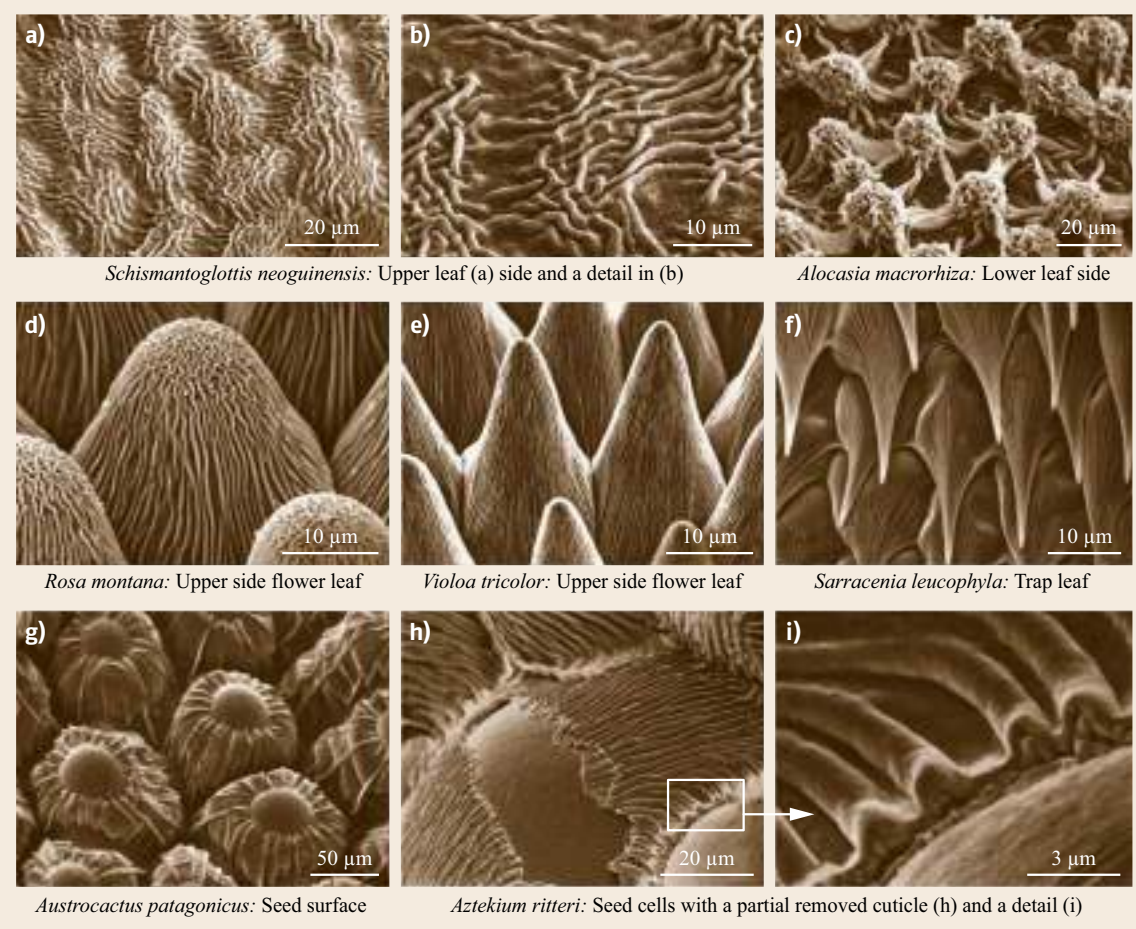

Fig. 36.15a–i SEM micrographs of cell surfaces with cuticular folding. In **(a,b)** the irregular cuticular folding on a leaf of *Schismatoglottis neoguinensis* is restricted to the central field of the cells. In **(c)** *Alocasia macrorhiza*, the cells are flat (tabular), with nodes like exposed central fields of the cells. The cells of a flower petal of *Rosa montana* with a rippled folded cuticle in the central field of the cells and parallel folding, running to the anticlinal walls of the cells, is shown in **(d)**. In **(e)** conical cells of the flower petals of *Viola tricolor* with parallel folding are shown. The cells of the inner side of a tube-like leaf of the carnivorous plant *Sarracenia leucophylla* is shown in **(f)**. These cells have a conical hair-papilla in the downward direction with a parallel cuticle folding, with larger distance at the base and denser arrangement at the cell tip. In **(g–i)** seed surfaces are shown. In *Austrocactus patagonicus* **(g)** the central field of the cells is unstructured, whereas a rough folding exists in the anticlinal fields. In *Aztekium ritteri* **(h,i)** a part of the cuticle has been removed to show the cuticle folding

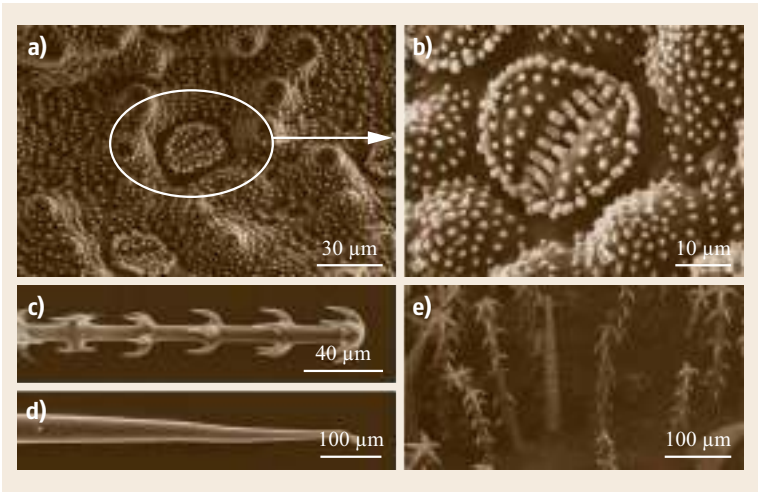

Fig. 36.16a–e Cell-surface structuring by subcuticular silicon dioxide and apatite insertions. SEM micrographs of the horsetail (*Equisetum arvense*) are shown in (a,b). (b) provides a detail of (a) and shows that the stomata and their surrounding cells have a micropattern of small enhanced spots, formed by subcuticular inserts of silicon oxide crystals. In (c–e) complex glochidiat hooked (e) and stinging (d) hairs are shown on the leaf surface in the flower nettle *Loasa*. The trichomes of Loasaceae are unique and mineralized by apatite. (c,e) from [36.79]

is performed by one group of elements, which seems to be a basic law [36.2]. The data gathered by investigating thousands of plant surfaces constitutes the rule that, for example, wax crystals and cuticular folds exclude each other. These frequently found morphological modifications of the outermost cell walls are known to influence the second hierarchical level. They are schematically shown in Fig. 36.17. In the first case, shown in Fig. 36.17a, the surface structure is induced by concavities of the cell wall, which lead to coves and folding of the surface. The second kind of structuring originates from subcuticular inserts of mineral crystals, such as silicon oxides (Fig. 36.17b). The third kind of surface structuring results from the folding of the cuticle itself (Fig. 36.17c). Additionally, on many plants,

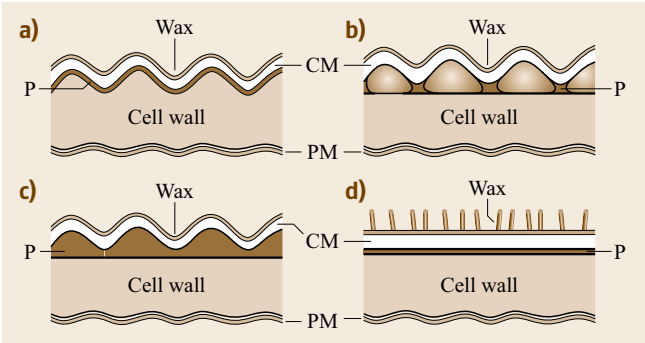

Fig. 36.17a–d Schematic of cross-sections through plant epidermis cells show different sources leading to microstructuring of cell surfaces. In (a) the surface profile is induced by coves of the underlying cell wall, in (b) by insertion of subcuticular minerals, in (c) by folding of the cuticle and in (d) by waxes, which are located on top of the cuticle (epicuticular wax). Wax = epicuticular waxes, CM = cuticular membrane, P = pectin, PM = plasma membrane (modified after [36.2])

waxes on top of the cuticle lead to surface structuring as shown in Fig. 36.17d. Waxes and their structural diversity have already been introduced; thus cuticular folds and subcuticular inserts are introduced in the next section.

Cuticular foldings have been described for nearly all epidermal surfaces of plants, but are frequently found in the leaves of flowers (petals), and on seed surfaces. They occur as folding or tubercular (verrucate) patterns, which originate due to the cuticle itself by an overproduction of cutin [36.80]. The pattern of cuticular folds can be categorized according to the thickness (width) of the folds, distances between the folds, and by their orientation [36.2]. Additionally, the pattern of folding within a single cell can be different in the central (inner area) and anticlinal field (outer area) of a cell. Fig. 36.15 shows different patterns of cuticle folding. On the leaves of *Schismatoglottis neoguinensis* (Fig. 36.15a,b) the folding is orderless and covers the central and anticlinal field of the cells. On the lower leaf side (adaxial) of *Allocasia macrorhiza*, shown in Fig. 36.15c, the cuticle forms node-like folding in the central part of each cell. The flower petals of *Rosa montana*, shown in Fig. 36.15d, have convex cells with a small central field with a rippled folded cuticle and parallel folds in the anticlinal field. The papilla cells of the flower petals of *Viola tricolor*, shown in Fig. 36.15e, have a parallel folding from the center to the anticlines of the cells. The cells inside the trap of the carnivorous plant *Sarracenia leucophylla*, shown in Fig. 36.15f, are hair-papillae, with a conical shape curved in a downward direction. On these, a parallel cuticle folding exists with larger distance at the base and a denser arrangement at the cell tip. The seed surface of *Austrocactus patagonicus*, shown in Fig. 36.15g, has cupular-formed cells with unstructured central fields and broad parallel folds

in the anticlinal fields. A high magnification SEM micrograph of the seed surface of *Aztecium ritteri*, shown in Fig. 36.15h,i, shows a partially removed cuticle and demonstrates that the origin of surface folding is caused by the cuticle itself.

Some microstructures on epidermis cells arise from subcuticular inserts of mineral crystals, as indicated in Fig. 36.17b. These subcuticular inserts can be solid crystals of silicon dioxide, as shown in Fig. 36.16a,b for tin plant or horsetail (*Equisetum*) plants. Calcium oxalate crystals are also frequently found in plants, and verification of silicon or calcium presence can be made simply by energy dispersive x-ray (EDX) analysis, included in an SEM. Silicon (Si) is a bioactive element associated with beneficial effects on mechanical and physiological properties of plants. It is a common element found in plants and occurs as monosilic acid or in the polymerized form as phytoliths ($SiO_2 \times nH_2O$) [36.81]. In plants, silica tends to crystallize in the form of silica in cell walls, cell lumina, at intercellular spaces and in the subcuticular layer [36.82]. Recently [36.79] investigated calcium apatite, a material that plays a crucial role in animals, in the complex trichomes of the family Loasaceae (Fig. 36.16c–e). Calcium oxalate crystals have been reported for more than 250 plant families [36.83], where they are deposed within the living tissue.

36.3.5 Third Sculptural Level

The third level contains unicellular (multicellular in certain hair types in plants) structures usually caused by particular shapes of the outer cell wall that may vary from convex to papillose cells and ultimately to hairs, which may be unicellular or multicellular (for a terminology see [36.2]). Dimensions range from about 2 µm to several centimeters, i. e., in trichomes (hairs). Structures of the second level may be superimposed onto structures of the third level (e.g., Fig. 36.22). To understand this level often a thorough microscopic analysis is essential, and the description and terminology for this diversity is complex.

The Outlines of Cells

The description of plant micro- and nanostructures requires the use of some basic uniform terms, for example to describe the outline of a single epidermis cell. Several variations are known and introduced in detail by *Barthlott* and *Ehler* [36.2], *Barthlott* [36.78] and *Koch* et al. [36.84, 85]. In the following, a brief introduction is given.

The boundary walls between two adjacent epidermal cells are called anticlinal walls, whereas the outer wall forming the cell surface is called the periclinal wall. The primary sculpture of a single cell encompasses the outline, including the shape and relief of the anticlines and curvature of the outer periclinal wall. There are two basic forms of cells, the tetragonal and polygonal form, both of which can have a uniform length of their sides or be elongated. Additionally, the course of the anticlinal walls can be straight or uneven. It is assumed that the outline of anticlines has an influence on the mechanical stability of the epidermis tissue, but experimental evidence for this hypothesis is not available. The cell sculptures or curvature of the outer epidermis wall (periclinal wall) can be tabular (flat), convex (arced to the outside) or concave (arced to the inside), and have a large influence on the surface roughness at the micrometer scale. Additionally, only the central area of a cell can form a convex outgrowth and form a papilla or hair-like structure. The convex cell type is the most common cell type of epidermal surfaces, often found on flower leaves, stems and leaves [36.86]. These cell morphologies originate by expansion of the outer side (periclinal wall) of the epidermis cells. They can be divided into several subtypes, depending on the outline of the epidermis cells and their aspect ratio (width to height), which determines their designation. In Fig. 36.18 a schematic of different convex cell outlines and their designations is given. The terminology is based on the cell outline and aspect ratios ($\beta =$ width/height) of the cells and includes: convex ($\beta \geq 3/1$), hemispherical ($\beta \approx 2/1$), cupola ($\beta < 3/2$), conical ($\beta > 3/2$), papilla ($\beta < 3/2$ and $> 1/2$), hair-papilla ($\beta < 1/3$ and $> 1/6$), and hairs ($\beta < 1/7$). In these, hairs are built by the outgrowth of a single surface cell. Hairs are often named trichome (Greek: trichoma).

The leaf surfaces of *Leucadendron argenteum* and *Kalanchoe tomentosa*, shown in the SEM micrographs in Fig. 36.14a,b, are two representative surfaces with hairs. Hairs can decrease, but also increase the loss of water and influence the wettability of the surfaces [36.87]. The wide spectrum of functions of plant hairs has been reviewed by *Wagner* et al. [36.66], and more recently by *Martin* and *Glover* [36.86]. With respect to their functions, it is important to notice that hairs can be glandular or nonglandular (nonsecreting), dead or living, and hairs can also be built up by several cells (multicellular), which are introduced later. Unicellular trichomes can be found on the aerial surfaces of most flowering plants (angiosperms), some conifers (gymnosperms) and on some mosses (bryophytes) [36.66]. Many plants of dry habitats show a dense cover of dead, air-filled hairs to reflect the visible light, which makes the surfaces appear white. The structures of hairs are often more complex; thus, the definition based on the aspect ratio fits well only

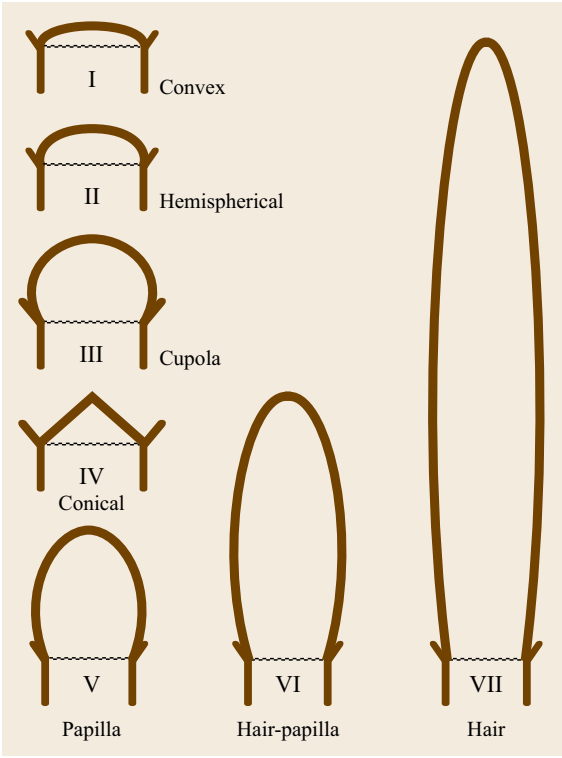

Fig. 36.18 A schematic of different convex cell outlines and their aspect ratios (β = width/height) of the convex cell types and their terminology: convex ($\beta > 3/1$), hemispherical ($\beta \approx 2/1$), cupola ($\beta < 3/2$), conical ($\beta > 3/2$), papilla ($\beta < 3/2$ and $> 1/2$), hair-papilla ($\beta < 1/3$ and $> 1/6$), and hair ($\beta < 1/7$)

for simple, undivided hairs. On the shoots of common beans (*Phaseolus vulgaris*), hairs form hooks to get better adhesion for climbing (Fig. 36.14c) and in *Caiophora coronaria* (Fig. 36.14d) and *Cynoglossum officinale* (Fig. 36.14e) the hairs have lateral barbed hooks. The stellate hairs of *Virola surinamenis* differ from the other epidermal cells, covered by a dense layer of wax crystals, by having completely smooth surfaces (Fig. 36.14f). Further trichomes are the simple or double-branched hairs and secretion glands on the leaves of *Cistus symphytifolius* and *Lavandula angustifolia* as shown in Fig. 36.14g,h. These complex hair structures require a more differentiated description than the aspect ratio used for simple hairs [36.88, 89]. The sizes and morphologies of trichomes are often species specific, making some trichomes useful as morphological features in plant systematics [36.89]. Deformation induced by water loss of dead desiccated cells can leads to concave cell morphologies and other complex modifications (Fig. 36.3). This is characteristic for seed coats and can result in most complex hierarchical sculpturing formed in cacti [36.90] or orchids [36.91].

36.3.6 Fourth Sculptural Level

The final level is made up of multicellular structures, caused by specific arrangement patterns of several epidermal cells. There is a wide variety of possibilities for this group of structuring. Multicellular hairs are common in all groups of vascular plants, apart from conifers.

Particularly interesting forms occur in the floating ferns of the genus *Salvinia*. Within this genus, morphologically different kinds of water-repellent (superhydrophobic) hairs exist [36.92], which in some species (*S. auriculata, S. molesta*) show functionally important chemical heterogeneities (Sect. 36.2) by utilizing hydrophilic anchor cells at the tip of the trichomes to stabilize the air–water interfaces [36.1, 69]. Four different hair types have been described for the genus *Salvinia* [36.92]. Based on these morphological types, the genus Salvinia is divided into four groups, each with several species. The Cucullata-type is characterized by solitary and slightly bent trichomes and occurs in *S. cucullata* and *S. hastate*. The Oblongifolia-type forms groups of two trichomes, which bend in the same direction and sit on an emergence. This type occurs in *S. oblongifolia*. The Natans-type, shown in Fig. 36.14i, has four trichome branches, each elevated on a large multicellular base and in total has a height of up to 1300 µm. The heights of the trichome groups decrease towards the leaf margins. This type occurs in *S. natans* and *S. minima*. In the Molesta-type (Fig. 36.23c) four trichome branches are grouped together, connected with each other by their terminal cells and sitting on a large emergence. The heights of these trichomes reach up to 2200 µm in *S. molesta*, but also decrease towards the leaf margins. This trichome-type is characteristic for, e.g., *S. molesta* and *S. biloba*. In all these species, the epidermis is covered with small three-dimensional waxes in the form of transversely ridged rodlets. The development of these complex structures has been studied in *S. biloba*, by *Barthlott* et al. [36.92]. In an early stage of leaf development, the hair formation starts with a grouping of four cells. During the ontogeny of the leaf, four branches develop from these initial cells and form a crown-like structure, in which the single branches are connected with each other. Later, the base grows by cell division and cell expansion to develop a large base below the crown structure.

36.4 Physical Basis of Surface Wetting

Wetting is the fundamental process of liquid interaction at solid–gaseous interfaces. It describes how a liquid comes into contact with a solid surface. The basics of surface wetting are summarized here; extensive literature on the topic exists [36.93–101].

36.4.1 Static Wetting Processes

A droplet on a solid surface wets the surface depending on the chemical properties of the phases, as well as on the surface structure. A parameter to quantify this wettability is the contact angle (CA). A high contact angle describes surfaces on which a water droplet forms a spherical shape and the contact area between the liquid and the solid is low. Contact angle measurement is the main method for the characterization of the hydrophobicity or hydrophilicity of surfaces. The wetting behavior of solid surfaces can be divided into four classes, defined by their CA, as well as CA-hysteresis for the case of superhydrophobic surfaces (Fig. 36.19). On superhydrophilic surfaces, where a fluid will spread and cover a larger area of the surface, the CA ranges from 0° to < 10°. Surfaces with a CA between > 10° and < 90° are termed hydrophilic surfaces. Unwettable surfaces have high contact angles, meaning the liquid on the surface forms a semispherical or spherical droplet. Surfaces on which the CA is > 90° and < 150° are hydrophobic surfaces. A superhydrophobic surface is defined as one that has a static CA of > 150°, and if those superhydrophobic surfaces have a low hysteresis or a low tilting angle (TA) of less than 10° they are superhydrophobic and can have self-cleaning properties. This definition of superhydrophobic surfaces has been used in many reviews [36.98, 102–106] and represents the most-used classification of surface wettability. The basis for studying the wettability of smooth surfaces is given by Young's equation [36.107]. The CA of a liquid on a surface depends on the surface tension (molecular forces) of the specific liquid, solid surface and the surrounding gas. Thus, wetting depends on the ratio between the energy necessary for the enlargement of the surface and the gain of energy due to adsorption (Fig. 36.19) [36.93, 108, 109]. The basis for studying equilibrium wetting on rough surfaces was established many years ago by *Wenzel* [36.110] and *Cassie* and *Baxter* [36.111] and [36.112]. The Wenzel equation expresses a general amplification of the wettability induced by roughness and applies to a CA where droplets are in equilibrium, but not to advancing and receding angles of a droplet on a rough solid surface that give rise to contact-angle hysteresis (CAH). Hysteresis is responsible for the sticking of liquids on a surface, and is the difference of an advancing and receding angle of a moving droplet ($CAH = CA_{adv} - CA_{rec}$, Fig. 36.19). If a droplet moves over a solid surface, the CA at the front of the droplet (advancing CA) is greater than that at the back of the droplet (receding CA). However, if the droplet rolls with little resistance, the contact angle hysteresis is small. Advancing and receding contact angles can also be determined when additional liquid is added to a sessile drop and the contact line advances; if liquid is removed from the drop, the CA decreases to a receding value before the contact retreats.

On water-repellent surfaces, a droplet applied starts to roll off the surface when it is tilted to a specific angle. This tilt angle (TA) is simply defined as the tilting angle of a surface on which an applied drop of water starts to move. Low TA (< 10°) is characteristic for superhydrophobic and self-cleaning surfaces. If the droplet is in Cassie–Baxter stage [36.111], with air trapped between the surface and the applied water droplet, the real contact between the droplet and the surface is very small

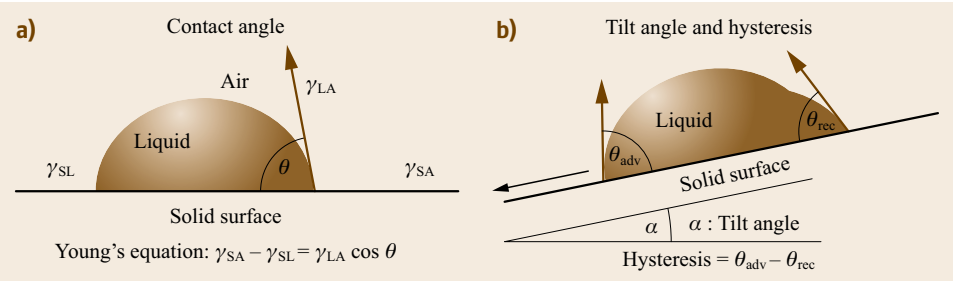

Fig. 36.19a,b The schematic shows the wetting of a solid surface. **(a)** γ_{LA}, γ_{LS} and γ_{SA} are the interfacial tensions at the boundaries between liquid (L), solid (S), and air (A), which determine the CA of an applied water droplet and is described by Young's equation. **(b)** The hysteresis of a water droplet on a tilted surface represents the adhesion of the liquid on the surface and can be determined by measuring the tilting angle or the advanced and receding angle of a water droplet

compared to wettable surfaces, on which an applied drop of water tends to spread, and contact angle is low. In intermediate wetting stages [36.113] high contact angles correspond with an increased contact between the surface and the water droplet applied. This phenomenon has also been described as the petal effect [36.109, 114] because of its occurrence in the flower leaves (petals) of some roses.

36.4.2 Dynamic Interactions

Dynamic interactions include bouncing, splashing and spreading of droplets. The impact behavior of falling drops has been subject to studies for several liquids, such as water, ethanol, emulsions etc. and various types of structured and unstructured, solid and liquid surfaces [36.115, 116]. In addition to the physiochemical surface properties and structures, other factors determine the impact behavior of falling drops: their velocity, size, surface tension and viscosity [36.117–119]. Falling drops can impact without any breakup or impact with a splash or splashing, in which the impacting drop releases smaller droplets flying away from the point of impact. Roughly two different types of splashing on incompliant surfaces are described, the *prompt splash* and the *corona splash*. The *corona splash* consists of relatively large droplets and is the outcome of the breaking up of fingers developing at a flattening drop's rim. In *prompt splash* very small and fast droplets are generated when the advancing lamella of a spreading drop is disturbed by rough surface structures higher than a specific fraction of the lamella, causing the lamella to rupture locally and release small splash droplets [36.120].

Dynamic interactions between water droplets and the surfaces are well researched in the different types of splash phenomena described e.g., in [36.115, 120–124]. More recently the contact times between droplets and surfaces came into focus: the time span a drop impacting and bouncing on a hydrophobic surface is in contact with the surface. The contact time as well as the shape of the rebound droplet strongly depends on the structure and the chemistry of the surface. A reduction of this contact time is of advantage in several applications, e.g., anti-icing, self-cleaning, or spray cooling [36.125]. The contact time might be important in biological surfaces.

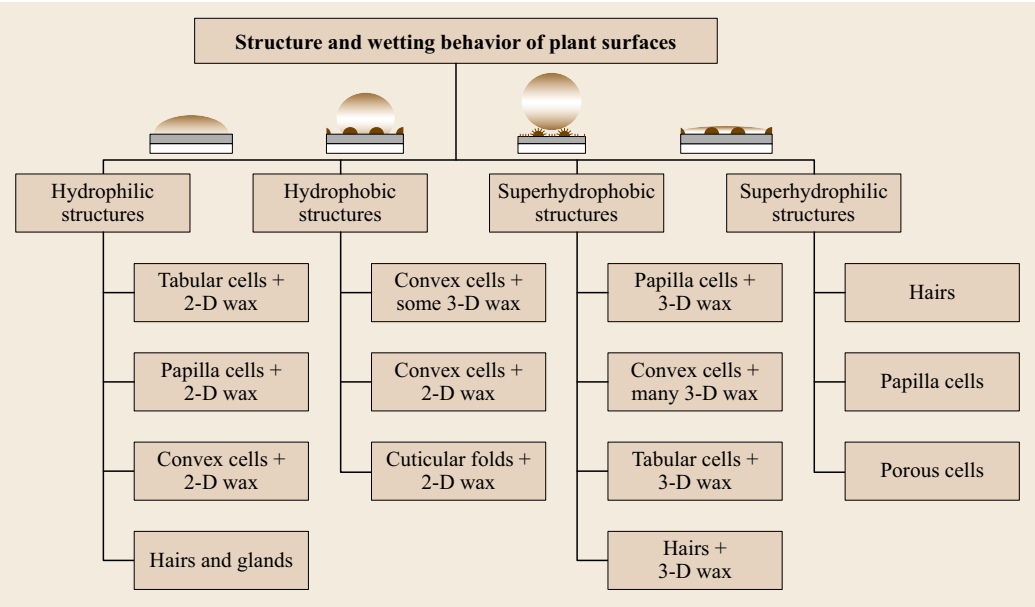
Dynamic wetting processes and their control may play an underestimated role in the interaction between plant surfaces and rain, the maintenance of air layers underwater, or e.g., in pesticide applications.

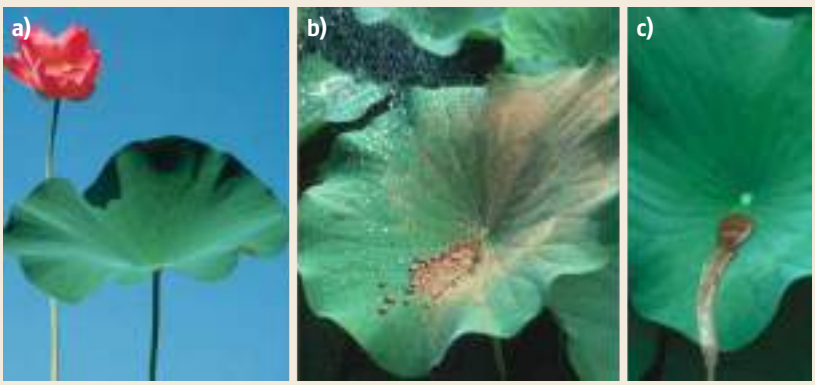
36.5 Superhydrophilic and Superhydrophobic Plant Surfaces

The wettability of plant surfaces plays a crucial role in their interaction with the environment. A physical constraint of water plants is that they must be hydrophilic, whereas in land plants the whole range from superhydrophilic to superhydrophobic occurs (Fig. 36.20).

Hydrophilic and superhydrophilic surfaces (contact angle – if measurable – between 0° and $< 90°$) are known from all aquatic plants and many surfaces of land plants that usually have a papillate cell morphology and cuticular folds, but also from leaves with flat, tabular cells. Surfaces covered by wax may become hydrophilic with the erosion of theses layers (e.g., *Carnegiea*, Fig. 36.1a), a very common process in many plants (see below). Modified wax layers may even become superhydrophilic like in the Atacama desert cactus *Copiapoa cinera* adapted to fog harvesting. Hydrophilic behavior in flower petals of the daisy family (Asteraceae) and their polymer replica was analyzed in detail by *Koch* et al. [36.126] and provides information for biomimetic applications (Sect. 36.7).

Superhydrophobicity was discovered in terrestrial plants, and is one of the main and most obvious characteristics of most vascular nonaquatic plants [36.1]. Superhydrophobic surfaces cover hundreds of millions of square kilometers on our planet's surface (Sect. 36.1). One precondition is always a hydrophobic chemistry of the surface and hierarchical sculpturing on two or more levels [36.1, 2, 8, 20] – these are the only two essentials for superhydrophobicity in organisms. In plants it is generated – with only a few exceptions – by 3-D wax crystalloids of the morphological and chemical diversity previously described and illustrated (Fig. 36.7). Superhydrophobicity in this cases is caused merely by a sculpturing on the second level. For reasons of stability under dynamic conditions and to minimize mechanical damage an additional third hierarchical level (usually convex cell surfaces) is essential – the best example are the lotus leaves (Fig. 36.21) with contact angles $> 160°$ and a tilting angle of $< 4°$ [36.16] (survey of recent literature in [36.1]). The various functions of superhydrophobicity are discussed in Sect. 36.6. However, there is a phenomenon that *hairy* surfaces with cellular trichomes only covered by nonstructured molecular films also commonly cause this effect. The classic examples are the superhydrophobic leaves of the Lady's mantle (*Alchemilla)* analyzed in detail by *Otten* and *Herminghaus* [36.23]. This is so obvious and often observed, that the names





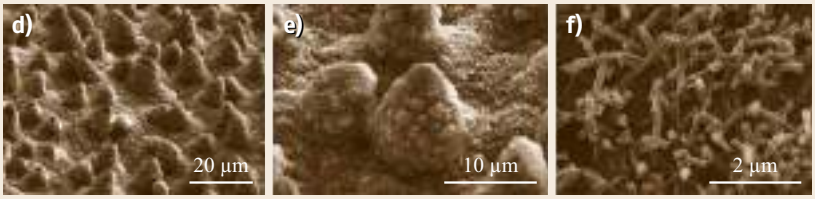


Fig. 36.20 Four groups of plant surface wettability and the possible surface structures and structure combinations. The drawings used for the four groups are correlated to specific contact angles. Both the hydrophobic and superhydrophobic surfaces can be built by convex cells with three-dimensional waxes on it, but only a dense layer of wax crystals results in superhydrophobicity

The lotus plant (*Nelumbo nucifera*) (a): Removement of dirt particles by water (b, c)

SEM micrographes of the lotus leaf (d) show the papillose cells (e) and wax tabules (f) on it

Fig. 36.21a–f Superhydrophobic and self-cleaning surface of lotus (*Nelumbo nucifera*). A flowering plant of lotus **(a)**, a lotus leaf contaminated with clay **(b)** and removal of the adhering particles by water **(c)**. The SEM micrographs **(d–f)** show the lotus leaf surface in different magnifications: **(d)** shows the papillate epidermis, **(e)** single-cell papilla and **(f)** the epicuticular nonacosan-10-ol tubules on the cell surface

Lady's mantle as well as *Alchemilla* refer to the superhydrophobic properties. The *Alchemilla-type* of superhydrophobicity also occurs in the feathers of many birds.

A list of extremely superhydrophobic plant surfaces was provided by *Neinhuis* and *Barthlott* [36.8]. Amongst the extremes – all measured with the same equipment under the same conditions – are plants

from most different relationships. Examples are: Indian cress (160° *Tropaeolum*), grasses (161° *Elymus*), Ginkgo trees (161° *Gingko*), lotus (162° *Nelumbo*, Fig. 36.22c), Californian poppy (162° *Eschscholzia*), Aroids (164° *Colocasia*, Fig. 36.22a), and *Euphorbia myrsinites* (162°, Fig. 36.22b). Extremely high contact angles caused by parallel oriented wax platelets are exhibited by some monocotyledons of the family *Alstroemeriacea* (*Peruvian lillies*); the extreme was measured in a climbing *Bomarea* reaching a static contact angle of 169° [36.127].

Superhydrophobicity is usually not very persistent in plant surfaces. Leaves, with a limited life span, do usually not last longer than one year. Persistent leathery leaves (like in many Mediterranean and tropical climates) are usually hydrophilic – but they may start as hydrophobic in their earliest developmental stages. These dynamics can be measured in the persistent leaves of *Welwitschia mirabilis*, a single leaf growing over two centuries from its base. They start superhydrophobic exhibiting tubular nonacosan crystals, which eroded after the first year causing the leaf to become wettable [36.1]. Plums are covered by a mechanically delicate whitish wax cover – touching it with a finger is enough to destroy the structure and thus the *glaucous* color. An extreme example is provided by the chemically complex brilliant white waxy coating of the succulent desert plants of the genus *Duddleya* (e.g., *D. brittonii*): it only takes a rain drop to destroy the unstable coating [36.68]. *Duddleya* is not self-healing, in contrast to other plants, were a wax cover destroyed may regenerate within hours.

Water plants are superhydrophilic, but when they rise above the water level they exhibit their old evo-

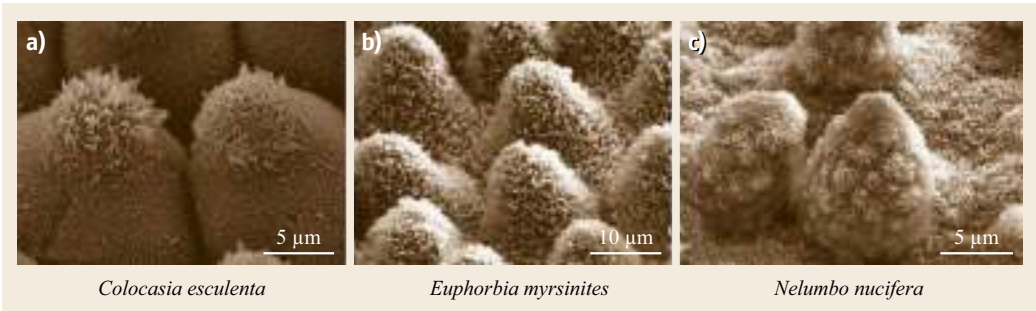

Fig. 36.22a–c Extremely superhydrophobic leaf surfaces of **(a)** *Colocasia esculenta*, (contact angle 164°) *Euphorbia myrsinites* (contact angle 162°) and lotus *Nelumbo nucifera* (contact angle 162°), data from [36.8]. Leaves of all three species are characterized by convex **(a,b)** to papillose **(c)** cells, covered by three-dimensional wax crystals

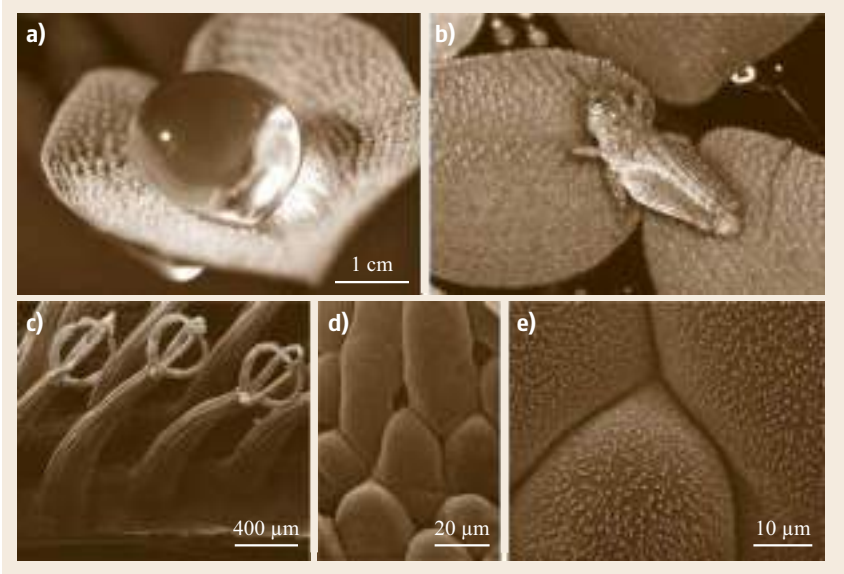

Fig. 36.23a–e Air-retaining surfaces of the floating fern *Salvinia*. In **(a)** a water droplet sits on the upper leaf side of *Salvinia biloba* and in **(b)** a mimicking grasshopper *Paulinia acuminata* feeding on the leaf even has a wax surface and is superhydrophobic. The SEM micrographs **(c–e)** of the leaf surface of *Salvinia* show the multicellular hairs **(c)**, and in higher magnification **(d)** the epidermis cells, and the wax rodlets **(e)** on the epidermis cells

lutionary potential: e.g., the flowering stalks of the watermilfoil *Myriophyllum* become superhydrophobic like the unique flowers of *Nymphoides* [36.1]. Floating species like *Salvinia* or *Pistia* are usually superhydrophobic. A striking example is illustrated in Fig. 36.23b: the grasshopper *Paulinia acuminate* feeds exclusively on *Salvinia* and optically mimics its color and surface (camouflage) – but it also is superhydrophobic based on wax crystals, the same adaption to its semiaquatic habitat as its host plant [36.1, 128].

Only few surfaces like lotus leaves have a very stable superhydrophobicity. As indicated in the introduction, superhydrophobicity usually disappears in aging biological surfaces and they become wettable (compare Fig. 36.1a).

36.6 Functional Diversity of Plant Surfaces

The surface of plants is the critical interface for interaction with the environment and fulfills many different functions (Fig. 36.24). Aspects and literature have been summarized by [36.1, 72, 73, 78, 129–131]. The surfaces are usually multifunctional and each attempt to categorize them is thus unrewarding [36.85, 132]. We simplify this in the following seven categories.

36.6.1 Mechanical Properties

The cuticle itself is a highly sophisticated chemically stable layer that serves as an elastic mechanical protective structure [36.76, 129]. The shape of a ripe tomato is maintained to a high degree by its thin cuticle. Hierarchical surface structures fulfill various mechanical tasks; they can reduce the ability of insects to walk (e.g., fish-hooked hairs on bean leaves against aphids, trapping surfaces in insectivorous plants or flowers of *Arum*) or increase the ability of insects to walk, as is the case in flowers, and even orient the visitors with cuticular folds [36.133]. Mechanochemical defense trichomes are common, such as in nettles (Urtica) or in Loasaceae (Fig. 36.14d)

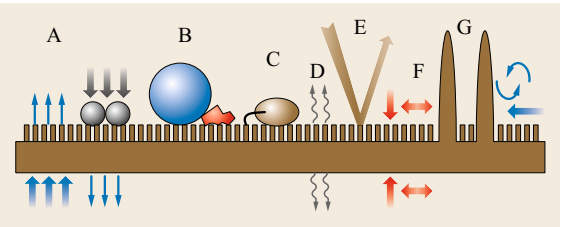

Fig. 36.24 Schematic of the most important functions of the plant boundary layer on a hydrophobic microstructured surface: A) transport barrier – limitation of uncontrolled water loss/leaching from interior and foliar uptake, B) surface wettability, C) anti-adhesive, self-cleaning properties (lotus effect) – reduction of contamination, pathogen attack and reduction of attachment/locomotion of insects, D) signaling – cues for host-pathogens/insect recognition and epidermal cell development, E) change of optical properties, F) mechanical properties – resistance to mechanical stress and maintenance of physiological integrity, G) reduction of surface temperature by increasing turbulent air flow over the boundary air layer (modified after [36.77])

36.6.2 Attachment

Attachment mechanisms are most common in zoochorous fruits like burrs, where complicated hooked spines and hairs have evolved in many groups (Asteraceae, Krameriaceae, Pedaliaceae) [36.134]. A particularly refined attachment mechanism with extractable cellulose threads occurs in the seeds of the orchid *Chiloschista* [36.91]. Attachment plays a role in the interaction between pollen and its disperser and the stigma, where it becomes deposed. Climbing plants like ivy (*Hedera*) or some highly specialized water plants growing on rocks in currents (e.g., *Podostemonaceae*) exhibit attachment devices by glue-like adhesives, which are not really surface phenomena.

36.6.3 Reflection, Absorption, and Transmission of Spectral Radiation

These phenomena are of crucial importance for light harvesting and temperature control under insolation. Colors as well as light reflection play an important role in the interaction between flowers and their pollinators.

Light Management

Absorption of light for photosynthesis is the precondition for plant life. Leaves need to collect electromagnetic radiation through photosynthesis while flowers need to harvest radiation in order to intensify their coloration to be more attractive for pollinators. In these processes the architecture of the plant surfaces plays an important role. While self-cleaning surfaces often combine convex- or concave-shaped epidermal cells

with water-repellent 3-D waxes, light-harvesting leaf surfaces often possess only convexly shaped epidermal cells. Specifically plants under low light conditions reduce the loss of light due to specular surface reflection by increasing the transmittance of energy via multiple reflections between the surface structures [36.135]. An extreme example is the *luminescent moss Schistostega* living in caves with batteries of spherical cells collecting the faintest light like lenses [36.136]. However, convexly shaped cells combined with a cuticular folding on top are well known for petal surfaces, especially in angiosperms [36.2]. These cuticular folds were thought to reduce the surface reflection [36.137], act as a specific optical signal for pollinators [36.2] and cause iridescence generated through diffraction gratings [36.138].

Coloration Signals

The intriguing interaction between flowers and their pollinators is the reason for the evolution of most refined coloration signals (e.g., [36.139]). The spectrum comprised virtually all grades of reflections (from black to white) and all visible colors, and even metallic-mirror-like surfaces have been evolved in the orchid *Ophrys speculum*, using thin layer iridescences like in our example (Fig. 36.4a). To intensify their color signal some flowers use refined surface structures. The surface architecture of the flowers of the so called *Johnny-jump-up*, *Viola tricolor*, is an excellent model for this color intensification process. *Viola* possess extreme papillated epidermal cells (aspect ratio about 2.93) covered with a fine cuticular folding (width about 0.26 μm). This surface topography acts as a light trap for incident light by reducing the specular reflection on the surface. Via this surface design more light passes through the cell wall. Furthermore, the extremely steep cell walls (papilla tip angle about 26°) cause an optimized scattering of the light within the petal (scattering angle of about 170°). This allows the absorption of more light by the pigments, which further results in the intensification of the color signal. Such a surface is highly interesting for biomimetic applications, for example in solar panel development. Flowers also use optical signals in the ultraviolet range, not visible to the human eye, but visible to visiting bees: *Bidens ferulifolia* in Fig. 36.25 provides an impressive example. Large databases on ultraviolet reflection of flowers are published [36.140–142]. Usually it is assumed that the reflection is determined only by chemical compounds (flavonoids) within the living cells (vacuoles), but we have recently shown that UV patterns are also supported by the surface structure. Another phenomenon caused by surface structures is iridescence of some leaves like in the fern *Elaphoglossum* (Fig. 36.4a). This phenomenon seems to occur mostly under low light intensities of tropical rainforest understories, but is also known in some flowering plants, e.g., the petals of some tulips [36.138, 143]. Camouflage (like in the grasshopper *Paulinia* Fig. 36.23b) plays an important role in desert plants (mainly South African Aizoaceae like the *living stones Lithops*): not only characteristics such as color, but also the microstructure of the surrounding environment are mimicked with high precision by their surfaces.

Temperature Control Under Insolation

The plant surface can only tolerate temperatures of up to 45 °C for living tissue. As a car top can heat up to more the 60 °C on a hot summer day, avoiding such temperatures is a crucial challenge for living tissue under solar radiation. Transpiration cooling is an obvious adaption, but inevitably connected with loss of water. Obviously, the highly reflective wax coatings or an indumentum of hairs decreases the heating [36.144–147]. An important aspect of temperature control – apart from reflections – may be the increase of turbulences by mechanical turbulence aids (e.g., the diversity of leaf mar-

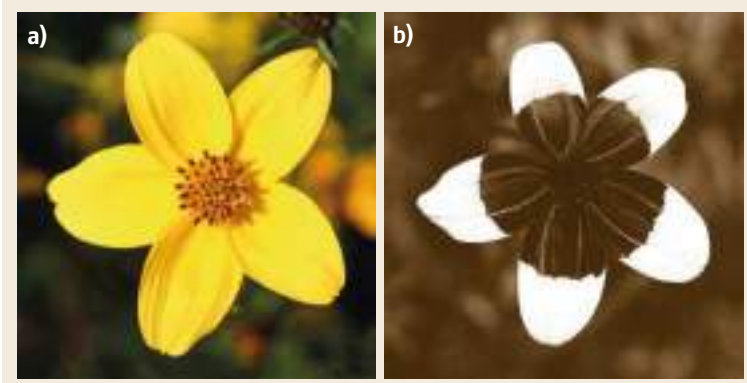

Fig. 36.25a,b Optical properties. Flower of *Bidens ferulaefolium* in the visible light for human eyes **(a)**. In **(b)** an ultraviolet image of the same flower is shown. Reflection and absorption of radiation are primarily influenced by chemical composition, but surprisingly also by the hierarchical surface architecture

gins) under dynamic (wind) conditions, which enhance the temperature exchange between the cooler air and the heated isolated leaf surfaces [36.148–151]. It is not by chance that succulents of the arid hot regions exhibit a high complexity of hierarchical surfaces sculpturing.

36.6.4 Reduction of Water Loss

Many of the land plant surface structures must be observed in context of reduction of water loss – a well-researched field. The cuticle, wax layers, and an indumentum of dense hairs play crucial roles in preventing loss of water; in some desert plants like *Sarcocaulon* the waxy layer might be more than one centimeter in thickness. This function is rather irrelevant for biomimetic applications: nonorganic materials like metals and synthetic polymers provide better solutions. *Uptake of water* is connected with superhydrophilicity (Sect. 36.6.5).

36.6.5 Superhydrophilicity

Superhydrophilicity is a physical constraint in water plants, but in land plants it is mainly connected with the uptake of water (roots, ephytic and fog collecting plants). Mosses without conductive tissue are superhydrophilic for an *ectohydric* water uptake; the most refined structures are found in *Rhacocarpaceae* (Fig. 36.26a,b) [36.152, 153]. All epiphytes (plants growing on other plants without contact to the soil) depend on rain, fog, and dew and they are all hydrophilic and most are even superhydrophilic [36.1]. The best-known examples are the hair-covered leaves of bromeliads (Fig. 36.26c). But there are many more plants with fog and dew collecting abilities in certain semiarid regions like the Atacama and Namib deserts [36.154–156], which are of particular interest for biomimetic application (fog collectors) (Fig. 36.26d). A remarkable case is the leaves of understory plants in tropical rainforests, like the superhydrophilic *Ruellia devosiana* with a strong convex sculpturing of its epidermis cells. Glands on the leaf surface release saponins, causing a thin hydrophilic coating, supporting a rapid spreading of water droplets [36.11].

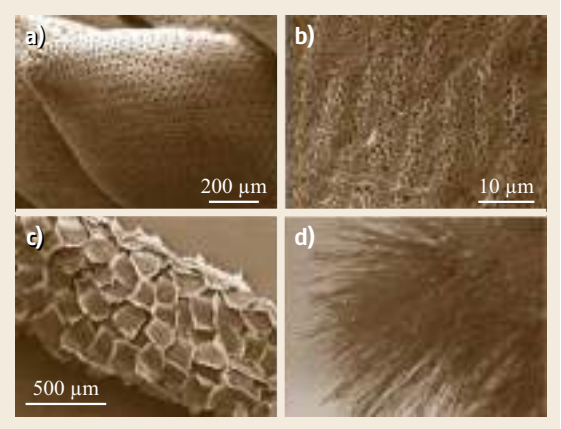

Fig. 36.26a–d In (a) the water absorbing pores of a *Sphagnum squarrosum* moss and in (b) the water adsorbing porous surface of the moss *Rhacocarpus purpurescens* are shown. In (c) the epiphytic growing Spanish moss (*Tillandsia usneoides*) is shown. (d) Water droplets in the needles of the Canary pine *(Pinus canariensis)* harvesting fog out of the trade wind clouds

Some superhydrophilic water plants have optimized surfaces and morphologies to resist water flows. By exhibiting grid-like leaves the Madagascar laceleaf (Fig. 36.5c) reduces its flow resistance. The superhydrophilic wave-swept giant seaweeds (Phaeophyta) are adapted by their morphology to reduce drag [36.157]. Their leathery thallus is covered by a mucilage, and recent work indicates that the superhydrophilicity of the mucilaginous surface acts as a drag-reducing agent like the mucilage of fish.

36.6.6 Superhydrophobicity

Superhydrophobicity is one of the most obvious characteristics of many land plant surfaces and may serve different functions. In particular the structures for air retention underwater are highly complex (e.g., *Salvinia*, Fig. 36.23), and they are often combined with a superimposed compartmentalization [36.1] of the whole organ surfaces from the microscopic to the macroscopic level (Fig. 36.27).

Superhydrophobicity serves many different functions, including:

1. *Unwettability per se* to avoid wetting for mechanical reasons: thin laminar leaves become too heavy when wetted. This is probably an important determination leading to the adaptation of superhydrophobicity in larger leaves in rainforests (e.g., *Cibotium*, [36.1]) – an extreme examples is the Titan Arum *Amorphophallus* (Fig. 36.1b).
2. *Reduction of adhesion* for insects – usually connected with superhydrophobicity – is caused by epicuticular wax crystals in insect-catching plants (e.g., *Sarracenia*, *Nepenthes*) or flowers that trap their pollinators (*Ceropegia, Aristolochia*) or to avoid unwanted nectar thieves (*Fritillaria, Lapageria*). Superhydrophobicity itself is not the primary function in these surfaces.

3. *Reduction of adhesion to avoid contamination* (*lotus effect* Fig. 36.21) enables plants to be cleaned from any kind of contaminating particle by raindrops, it is probably the most important function of superhydrophobicity in plants [36.1, 16, 159, 160]. Biologically, such surfaces in plants and animals should be primarily seen as a defense mechanism against fungal spores and the colonization of other microorganisms.
4. *Air layers for buoyancy*. Nonpersistent air layers for temporary buoyancy in water play an often underestimated role in very small seeds (Fig. 36.27a) and spores that may fall or are dispersed into water.

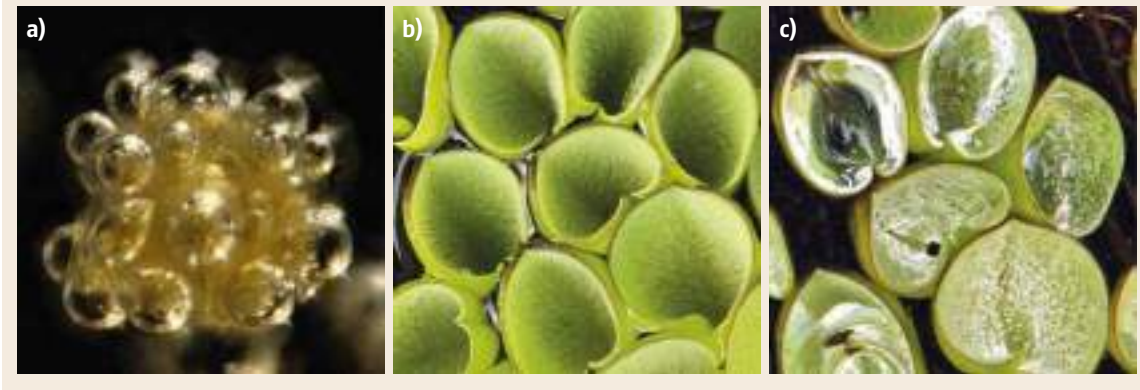

Fig. 36.27a–c Compartmentalization of surfaces generating small functional units for air retention **(a)** in microscopic dimensions in the seed of *Aeginetia indica* illustrated in Fig. 36.3 for temporary floating. A particularly refined compartmentalization system **(b,c)** is exhibited in *Salvina cucullata* in a macroscopic dimension: the superhydrophobic leaves (diameter around 1.5 cm) form hood-like compartments **(b)**, and when submersed in water **(c)** each leaf holds a very stable large air bubble

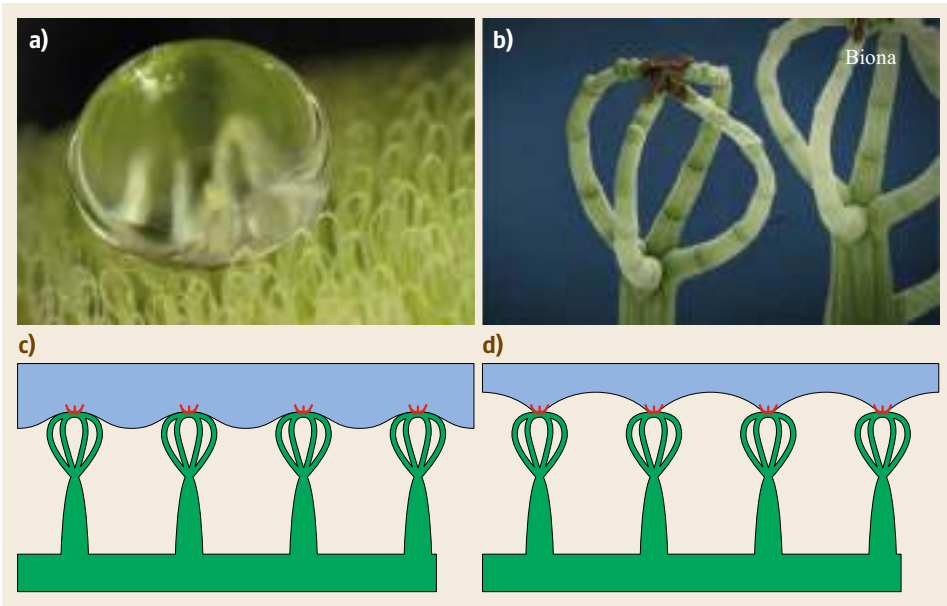

Fig. 36.28a–d The Salvinia paradox of chemical heterogeneities. **(a)** Water droplet on the eggbeater-shaped trichomes of *Salvinia molesta*. The deformations at the contact points of the droplet with the tips of the trichomes indicate an adhesion of the water; the droplet does not roll off an inclined surface. **(b)** Colored SEM image of the wax-covered superhydrophobic trichomes (green coloration) and the terminal hydrophilic four anchor cells for pinning the air–water interface. **(c,d)** Schematic of the air–water interface under dynamic hydrostatic conditions. **(b)** from [36.158]

5. *Air layers for gas exchange (respiration)* play mainly a role in animals (survey in [36.161, 162]), but also in plants like *Salvinia* that become temporarily inundated underwater.
6. *Air layers for fluid drag reduction* (survey in [36.1]). We could show that persistent air layers reduce the friction. The mechanism of this drag reduction is fairly simple: the air layer serves as a slip agent. On solid surfaces, the velocity of the water directly at the surface is zero due to the friction between the water and the surface molecules. If an air layer is mounted between the water and the solid surface, then the water streams over the air layer. The viscosity of air compared to water is 55 times lower, and because of this the air layer serves as a slip agent and the drag is reduced. Air layers as slip agents have evolved in many insects and play probably no role in plants. However, *Salvinia* provides the best example for the maintenance of permanent air layers underwater (Salvinia effect), showing the four essential criteria for air retention: hydrophobic chemistry, hair-like structures, undercuts and elasticity of the structures. Also the fifth, nonessential criteria, hydrophilic chemical heterogeneities of anchor cells within its superhydrophobic surface (Salvinia paradox, Fig. 36.28) could be found in some *Salvinia* species [36.69, 163–170].

36.6.7 Anti-adhesive *Slippery* Surfaces and Aquaplaning

Many plants have evolved special structured surfaces that hinder the attachment of animals, especially insects, to protect themselves against herbivores [36.171]. Most insects possess two different types of attachment structures: claws and adhesive pads [36.172, 173]. Whereas the former are used to cling to rough surfaces, the latter enable them to stick to perfectly smooth substrates. One strategy to reduce the attachment of insects is the secretion of epicuticular waxes that assemble into three-dimensional microstructures. The other strategy is the development of a slippery surface by inducing aquaplaning.

Aquaplaning

Several *Nepenthes* species do not possess a waxy layer, but are nevertheless fully functional insect traps. It was found that *Nepenthes* evolved another capture mechanism, which is based on special surface properties of the pitcher rim (peristome) (Fig. 36.29a,b). The peristome is characterized by a regular microstructure with radial ridges of smooth overlapping epidermal cells, which form a series of steps towards the pitcher inside. The peristome ridges (Fig. 36.29c) mostly extend into tooth-like structures at the inner edge, in between which large glands (extrafloral nectaries) are situated. Secretion of nectar by the glands attracts small insects, but also leads to a hydrophilic coverage of the surface. The plant surface microstructure combined with hydrophilic surface chemistry renders the pitcher rim completely wettable. Water droplets spread rapidly and form homogeneous thin films, which make the peristome extremely slippery for insects. When the peristome is wet, the fluid films prevent the insects' tarsal adhesive pads from making close contact with the surface, similar to the aquaplaning of a car tire on a wet road. In addition, the anisotropic microstructure of the peristome surface allows interlocking of claws only while the insect is running towards the pitcher inside, but not on the way out [36.174]. Under natural conditions the slippery water films are caused by rain, condensation and nectar secretion. In contrast to this, dry peristomes are not slippery for insects. This weather-dependent variation of peristome slipperiness leads to an intermittent and unpredictable activation of *Nepenthes* pitcher traps, which might make the evolution of specific avoidance behaviors more difficult [36.175].

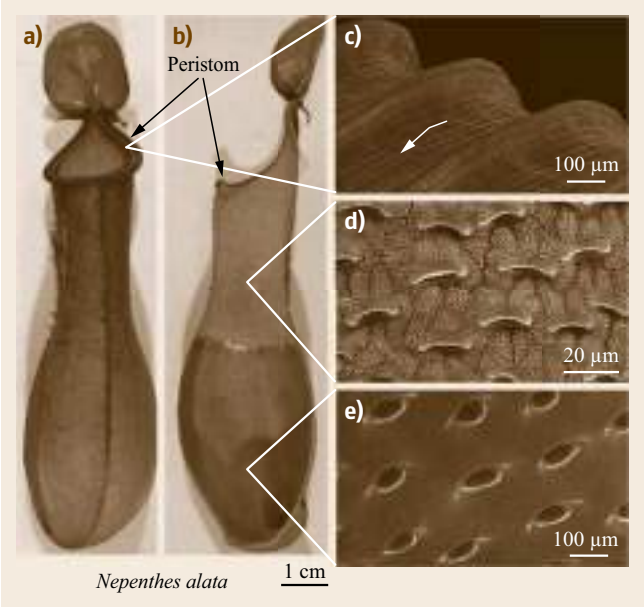

Fig. 36.29a–e Pitcher traps of the carnivorous plant *Nepenthes alata*. In **(a)** the complete pitchers trap of *N. alata* and in **(b)** a longitudinal cut through the trap are shown. **(c)** shows parallel ridges of the hydrophilic peristome. The *arrow* indicates the direction toward the inside of the pitcher (courtesy Holger Bohn). In **(d)** the waxy and slippery surface inside the trap with inactive stomata is shown. In **(e)** glands located in the digestive zone at the lower part of the trap are shown

36.7 Biomimetic Application

Bionics or biomimetics describes processes in which structures and concepts evolved by living organisms are taken and implemented into technologies (surveys in [36.1, 12, 20]). Bionics or biomimetics is an old field (historical survey in [36.12]), but functional surfaces came surprisingly very late to bionic applications. The first example was the hook-and-loop fastener by the Swiss engineer Georges de Mestral in the 1950s, popularly known as Velco®. It is based on plant surfaces (burrs). The drag reducing riblets of the shark skin were analyzed in the 1980s [36.18] and together with the self-cleaning lotus surfaces [36.2, 16] ushered in a new era of biomimetic applications – including the swimming competition in Olympic games (Sect. 36.7.6).

Surfaces in engineering are thin boundary layers, and they are exposed to the harsh physiochemical and mechanical influences of the environment. Thin layers, and in particular the biomimetic interesting hierarchical structures, have a restricted stability and durability. Nanocoatings play a most important and increasing economic role (compare [36.176]). We live – in the literal sense of Mark Twain's novel – in *the gilded age* of surface applications. The bulk of a technical solid is usually stable, but every homemaker knows the difference between the durability of a silver spoon in contrast to a silvered utensil. A medieval iron pan could still be used in the kitchen over the next centuries – but a polymer coated anti-adhesive pan lasts only a few years. The extremely long lifespan of spectacle glasses is today limited by the sophisticated and convenient anti-reflex coatings. In colloquial language, there is an obvious difference between *solid* and *superficial*. We need coating technologies – but durability and persistence is a major technical challenge for engineers and material scientists in a world of decreasing natural resources that must be used sustainably.

This section is organized using the same scheme as the previous section on plant functionality.

36.7.1 Mechanical Properties

Mechanical properties play a very important role in biomimetic composite materials, but are nearly negligible for surfaces. Technical materials available today (polymers, metals, etc.) have often superior mechanical properties.

36.7.2 Attachment

Attachment mechanisms of plants were the first biomimetic surface application and have been around since 1958 (see above) with the Velcro® hook-and-loop fasteners. Plants, in contrast to animals (e.g., geckos), are only a limited source of inspirations for attachment mechanisms.

36.7.3 Reflection, Transmission, and Absorption of Spectral Radiation

These phenomena are of great importance for biomimetics. The applications concentrate on light harvesting by bioinspired surfaces of solar panels. An appropriate model for such surfaces are the petals of *Viola tricolor* and its related species (Sect. 36.6.3). They show a highly reduced reflection of light and an optimized scattering within the petals. Additionally, they are superhydrophobic, showing a contact angle of 169° [36.177]. Temperature control under insolation (e.g., car tops, roofs) is another field of interest. Coloration technologies have always been bioinspired (like indigo and purple as ancient dyes used for millennia). Flowers exhibit sophisticated structures to intensify colors by hierarchical structuring. However, most inspirations are provided by animal coloration, like the iridescence of peacock feathers or butterfly (*Morpho*) wings. Butterflies also provide ultrablack colorations [36.178] like the Gaboon viper [36.179]. It is not by chance that the darkest technical black (Vantablack) is produced by carbon nanotubes.

36.7.4 Reduction of Water Loss

Reduction of water loss is essential for terrestrial plants, but like the many mechanical properties (Sect. 36.7.1) of minor importance for biomimetic applications. Technical materials like aluminum foil prevent loss better than a cuticle.

36.7.5 Superhydrophilicity

Superhydrophilicity has recently become relevant for technical applications, which are most diverse. Biomimetic fog-collecting meshes and other devices will probably play an increasing role in certain arid regions (e.g., Chile, Namibia) and it was shown that a biomimetic superhydrophilic hierarchical structuring increases the collection efficiency [36.155, 156, 180, 181]. *Koch* et al. [36.126] have shown that the hydrophilic *Gazania* petal structures provide a model for the design of microfluidic devices for small-volume liquid transport by capillary forces, which is beneficial in both fog harvesting and microfluidic devices.

Evidently, superhydrophilic surfaces are wettable, but the water film evaporates very fast and leads to the

fast drying *no-drop* glasses (e.g., Alltop®) and a sophisticated façade paint (StoColor Dryonic®). Drag reduction by mucilaginous surfaces seen in fish also play a technical role, and we have seen evidence in seaweed surfaces that plants have also evolved a similar technology.

The form and dynamics of bouncing droplets [36.95, 182] is influenced by surface chemistry and structure: superhydrophilic surfaces may prevent splashing, an important effect for biomedical applications (hygiene) or agriculture [36.183]. In plants, this phenomenon was analyzed in *Calathea zebrina*, a hydrophilic tropical understory plant, and its corresponding polymer replica (Fig. 36.30), by [36.124]. The antisplashing effect is promising for biomimetic applications.

36.7.6 Superhydrophobicity

The most obvious feature of many plant surfaces, superhydrophobicity has had an increasing and most diverse role in biomimetics as early as the 1990s (survey in [36.1]). Superhydrophobicity does not exist in abiotic nature and is one of the most important biomimetic applications for different aspects. Superhydrophobicity is generated in many plants by nonacosan-10-ol tubules with a diameter of 110 nm (Fig. 36.13). It could be shown that carbon nanotubes can also be used to generate superhydrophobic, even air-retaining surfaces [36.184].

Pure Water Repellency

Pure water repellency (e.g., umbrellas to textile building) is usually applied by sprays providing a sculpturing by nanoparticles on e.g., textiles (which are intrinsically hierarchically structured). It is obvious that dry conditions further reduce corrosion, and anticorrosion coatings are the focus of technical applications [36.185]. This also applies for anti-icing properties. A whole range of products and techniques are available, mostly coatings or sprays, and the product names often indicate their function (e.g., *NeverWet*). Dry surfaces may allow new dimensions in textile-based architecture owing to weight reduction during rainfall. Anti-ice and antifrost performance is increasing in importance [36.186, 187].

Self-Cleaning Lotus Effect

Self-cleaning surfaces are by far the most important applications, [36.1] and a vast literature exists beginning in 1997 [36.20, 54, 188–190]. It is also one of the most important applications in façade paints, with the added advantage that they remain functional for several decades.

The lotus effect is evolved in plants predominantly as a defense mechanisms against pathogens: the attachment e.g., of fungal spores is dramatically reduced [36.191] and no water films are available as a precondition for colonization or the formation of biofilms. This has an unexpected application: in commercial agriculture all plants are treated with pesticides and surfactants have to be added. It was shown that the application of the solution containing only the surfactant (without the active ingredient) increases the chances of infection significantly [36.191–196]. This phenomenon will hopefully lead to the development of a new generation of less aggressive, bioinspired surfactants for pesticide application.

Superhydrophobic Plants Surfaces

Superhydrophobic plants surfaces, like those of *Salvinia*, have a striking capacity to collect and adsorb spilled oil from water [36.197], a basis for biomimetic materials. Hydrophobic sand coating can be used to control deep drainage in tailings [36.198].

Air-Retaining Salvinia Effect

Air-retaining surfaces are a recent development, and only prototypes exist [36.1, 199, 200]. Fluid drag reduction of up to 30% in a hydrodynamic water channel has been measured [36.201]. The main application is seen

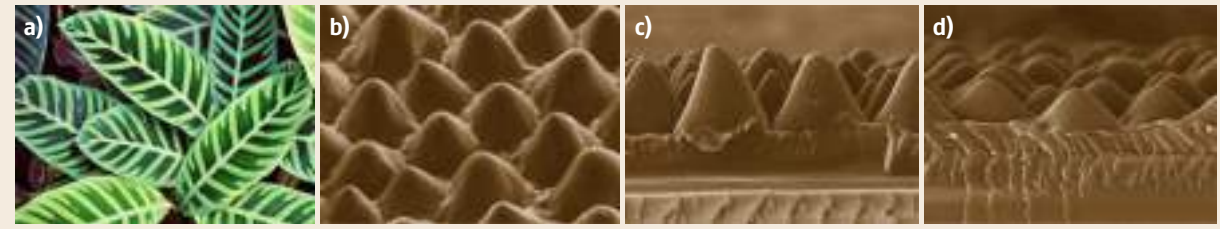

Fig. 36.30 **(a)** *Calathea zebrina* leaves with their light and dark green pattern. **(b)** SEM micrograph of the leaf surface (tilt angle 45°). SEM of the replicated dark leaf areas **(c)** and bright leaf areas **(d)** in side view (90° tilt angle). The visible color differences in the leaf are mirrored in the different shapes of the cell papillae of the light and dark surfaces areas

in ship hulls: container ships transport about 80% of the global goods and a reduction of the fuel (oil) consumption of 125 million t and of 395 million t of CO_2 is estimated. A novel technology using air-retaining grids has recently been introduced and can be combined with the existing refined microbubble technologies, where microbubbles adhere to the grid surface and the air layer under the grid can be regenerated. It is obvious that a permanently intact air layer prevents biofouling. Oil pollution is an unfortunate and unavoidable problem in our oceans. One possible solution is to create a hydrophobic barrier at the waterline of the ship to separate the ship hull from the water interface and avoid oil from creeping into the structures and suppressing the air.

Biomimetic drag-reducing boat surfaces based on shark skin riblets have been applied in America's Cup contests in 1987 and 2010; the Speedo Fastskin® swimming suits introduced in 2000 were adopted by almost all gold medal winners in the Olympic Games in Beijing 2008 (Fig. 36.31). But riblet structures reduce the friction only about 3%; the more complex Salvinia effect technologies can achieve about 30%. Swimwear covering the body almost totally was banned in 2009; however there is some evidence that in the Olympic Games in Rio 2016 a refined technology of bionic swimming suits combining superhydrophobic Salvinia-effect areas with shark riblet areas may have been applied. Underwater persistent air layers will probably fulfill many other functions like gas exchange (*plastron* in biology) or even refined sensory functions like in the backswimmer *Notonecta* [36.202].

36.7.7 Other Applications

As indicated in the preceding section, there are additional functions. Like the *aquaplaning* effect of the surfaces of the carnivorous *Nepenthes* plants that produce water films and become slippery to trap insects [36.174, 203]. In particular slippery liquid-infused surfaces (SLIPS) are of focal interest (e.g., [36.204, 205]).

Fig. 36.31a,b Some Olympic records today are also a triumph of bionics. Mark Spitz **(a)** wore his famous prebionic swimsuit in the 1972 Olympics in Munich. In contrast, biomimetic swimsuits covering almost the entire body were popular after 2000; the suits were based on the biomimetic drag-reducing shark riblet technology. At the World Swimming Championship in July 2009 in Rome almost all world records were broken using full-body biomimetic polyurethane swimsuits. Subsequently the length of swimwear was limited by the World Swimming Federation FINA in December 2009. But almost full-body swimwear is back today, as e.g., the swimming suit of Nađa Higl **(b)**: somewhat smaller than in 2009, but still covering large parts of the swimmers. Today it seems to be a high-tech combination of chemically heterogenic surfaces: shark riblets (drag reduction about 3%) and superhydrophobic Salvinia-effect (drag reduction about 30%) areas. For divers, drag reduction plays no role – the divers in Rio de Janeiro 2016 were still dressed like Mark Spitz in 1972. 36.8 Living Prototypes: Evolution of Plant Surfaces and Biodiversity

The often-used phrase *inspired by nature* for biomimetics is misleading: a nuclear reactor is inspired by natural nuclear fission or the nuclear fusion in our sun. Thus a nuclear reactor is inspired by nature – but not bionic. Biomimetics is exclusively based on living organisms and the evolution of some 10 million living prototypes (survey in [36.1]). Superhydrophobic surfaces occur exclusively in living organisms, which evolved hierarchical structured superhydrophobic surfaces based on a very limited selection of molecules. There is no evidence for the occurrence of superhydrophobic surfaces in inorganic *nature* (man-made technical products are excluded). Surfaces are the crucial interface between an organism and its environment – 3.5 billion years of mutation and selection have created a stunning diversity in an estimated 10 million different species of plants and animals (survey in [36.1]). The two basic phases with contrasting physical constraints are life in water and life outside of water.

36.8.1 Water Plants

Nonvascular primary water plants evolved in water (originally the oceans) a couple of billion years ago and have no true conductive tissue. The groups are phylogenetically very different nonrelated clades; they comprise microscopic unicellular algae up to seaweeds that might reach a height of more than 45 m in *Macrocystis*. The common feature is their wettability (superhydrophilicity) and usually the absence of hierarchical structuring: flat and mucilaginous surfaces are characteristic. In certain groups of unicellular algae (e.g., Coccolithophora and Diatoms) complex surface structures occur, but usually embedded in mucilaginous or plasmatic covers; they are probably not the environmental interface.

Vascular secondary water plants are plants of terrestrial origin, which recolonized aquatic habitats in freshwater (e.g., *Elodea, Potamogeton*) or even the oceans like seagrasses (e.g., *Posidonia, Zostera*). They exhibit the characteristic superhydrophilic flat surfaces, often becoming mucilaginous by biofilms, as primary water plants. However, they retain the ability of their ancestors to produce superhydrophobic surfaces when leaves or flowering shoots emerge from the water (e.g., in *Myriophyllum*). The ancestral nonvascular *Bryophyta* (mosses, hornworts, and liverworts) depend on the uptake of water through leaves and are superhydrophilic, occasionally exhibiting refined absorption structures like *Rhacocarpus* [36.153]. However, some (e.g., *Funaria hygrometrica*) have the ability to produce superhydrophobic wax covers in their spore capsules (Fig. 36.32b); the same is true for propagation structures of lichens (Fig. 36.32a) [36.206] and the aerial hyphae of fungi (Fig. 36.32c) or even the capillitium of slime molds (Fig. 36.32d) [36.1].

36.8.2 Land Plants

True land plants are the vascular or higher plants, a well-defined phylogenetic unit. They comprise the ferns, clubmosses and horsetails, gymnosperms (including conifers) and the flowering plants (angiosperms). Higher plants evolved with the conquest of land in the late Ordovician or Silurian, 430–500 million years ago and evolved mechanically stabilizing lignose vascular tissues and a protective polymer layer, the cuticle (Sect. 36.3) on their stem and leaf surfaces; as a consequence of this rather impermeability, surface pores (stomata) evolved to enable and control gas exchange. It was shown by a phylogenetic analysis [36.1] that superhydrophobicity caused by epicuticular wax crystals evolved simultaneously with the conquest of land – a possibly overlooked evolutionary key invention for plant life outside of water and probably also for

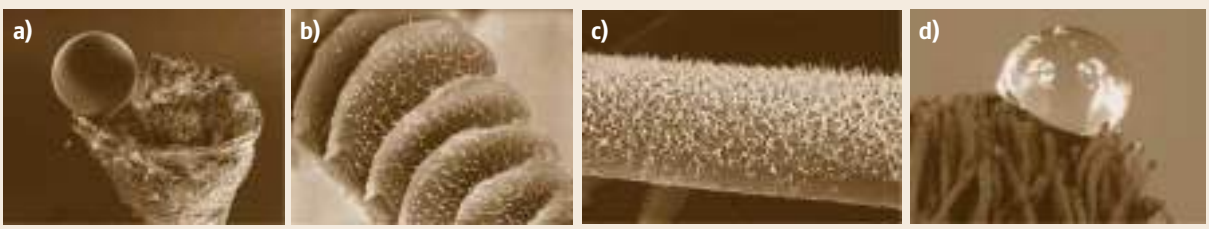

Fig. 36.32a–d Superhydrophobicity in lichens mosses, fungi, and slime molds. **(a)** Fruiting body of the lichen *Cladonia chlorophaea* with water droplet. **(b)** Peristome of the moss *Funaria hygrometrica*, covered by wax rodlets. **(c)** The aerial hyphae of the gray mold (*Botrytis*) are covered by wax-like crystals. **(d)** The fruiting body (capillitium) of the slime mold *Stemonitis* possesses a superhydrophobic surface caused by a granular layer of unknown chemical composition

insects. One of the most common waxy substances is the fatty secondary alcohol nonacosan-10-ol, which is responsible for the superhydrophobicity of many ferns, conifers or even lotus leaves as long ago as 250 million years [36.1].

Some 450 000 different species of plants are part of the astonishing biodiversity of our planet, which, including animals, comprises some 10 million species – but we know of less than 20% of them. Plants have evolved most intriguing functional surfaces over millions of years, like in the lotus (*Nelumbo*) or the floating ferns (*Salvinia*). Evolution is a slow process spanning billions of years. Mutation and selection (*trial and error*) exploited all constructional possibilities within this time and with the limited materials. But millions of years of research and development for technical engineering today is not a possibility: materials science has a goal of fabricating a particular product within a limited time, using experimental trial-and-error approaches, calculation and modeling. We lose a high amount of biodiversity in our changing world and it has been brought to our attention [36.12, 207] that this also means the loss of biological role models, the *living prototypes* for engineers.

36.9 Conclusions

The diversity of plant surface structures is a result of several billions of years of evolutionary processes. Plants evolved a stunningly high diversity of surfaces and functionality for their interaction with the environment – the self-cleaning properties of the lotus is only one example. Millions of years of mutation and selection, trial and error, mean free information for engineers and materials scientists.

Bionics is an old field of research and development starting around 1800 – but surfaces played a surprisingly late role for biomimetic applications, the only exception is the hook and loop fasteners (Velcro®) in the 1950s based on burrs. The publication of the lotus effect in 1997 [36.16] created awareness by engineers and materials scientists, and terms like *superhydrophobicity* came into use in the last two decades and opened a new era in surface technologies (survey in [36.1]). Surfaces play an increasing role, and the global market for nanocoatings is estimated to reach 14.2 billion US dollars by 2019 [36.176].

Biological surfaces have provided a remarkable number of innovations in the last three decades. Surface technologies have been largely influenced by research on biological interfaces and came rather late into focus in technical innovations. All data indicate we are only in the beginning of a new era of biologically inspired surface technologies.

Understanding biological surfaces is crucial – we have shown that we are still in the beginning of this process. But we are also in the beginning of a dramatic loss of biodiversity in the Anthropocene. Some 10 million different species (possible biological role models) exist – we lose a high amount of biodiversity in our changing world and it has been brought to our attention [36.12, 207] that this also means the loss of biological role models, the *living prototypes* for engineers. Bionics is another intrinsic value to the diversity of life that should be treasured.

Acknowledgments. This survey is based on over three decades of research on surfaces by a large working group with ever-changing members: first and foremost, we acknowledge all the students who had successful theses in this field. Their names can be found in the papers quoted in the references. We acknowledge the discussions with colleagues and friends in particular we would like to thank Horst Bleckmann (Bonn), Alfred Leder, Martin Brede (both Rostock), Thomas Schimmel, Stefan Walheim, Markus Moosmann, Torsten Scherer (all KIT Karlsruhe), Walter Erdelen (former UNESCO Paris), Anna-Julia Schulte (Euskirchen), Daud Rafiqpoor, Birte Böhnlein, Peter Häger (all Bonn), Gerhard Gottsberger (Ulm), Stanislav Gorb (Kiel), Georg Noga (Bonn), and Maximilian Weigend (Bonn). Technical assistance was provided over the years by Hans-Jürgen Ensikat, the late Wolfgang Roden, Alexandra Runge, Bernd Haeseling, and Danica Christensen. Our work in bionics and biodiversity was supported by the Deutsche Bundesstiftung Umwelt DBU, the German Research Council DFG, the Federal Ministry for Science and Education BMBF, and the Academy of Science and Literature in Mainz.

37. Bioinspired Nanostructured Antibiofouling and Anti-inorganic Surfaces

Bharat Bhushan

In this chapter, biofouling and inorganic fouling are introduced. I then summarize fields susceptible to fouling followed by discussion of biofouling and inorganic fouling formation mechanisms, antifouling strategies from living nature, and current prevention and cleaning techniques. Finally, demonstrations of the antifouling uses of bioinspired rice leaf surfaces are presented. The data shows that micropatterned surfaces facilitate antifouling.

Fouling is generally undesirable for most applications [37.1, 2]. Fouling includes biological fouling (commonly referred to as biofouling) and inorganic fouling. Biofouling is the accumulation of unwanted biological matter on surfaces, with biofilms created by microorganisms and macroscale biofouling (simply called macrofouling) created by macroorganisms. Inorganic fouling results from the accumulation of particles including deposits of dirt, corrosion, crystals, suspended particles, oil, and ice. The type and extent of fouling depends on the environment, inorganic deposits, and organisms. In biomedical contexts, fouling typically takes the form of biofilms [37.3–7], whereas marine and industrial biofouling typically includes macrofouling [37.8–11] and inorganic fouling [37.12–15].

Bixler and *Bhushan* [37.16] presented a review of the field. On the basis of the review, we begin with discussion of fields susceptible to fouling, followed by biofouling and inorganic fouling formation mechanisms, antifouling strategies from nature, current prevention and cleaning techniques in antifouling, and end with demonstrations of the use of bioinspired rice leaf surfaces for antifouling, based on *Bixler* et al. [37.17].

37.1 Fields Susceptible to Fouling

Fouling is prevalent in the medical, marine, and industrial fields, causing significant health risks and loss of resources [37.4, 9–11]. Examples of various types and problems incurred through fouling are shown in Table 37.1; the Table highlights the many applications susceptible to biofouling and inorganic fouling [37.16].

Figure 37.1 shows that biofouling in the human body can occur in regions such as prosthetic implants, biosensors, catheters, dental implants, and medical equipment [37.16]. Biofouling may lead to implant rejection, malfunction of biosensors, and spread of infectious diseases [37.4–7]. Biofilms on medical devices including a ventilation tube, needleless connector, and pacemaker wire are shown in Fig. 37.2 [37.16]. Biofouling can also occur in marine environments where noticeable marine growth

Images include a ventilation tube **(a)** [37.18], needleless connector **(b)** (adapted from Janice Carr), and a pacemaker wire **(c)** (after [37.19]). Such biofilms may lead to infections that require device removal since antibodies are often ineffective

appears on ships and underwater structures. This magnifies ship drag, corrosion, fuel consumption, and engine stress [37.10, 15, 20–22]. Industrial biofouling occurs in areas such as power plants, water treatment systems, and food or beverage industries, as shown in Fig. 37.3 [37.16]. Issues include pipe blockage, decreased reverse osmosis (RO) membrane flux, contaminated water, and reduced heat exchanger efficiency [37.7, 9, 12].

Inorganic fouling creates concern in many industries with decreased performance in applications ranging from power production to consumer products. For example, the interior surface of a heat exchanger tube from a nuclear reactor is shown in Fig. 37.4 [37.16], and corrosion deposits are readily apparent, which leads to inefficient performance [37.23], www.hcheattransfer.com. Inorganic fouling also includes undesirable fingerprints on transparent surfaces such as electronic touch screens (mobile phones, tablets, music players, GPS devices), eyeglasses, computer screens, and window glass [37.26]. Furthermore, inorganic fouling includes ice on airplane wings, helicopter blades, oil platforms, power lines, locks and dams, and wind turbines [37.27, 28].

Table 37.1 Fields susceptible to biofouling including common examples (adapted from [37.16])

Type	Problems
Medical	
Orthopedic implant	Removal due to infection
Respirator	Ventilator-associated pneumonia
Contact lens	Eye infection
Catheter	Urinary tract infections
Hemodialysis	Infectious break-outs
Teeth/dental implant	Periodontal disease, gingivitis
Biosensor	Failure from fibrous encapsulation
Marine	
Ship hull	Increased fuel consumption
Ship engine	Increased stress from extra drag
Marine platform	Increased marine structure load/stress/fatigue
Metal	Increased biocorrosion
Industrial	
Membrane	Reduced flux
Fluid flow	Frictional loss in pipes
Drinking water	Pathogens in potable water
Food, paper, and paint	Food spoilage and worker health risks
Metal cutting fluid	Filter blockage and worker health risks

37.2 Biofouling and Inorganic Fouling Formation Mechanisms

In this section, we discuss the type, formation, and morphology characteristics of biofouling and inorganic fouling (based on [37.16]).

37.2.1 Biofouling Formation

In biofilms, microorganisms adhere to one another and the substrate with an adhesive called the extracellular polymeric substance (EPS). The biofilm continues to grow and become more diverse by attracting additional microorganisms through chemical *messages*. Colonization is the process of organisms collecting and growing on a surface, and the morphology is characterized by the thickness, density, structure, composition, bioadhesive strength, and weight of the fouling organisms [37.7, 11, 18, 19, 29, 30]. In the marine environment, this usually starts with the formation of a biofilm that attracts larger macrofoulers [37.3, 10, 11, 31]. For instance, tubeworms prefer to settle on biofilms, whereas bryozoans and barnacles do not require a biofilm [37.32]. Figure 37.5 illustrates the five-stage colonization process, which includes initial attachment, irreversible attachment, initial growth, final growth, and dispersion (adapted from D. Davis, [37.16]). Initial attachment starts the colonization process, which begins within a few days to a few weeks in a nutrient-rich environment. The biofilm covered surface then attracts other organisms that may have been previously deterred. Initial attachment of microorganisms is reversible, but once they secrete the EPS, the bond becomes irreversible. This permanent attachment allows initial growth, final growth, and dispersion [37.3, 10, 31, 33].

Biofouling growth rates depend on the organism, substrate, flow velocity, shear stress, and temperature [37.10, 34, 35]. Organism transportation to a surface is either passive from the current or active from the propagule, juvenile, or adult organism. Active mechanisms include electrostatic repulsion, Brownian motion, turbulent pulsations, and cell outgrowths [37.10, 32]. Underwater environments are ideal for biofouling since currents deliver nutrients and carry away wastes, promoting colonization by planktonic and sessile organisms.

The tenacity of the biofouling is dependent upon bioadhesion [37.3, 10, 31, 33]. Bioadhesion is the adhesion strength of biofouling on a hard surface [37.36]. This depends on the organism type, the substrate, and the separating fluid [37.37], and is related to influences of electrostatic forces and surface wettability [37.38–41]. Biofilm bioadhesion is a two-stage process, starting with the initial attachment and then the irreversible attachment. Initial attachment is controlled by a physical adhesion between the microorganism and the substrate. Also known as adsorption, the initial colonists attach to a surface through weak, reversible van der Waals bonds, which are slightly stronger than the electrostatic repulsive force. Irreversible attachment is accomplished with secretion of the EPS, which exhibits a sponge-like matrix. This adhesive permanently bonds the microorganisms to one another and collectively to the surface [37.3, 10, 42].

37.2.2 Inorganic Fouling Formation

Inorganic fouling is composed of nonbiological particles that may form in addition to or independently of biofouling. Particles originate from corrosion, crystallization, suspended particles, oil, and ice. For instance, salts from aqueous solutions crystallize and deposit

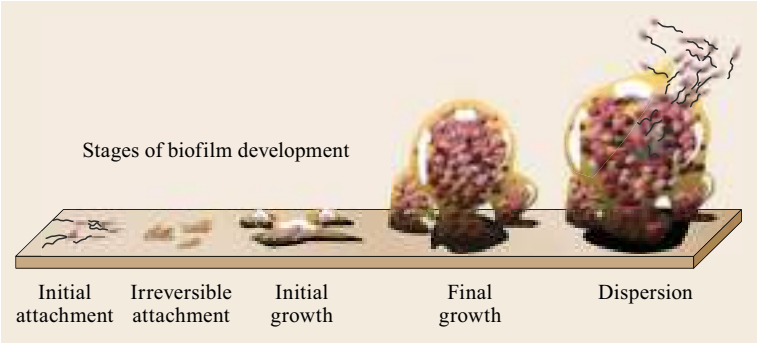

Fig. 37.5 Biofilm development process. Schematic illustrates the five-stage colonization process (adapted from D. Davis)

on surfaces. Other deposits may result from minerals found in water such as magnesium, calcium, and barium [37.7, 9, 12, 16].

Types of inorganic fouling include particulate, freeze, and gas stream particulate fouling. Particulate fouling occurs when suspended solid particles deposit onto a heat transfer surface [37.43]. Deposition of crystals from freeze fouling occurs in locations such as cold-region oil pipelines when waxy hydrocarbons make contact with cold pipe walls. Gas stream particulate fouling occurs in gas lines, reactors, combustion chambers, and heat exchangers. This includes mineral, organic, and inorganic particles, which are common in oil or gas combustion systems [37.44]. Biofouling may initiate inorganic fouling, where biocorrosion causes the formation of corrosion particles. Such fouling is prevalent in boilers, cooling condensers, desalination plants, food-processing equipment, geothermal plants, and oil-production equipment [37.14]. Heat exchangers can develop hard deposits called *scale* or more porous deposits such as *sludge* [37.13].

37.2.3 Surface Factors

Biofouling and inorganic fouling depend on various surface factors including wettability, microtexture, and contours [37.8, 10, 11, 16, 31, 45]. For instance, bryozoan and mussel larvae prefer hydrophobic surfaces [37.46]; hydroids, bryozoans, and ascidians prefer microtextured surfaces; larvae, sponges, barnacles, ascidians, and mollusks prefer light-colored surfaces; barnacles prefer convex contours; and calcareous sponges prefer concave contours [37.10].

Surface wettability influences fouler colonization, with surfaces ranging from superhydrophobic to superhydrophilic [37.8, 10, 11, 31, 45, 47]. Water droplets on a hydrophobic surface will *bead up*, whilst droplets on a hydrophilic surface will spread out evenly.

Low adhesive, superhydrophobic surfaces promote contaminant removal with the application of liquid through *self-cleaning*. Sheeting action of sliding liquid on a superhydrophilic surface can promote self-cleaning, where the liquid helps collect and remove fouling and disrupt microorganism settlement [37.48]. In general though, microorganisms prefer to colonize hydrophilic surfaces, although some actually prefer hydrophobic surfaces. For example, *Ulva linza* prefer hydrophobic surfaces, whereas *Balanus amphitrite* prefer hydrophilic surfaces. Furthermore, microorganisms such as *Ulva linza* attach more easily to hydrophobic surfaces, but experience decreased adhesive strength [37.40].

Surface microtexture influences organisms such as hydroids, bryozoans, and ascidians that seek shelter against strong currents by settling in grooves, pits, cracks, and crevices [37.8, 10]. Microorganisms prefer to settle in areas slightly larger than themselves for maximum protection and surface area contact with the substrate. The antifouling occurs when the gap between features is less than the approximate size of fouling microorganisms [37.16, 40, 49–52]. Fewer attachment points between the microorganism and substrate translate into lower bioadhesive strength [37.53]. Bioadhesion is also affected by the effectiveness of EPS flowing into crevices formed by surface roughness, which depends on the adhesive viscosity. Furthermore, when the adhesive only contacts the surface asperity peaks or tops of microtexture ridges, the applied force to break bonds is significantly reduced [37.54].

Several bioassay antifouling experiments have been performed with different microorganisms and microstructured surfaces – using pillars, ribs, and a combination thereof with various diameters, widths, lengths, heights, and pitches [37.17, 49–53, 55, 56]. Laboratory research suggests that samples with appropriately sized topographies prevent colonization by various microorganisms including green algae *Ulva* spores [37.49, 51], porcine cardiovascular endothelial cells [37.49], and *Balanus amphitrite* cyprids [37.50]. Such microorganisms have been exposed to samples and the antifouling effectiveness is determined by counting settled cells using light [37.49] and fluorescence microscopy [37.51].

Up to 85% spore settlement reduction is reported with microsized ribs when compared to flat control samples [37.49]. This reduction is attributed to the microsized feature spacing that is slightly smaller than the microorganisms under investigation. The so-called engineered antifouling microtopographies are designed to target specific microorganisms based on their shape and size [37.50, 51]. *Bixler* et al. [37.17] reported that reduction in biofouling occurs even if the microsized feature spacing is larger than the microorganisms. Sharp feature edges discourage the settling and eventual colonization of microorganisms on the surface.

Figure 37.6 shows surface topography antifouling mechanisms demonstrating wettability and texture properties that influence microorganism settlement and colonization [37.16]. Microorganisms search for an ideal site to settle, which can depend on parameters such as wettability and texture [37.38, 40]. During the search process, microorganisms will settle, move on, or expire in the process. In general, biofouling on superhydrophobic surfaces wash off more easily (self-cleaning) as compared to superhydrophilic surfaces. The images at the bottom of Fig. 37.6 show a variety of examples found in nature, including the hydrophilic elephant ear (*Alocasia odora*) [37.39], microtextured shark skin (*Carcharhinus galapagensis*) [37.57], hydrophobic water fern (*Regnellidium diphyllum*) [37.39], and superhydrophobic nanocolumns on an insect wing (*Cicada orni*) [37.58].

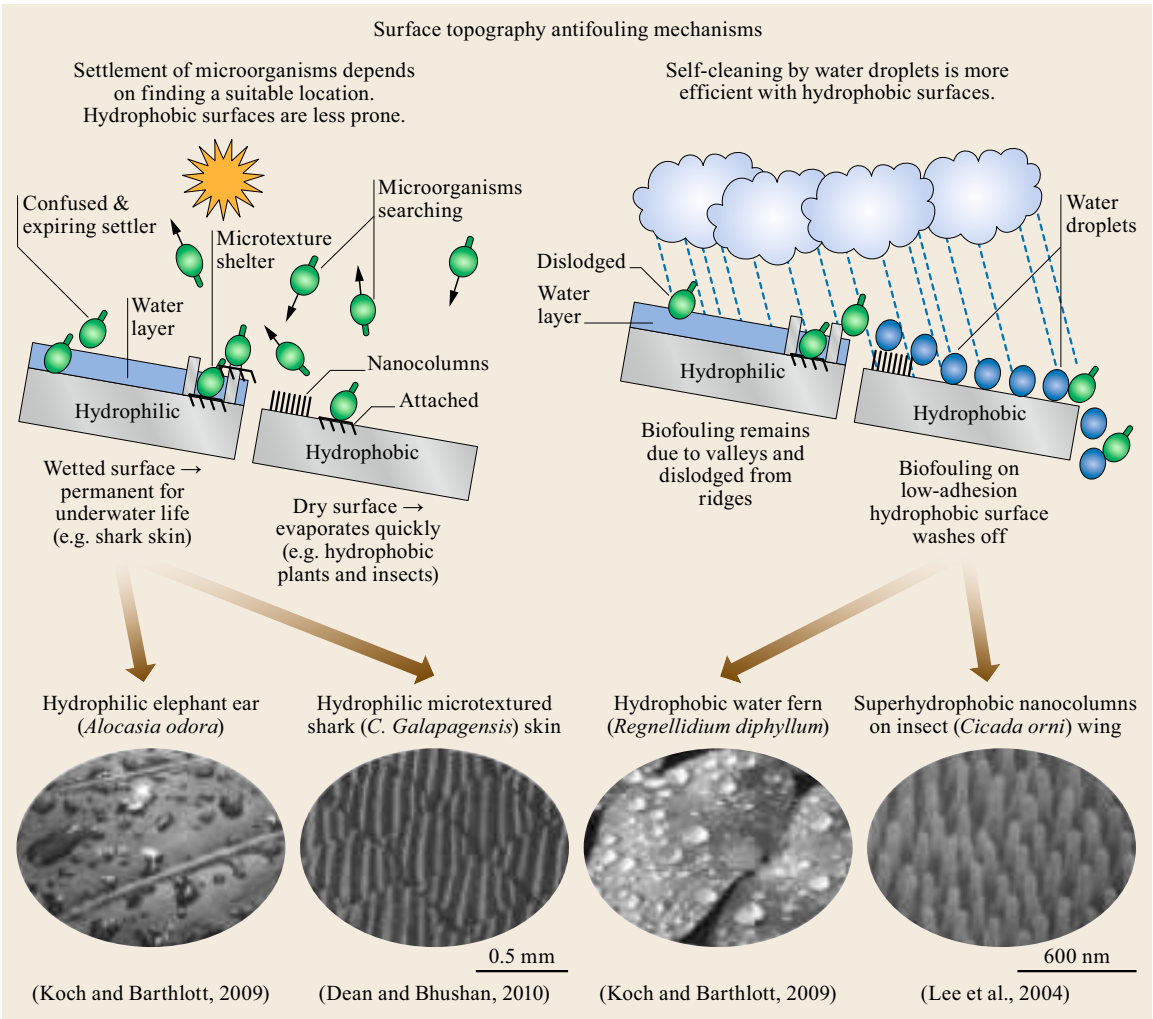

Fig. 37.6 Schematic shows surface topography antifouling mechanisms demonstrating wettability and texture properties that influence microorganism settlement and colonization (adapted from [37.16]; *Koch* and *Barthlott*, 2009 [37.39]; *Dean* and *Bhushan*, 2010 [37.57]; *Lee* et al., 2004 [37.58])

37.3 Antifouling Strategies from Living Nature

In living nature, many plants and animals thrive due to their antifouling and self-cleaning characteristics [37.16, 32, 39, 59–62]. *Bixler* and *Bhushan* [37.16] provide a number of examples of antifouling strategies from living nature, including a variety of both ambient and aquatic species. Common antifouling mechanisms include wettability, low drag, low adhesion, microtexture, grooming/mechanical cleaning, and chemical secretions [37.16].

Desirable wettability properties include superhydrophobic and superoleophobic low-adhesion self-cleaning surfaces that resist fouling, as liquids wash away contaminant particles [37.16]. Figure 37.7a shows various superhydrophobic examples including the lotus leaf, rice leaf, butterfly wings, and hydrophobic pigeon feathers. Figure 37.7b shows examples of superoleophobic-in-water fish scales and shark skin, which exhibit low drag during swimming.

Superhydrophobic lotus leaves exhibit antifouling with self-cleaning properties [37.64, 65]. It is believed that since lotus plants thrive in humid, marshy environments, self-cleaning prevents unwanted fouling, which may inhibit photosynthesis. Lotus leaf hierarchical micropapillae, which are microbumps superimposed with low surface energy waxy nanotubules, provide superior self-cleaning properties [37.64, 66]. In nature, rain droplets impact the lotus leaf surface and effectively roll off due to the water repellency effect. This leads to self-cleaning, where droplets collect and remove any contaminant particles (Fig. 37.8a). It should be noted that many other plant species also exhibit self-cleaning properties due to superhydrophobic and low adhesion characteristics.

Fish skin and the skin of fast-swimming sharks exhibit low drag, antifouling, and self-cleaning properties [37.57, 67]. Fish skin is covered by oriented scales with concentric rings overlapping and hinged such that water flow is from head to tail. Sharks exhibit low drag skin in order to swim quickly to catch prey, and thus antifouling is necessary in order to maintain the low drag. Shark skin consists of microstructured riblets on dermal denticles to reduce drag and prevent biofouling, and in comparison to other aquatic species such as whales, which are often covered with barnacles, sharks remain clean (Fig. 37.8b) [37.16, 67].

Rice leaves and butterfly wings exploit a combination of antifouling properties from the shark skin and lotus leaf [37.17, 63]. It is believed that since rice plants thrive in humid, marshy environments, self-cleaning prevents unwanted fouling, which may inhibit photosynthesis. Since butterflies are fragile and unable to clean their wings, such properties are critical to maintain structural coloration and flight control [37.68]. Hierarchical structures consisting of micropapillae superimposed with waxy nanobumps in rice leaves and microgrooves on top of shingle-like scales in butterfly wings provide superhydrophobicity and low adhesion exhibiting the lotus effect. Sinusoidal grooves in rice leaves and aligned, shingle-like scales in butterfly wings provide anisotropic flow exhibiting the shark skin effect. A combination of anisotropic flow, superhydrophobicity, and low adhesion leads to drag reduction and antifouling. Because of these anisotropic flow characteristics, droplets roll down the blade of the rice leaf and axially away from the butterfly body [37.63, 69]. In addition, the hierarchical structure reduces coverage and colonization of biofouling products [37.17].

Pigeon feathers are hydrophobic and remain clean [37.70]. The feathers are formed by barbs and barbules. The hydrophobic properties of the outer feathers (pennae) are due to a combination of this complex feather microstructure and the presence of preen oil (preen wax) spread mechanically by the bird during the preening procedure. Air pockets are then trapped by the feather microstructure, responsible for hydrophobicity.

Certain microtextured surfaces resist biofouling as organisms seek ideal surface features for settlement, and may be deterred if no suitable surface is found. Various examples are shown in Fig. 37.6.

Grooming/other mechanical cleaning is the physical removal of biofouling from the host, which effectively controls slow- and fast-growing biofouling. Decapods and crustaceans groom other creatures with special brush structures which remove foulers from gills and appendages. Echinoderms and bryozoans use special structures called pedicellaria to groom macroepibionts, while crayfish depend on *Branciobdellid annelids* to feed on foulers in their gills [37.16].

Any physical action that prevents or removes fouling may be present in conjunction with other antifouling mechanisms, such as low drag, low adhesion, and chemical secretions. Figure 37.9a illustrates a mechanical cleaning example, combining wiping with chemical secretions, as demonstrated in the human eye via the lachrymal gland secreting tears, puncta collecting tears, and the eyelid wiping the cornea [37.71]. Chemical secretion methods range from preventing to removing biofouling. Figure 37.9b shows the red seaweed (*Delisea pulchra*), which uses a halogenated furanone to manipulate colonizing bacteria *attraction* messages [37.72]. Other chemical examples include

snails that leave a predatory mucous trail, antimicrobial coral egg shells, mucus on shark skin, and antifouling chemicals produced by the bacteria *Roseobacter gallaeciensis* [37.16]. Furthermore, blood cell protein adsorption and cell adhesion are inhibited with phosphorylcholine [37.16].

37.4 Antifouling: Current Prevention and Cleaning Techniques

Bixler and *Bhushan* [37.16] report that reducing or eliminating fouling is accomplished through a variety of methods in medical, marine, and industrial applications. Common controls exist, such as microorganism-resistant coatings and self-cleaning low-adhesion surfaces. Improving biocompatibility can also reduce medical biofouling, since microorganisms will be less likely to target any implanted device.

37.4.1 Prevention Techniques

Medical biofouling is of great concern for the health of patients [37.16]. Fouling of medical devices can significantly alter the properties of the fouled materials. Multiple coatings and antifouling techniques have been reported [37.24], and many incorporate hydrophobic polymers with antimicrobial properties [37.16, 73]. Example applications include catheters, endotracheal tubes [37.74], and orthopedic hip implants. Superhydrophobic and low-adhesion *self-cleaning* surfaces are believed to minimize protein bioadhesion, and antimicrobial surfaces reduce ambient microorganisms [37.33]. Surfaces with superhydrophilic polyethylene glycol or polyethylene oxide exhibit less protein adsorption and bioadhesion [37.54, 75]. Other coating examples include self-assembled monolayers (SAMs), which are desirable since they coat surfaces with a molecularly thick biocompatible film. This is especially important for applications such as biomedical micro/nanoelectromechanical systems (BioMEMS/NEMS) [37.1, 76]. Figure 37.10a from *Bixler* and *Bhushan* [37.16] shows an orthopedic hip implant cov-

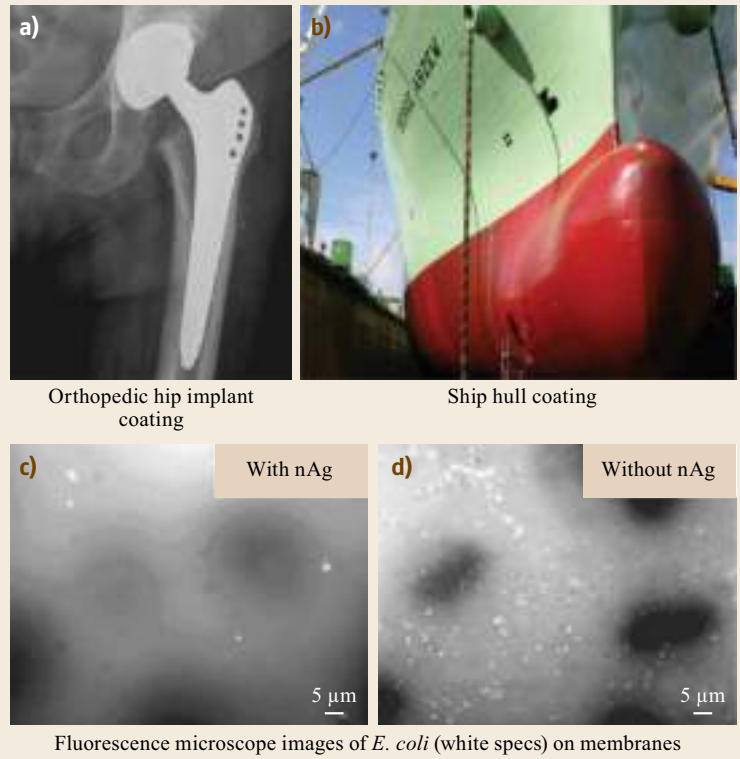

Fig. 37.10a–d Medical, marine, and industrial antifouling coating examples [37.16]. ered with a biocompatible coating designed to control biofouling, wear rate, and promote bone growth [37.78, 79].

Additional medical prevention techniques include hydrophilic red blood cell plasma membranes that reduce biofouling in medical devices and other synthetic membranes [37.80]. For instance, Advanced Hydro hydrophilic polymer coatings on water purification and filtration membranes provide a 30–50% reduction in fouling (www.advancedhydro.net). Clean Membranes utilize a *smart-comb* copolymer in ultrafiltration membranes to provide antifouling and increased permeability (www.cleanmembranes.com). Superhydrophilic and antimicrobial nanoparticles in a polyamide thin film coating provide antifouling for reverse osmosis (RO) membranes (www1.cnsi.ucla.edu). Furthermore, studies show success using titanium dioxide (TiO_2) nanoparticles as a thin film on reverse osmosis membranes to control biofouling due to the photocatalytic effects that reduce bacteria [37.81]. Similarly, ultrafiltration membranes impregnated with antimicrobial and hydrophilic silver nanoparticles (nAg) provide antifouling benefits. Figure 37.10c,d from *Bixler* and *Bhushan* [37.16] compares such treated and untreated polysulfone ultrafiltration membranes, showing fewer *E. coli* (*Escherichia coli*) attached to the nAg membrane [37.77].

Tributyltin coatings have been efficacious in marine antifouling applications, and were commonplace. Unfortunately, toxicity and other properties make tributyltin coatings unsuitable for in vivo use. Because of tributyltin toxicity to marine organisms, antifouling preparations containing it were banned in 2008 by the International Maritime Organization, adding urgency to the development of more environmentally friendly antifouling and foul-release coatings. As a result, many researchers have been exploring environmentally friendly methods such as new nontoxic antifouling paints and foul-release coatings [37.8, 10, 11, 82]. Marine foul-release coatings are nontoxic hydrophobic surfaces that promote self-cleaning. Nano/microtextured surfaces control surface energy, charge, conductivity, porosity, roughness, wettability, and friction [37.83]. Hydrophobic materials such as fluoropolymers and silicone elastomers are nontoxic, adhesion resistant, environmentally friendly, and easy to clean [37.84]. Siloxane elastomers provide a combination of lower elastic modulus and lower surface energy, creating a hydrophobic, low-stick surface. Silicone foul-release coatings are used for some

quick-moving boats, but wear away over time [37.54, 87]. Figure 37.10b from *Bixler* and *Bhushan* [37.16] shows a foul-release organic tin-free hull coating called *Green Ocean Coating Heavy Duty* by Advanced Marine Coatings, whose smoothness and hardness reduces cleaning cycles (www.bayermaterialscience.com).

Industrial antifouling is accomplished similarly to marine antifouling, with coatings that prevent and remove fouling [37.16]. For instance, industrial heat-

exchanger applications utilize SAMs to reduce bioadhesive strength between foulers and a heated surface, using low surface energy hydrophobic properties. Materials such as silicon can withstand temperatures up to 200 °C whilst materials such as hexadecyl disulfide can withstand up to 225 °C. SAMs furthermore offer corrosion protection by limiting the oxygen and water diffusion at the substrate surface. This technique could be widely used for heat exchangers but needs long-term durability testing [37.88].

37.4.2 Self-Cleaning Surfaces and Cleaning Techniques

Even though fouling prevention is the goal, in many cases fouling is not completely preventable and a surface must be cleaned. In response, several self-cleaning coatings have been developed for various applications. *Bixler* and *Bhushan* [37.16] report example self-cleaning products including hydrophobic paints, roof tiles, and fabrics as well as self-cleaning hydrophilic windows and membranes. Examples are Lotusan paints by Sto (www.stocorp.com), Tegotop paints by Degussa (www.goldschmidt.com), Erlus Lotus roof tiles (www.erlus.com), NanoSphere fabrics by Schoeller Technologies (www.schoeller-textiles.com), and SunClean glass by PPG Industries (www.ppg.com). Self-cleaning is demonstrated with the hydrophobic Lotusan roll on and Tegotop spray paints that create a microstructure surface (www.stocorp.com; www.goldschmidt.com), hydrophobic Erlus Lotus roof tiles with an etched surface finish (www.erlus.com), and hydrophobic NanoSphere fabrics with integrated nanoparticles (www.schoeller-textiles.com). Self-cleaning hydrophilic SunClean glass with titanium dioxide uses the sheeting action of water to efficiently gather and remove contaminants (www.ppg.com). Figure 37.11 shows the improved cleanliness with Lotusan hydrophobic self-cleaning paints on concrete and stucco (www.stoco2rp.com), and the improved clarity with SunClean hydrophilic self-cleaning glass (www.ppg.com) [37.16].

Physical cleaning and chemical disinfecting are often considered effective methods to remove fouling [37.7, 9, 11, 16, 89, 90]. Most employ mechanical methods such as a manual scrubbing to disrupt and remove the fouling. Figure 37.12 illustrates common methods of cleaning and disinfecting such as medical sterilization, chemical disinfection, high-pressure water spray, automatic brush scrubbing, and membrane cleaning techniques [37.16]. Included are a steam sterilization medical autoclave, Listerine antiseptic mouth rinse, water spray on a low-adhesion ship hull, automatic brush washing system, and microfiltration membrane using sonication, chemicals, and water backwash [37.16, 86]. Disinfecting is commonly employed in dental applications with antiseptic mouth rinses such as Listerine. For example, the active ingredient chlorhexidine attacks and reduces dental biofilm to control plaque and gingivitis in the oral cavity [37.91]. The biofilm is reduced when the individual bacteria walls rupture (www.jjdentalprofessional.com). Mouth rinses combined with brushing and flossing increase the effectiveness, since such *mechanical methods* disrupt the biofilm [37.90].

37.5 Bioinspired Rice Leaf Surfaces for Antifouling

In this section, we present data on an antibiofouling study carried out by *Bixler* et al. [37.17] on rice leaf-inspired surfaces. The rice leaf is particularly intriguing due to its relatively simple micropapillae morphology. Bioinspired rice leaf surfaces using microsized pillar patterns can be produced with silicon master patterns fabricated by photolithography [37.92]. Sample geometrical dimensions are based on actual rice leaf morphology. Actual rice leaf surfaces are covered by a sinusoidal pattern of micropapillae with height 2–4 μm, diameter 2–4 μm, pitch 5–10 μm, and peak radius 0.5–1 μm [37.63, 69].

37.5.1 Fabrication of Micropatterned Samples

The bioinspired rice leaf surface shown in Fig. 37.13 was created to replicate the rice and butterfly wing effect, and was designed to include anisotropic flow and superhydrophobic characteristics. Samples were created using silicon master patterns and the soft-lithography technique [37.92]. Silicon master patterns with pits (negative versus positive features) were fabricated in order to emboss polymer films and to accurately produce master patterns. Polydimethylsiloxane (PDMS) replicas were produced from silicon master patterns using a three-step soft-lithography procedure [37.92]. PDMS (184 Silicone Elastomer by Dow Corning) was chosen due to its low surface energy property which leads to high contact angle. A nanostructured superhydrophobic coating with 50 nm hydrophobized silica nanoparticles and methylphenyl silicone resin was applied to make them superhydrophobic.

Micropatterned plastic sheets were also produced using a commercial hot embossing procedure in a clean room environment [37.92]. The hot embosser pro-

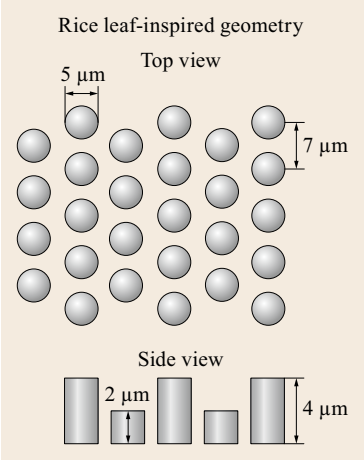

Fig. 37.13 Rice leaf-inspired geometry for antifouling. Shown are micropatterned surfaces with dual height pillars. Pillars are arranged in a hexagonal array in order to maintain consistent gaps to promote antifouling (adapted from [37.92])

duced single-sided embossed plastic sheets from a silicon master pattern using a combination of heat and pressure. Poly(methyl methacrylate) (PMMA) plastic sheets were selected, which were optically clear and 175 μm in thickness. PMMA molds relatively easily due to its softening temperature.

37.5.2 Antibiofouling Measurements

For studies to evaluate antibiofouling benefits, *Bixler* et al. [37.17] considered several foulers primarily based on their size and availability. These include zoospores (*Enteromorpha*) [37.55] and (*Ulva linza*) [37.93], proteins [37.94], *E. coli* [37.95], and MRSA (*Methicillin-resistant Staphylococcus aureus*) [37.96]. They selected the microorganism *E. coli* due to its prevalence in the medical industry, availability, and access to facilities for safe handling. The multistep antibiofouling measurement process is shown in Fig. 37.14 with each process from *E. coli* broth creation to the final counting [37.17]. The dimensions of single wild-type *E. coli* cells were approximately 0.5–0.75 μm wide and 2 μm long. When actively growing and dividing, the cells stretch to ≈ 4 μm before dividing into two cells.

The bioassay procedure began with a stock solution of *E. coli* (HB2151 *E. coli* clones from The Medical Research Council, Cambridge, England) streaked onto TYE (Tryptone and Yeast Extract) dehydrated agar plates for bacterial colony growth. The plates were then placed in an incubator (Labnet, model 311 DS) at 37 °C overnight, and then stored at 4 °C until use. To prepare the *E. coli* broth, a single colony was picked from streak plates and inoculated into 50 ml sterile LB (Luria Broth, Lennox from Fisher Scientific, Pittsburgh, PA) in a beveled flask. *E. coli* was grown for 16 hours with shaking at 250 rpm at a temperature of 37 °C. After incubation, the *E. coli* solution was diluted to 1/100

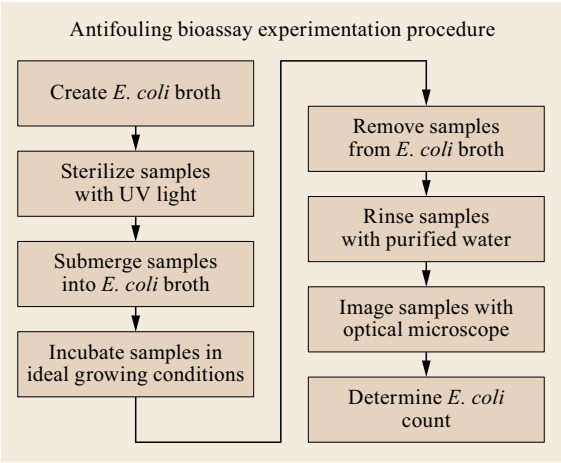

Fig. 37.14 Antifouling bioassay experimental procedure with *E. coli* cells in the laboratory. As shown, samples are sterilized, submerged into broth, placed in an incubator, rinsed to remove loose cells, and imaged with an oil immersion light microscope to determine cell counts (after [37.17])

and 1/10 into sterile LB broth and placed on ice until use.

Bixler et al. [37.17] placed the flat control sample (PDMS), a replica sample (PDMS), and an embossed sample (PMMA) in the bottom of a sterile, polystyrene culture dish and sterilized for 10 min via ultraviolet exposure (30W T8 Hot Cathode Germicidal Sterilamp fluorescent light bulb, Philips TUV30W G30T8 360164). *E. coli* broth was added to the culture dish until all samples were covered and then incubated at 37 °C for either 2 or 4 hours. The aforementioned concentrations and incubation times were determined from trial and error with samples to achieve an appropriate level of *E. coli* growth. The goal was to visually determine a difference at 1000× magnification between flat control and other samples under investigation.

After incubation, samples were removed from the *E. coli* broth and rinsed at a 45° angle. Rinsing removed any unattached *E. coli* from the surface prior to imaging. An autopipette (Pipet-Aid from Drummond Scientific, Broomall, PA) was clamped and held on a stand over the rinsing station with a liquid fall height (distance between pipette tip end and sample) of 7 cm. Samples were rinsed with 10 ml of sterile PBS at a flow rate of approximately 2 ml/s, and then immediately placed onto a glass microscope slide with a glass cover slip on top. Using a light microscope and CCD (charge coupled device) camera (Nikon, Diagnostics Instruments, Inc.), a 140 μm by 140 μm area of each sample was imaged and flat samples analyzed with image processing software (SPIP 5.1.11, Image Metrol-

ogy A/S, Horshølm, Denmark). Images were collected with a 100× oil immersion objective lens for a total magnification of 1000×. For flat control samples, image processing software (SPIP 5.1.11, Image Metrology A/S, Horshølm, Denmark) was utilized to determine total coverage area of *E. coli*. For the samples, the *E.coli* was manually counted five times in circular areas 35 μm in diameter using two samples within the same bioassay.

37.5.3 Anti-inorganic Fouling Measurements

To understand the anti-inorganic fouling effectiveness of the samples, self-cleaning experiments were conducted [37.92]. These experiments included contaminating samples, employing a wash technique, and determining the percentage of inorganic particles removed. Depositing contaminate particles on the tilted (45°) replicas involved a glass contamination chamber (0.3 m in diameter and 0.6 m high). A tray containing 0.2 g of hydrophilic silicon carbide (SiC) contaminants (400 mesh particle size by Aldrich, with sizes ranging from 10–15 μm) was placed in the top chamber with an air hose directed at the center. These particles were chosen because of their similar properties to natural dirt (shape, size, and hydrophilicity). Contaminants were blown with laboratory air for 10 s at 300 kPa, and then allowed to settle for 30 s before the separator panel was removed.

After 30 min, the samples were removed and subjected to prewash experiment particle analysis. Using a light microscope and CCD camera, a 280 μm by 210 μm area of each sample was imaged and analyzed with SPIP image processing software. This process was performed before and after each wash experiment. Wash experiments consisted of exposing the tilted (45°) replicas to water droplets falling from specified height and drip rates (total duration of 2 min using 10 mL water). Droplet velocity was approximately 5.6 m/s at a height of 0.4 m. This translates into pressures of 4000 Pa.

37.5.4 Results and Discussion

Antibiofouling

To understand the antifouling effectiveness of the various samples, *Bixler* et al. [37.17] conducted a series of bioassay experiments. Figure 37.15 shows light microscope images of the *E. coli* colonized on a flat sample at two magnifications [37.17]. As shown, the *E. coli* are long cylindrically shaped microorganisms and tend to cluster in groups and align themselves from head to tail.

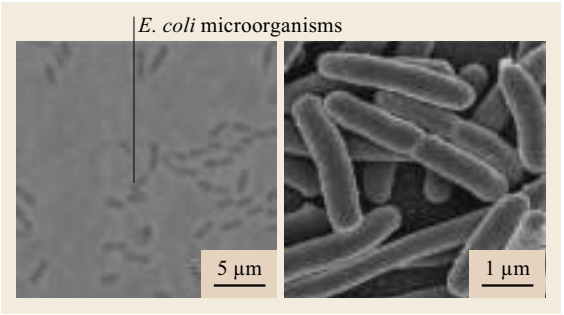

Fig. 37.15 Images of *E. coli* on flat surfaces after the bioassay procedure [37.17] and at a higher magnification (adapted from www.universityofcalifornia.edu)

Figure 37.16a shows light microscope images of flat PDMS samples at the two concentrations and two incubation times (with *E. coli* highlighted by the SPIP software) [37.17]. Figure 37.16b shows the tabulated results of percentage coverage area of the *E. coli* on the surfaces for 1/100 and 1/10 concentrations at 2 and 4 h incubation time. The greatest coverage occurs at the higher incubation time as *E. coli* growth occurs exponentially over time. Furthermore, as expected, the lower concentration does not provide as much coverage area, however the differences are within 10% for both incubation times.

Figure 37.17 shows light microscopic images of the flat PDMS control sample, replica sample, and the embossed sample. Antifouling is determined by counting the total number of *E. coli* on the flat control samples and comparing that to the other samples, with results reported in percentage *E. coli* reduced coverage. Figure 37.18 shows the percentage reduced coverage compared to the flat control samples. As anticipated due to the discontinuities of the various surfaces, patterned samples provided antifouling benefits. In general, the antifouling benefit is greater with the 2 h incubation duration as compared to the 4 h duration. It is believed that the longer duration leads to more significant coverage, and the features provide less overall benefit. It should be noted that the replica sample and embossed sample performed similarly, indicating minimal differences between samples fabricated from PDMS or PMMA.

Anti-inorganic Fouling

To understand the anti-inorganic fouling effectiveness of the various samples, *Bixler* and *Bhushan* [37.92] conducted a series of self-cleaning wash experiments. Figure 37.19 presents the before and after images for flat PDMS and PMMA control samples, the replica sample, and the embossed sample [37.92]. These images were used with SPIP imaging software to quantify the percentage of particles removed. Figure 37.20

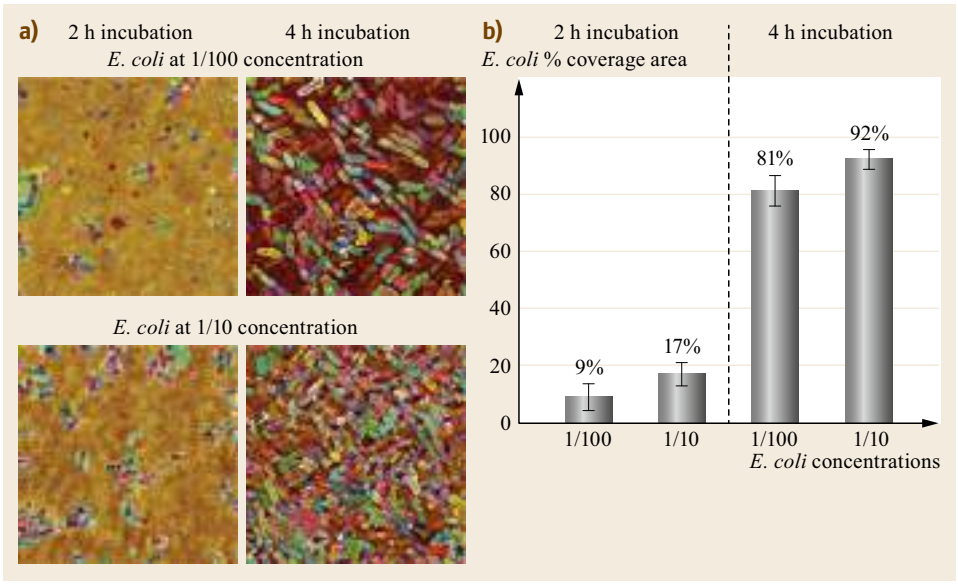

Fig. 37.16 **(a)** Light microscope images of flat PDMS control samples and **(b)** percent coverage area after *E. coli* bioassay with two concentrations and two incubation times. *E. coli* covers the majority of the surface after 4 hours in ideal growing conditions. This baseline serves to compare the replica sample and embossed sample when calculating percentage reduced coverage (adapted from [37.17])

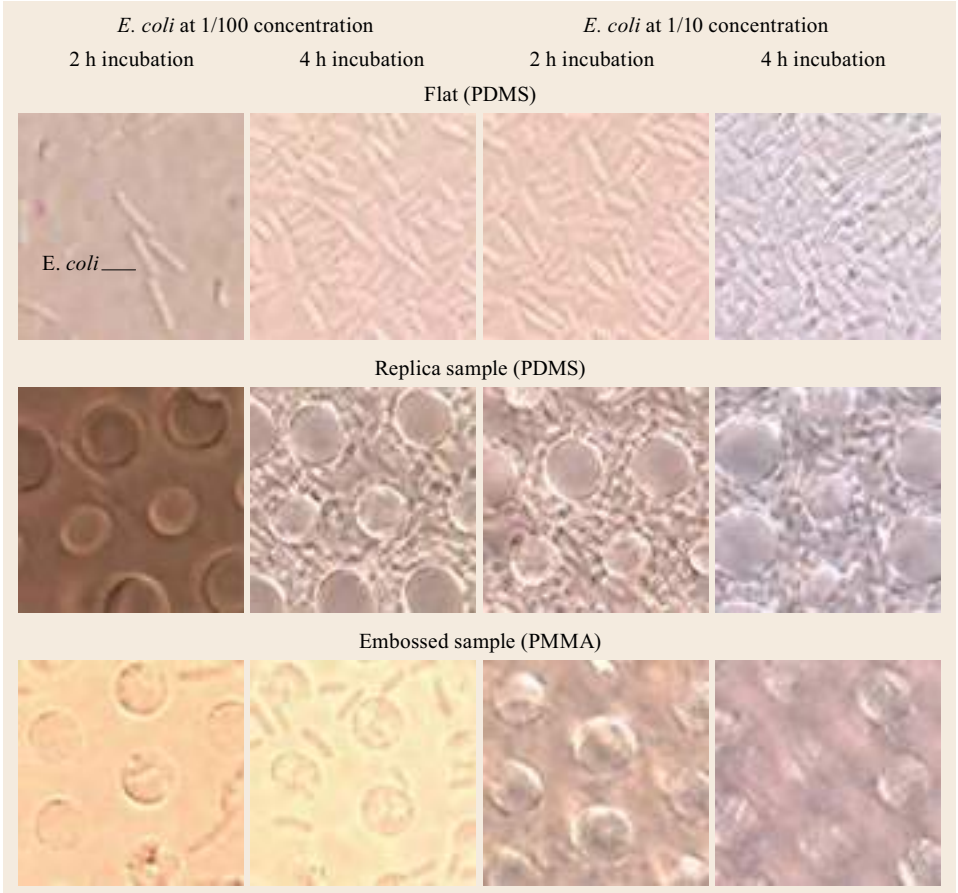

Fig. 37.17 Light microscope images using oil immersion techniques at 1000× magnification of samples after bioassay experiments using *E. coli*. Images of flat PDMS, the replica sample, and the embossed sample are shown with two *E. coli* concentrations and two incubation times. The long and narrow cylindrically shaped objects are the *E. coli*. Antifouling analysis was conducted using the images and particle analysis software to quantify effectiveness (adapted from [37.17])

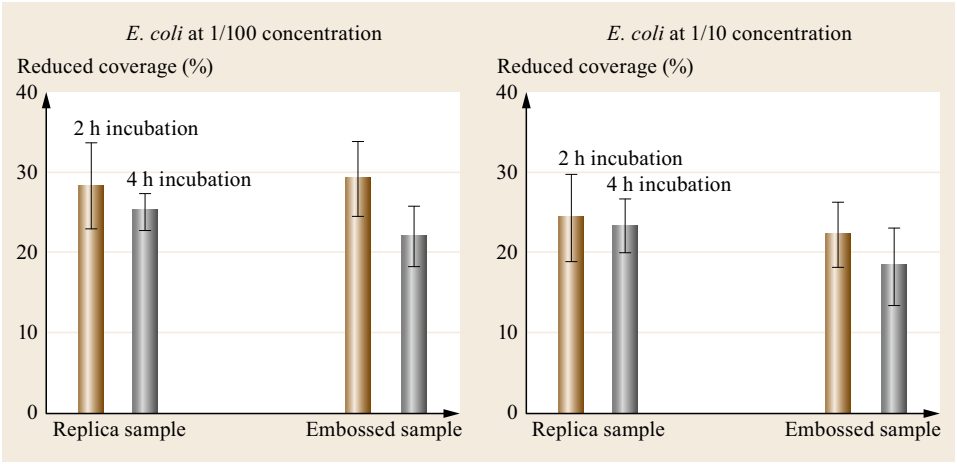

Fig. 37.18 Antibiofouling results from *E. coli* bioassay experiments. Results are presented for flat PDMS, the replica sample, and the embossed sample. The percentage reduced coverage is calculated from the flat PDMS control samples. It is believed that antifouling efficiency improves with high CA and low CAH. Error bars show ±1 standard deviation (adapted from [37.17])

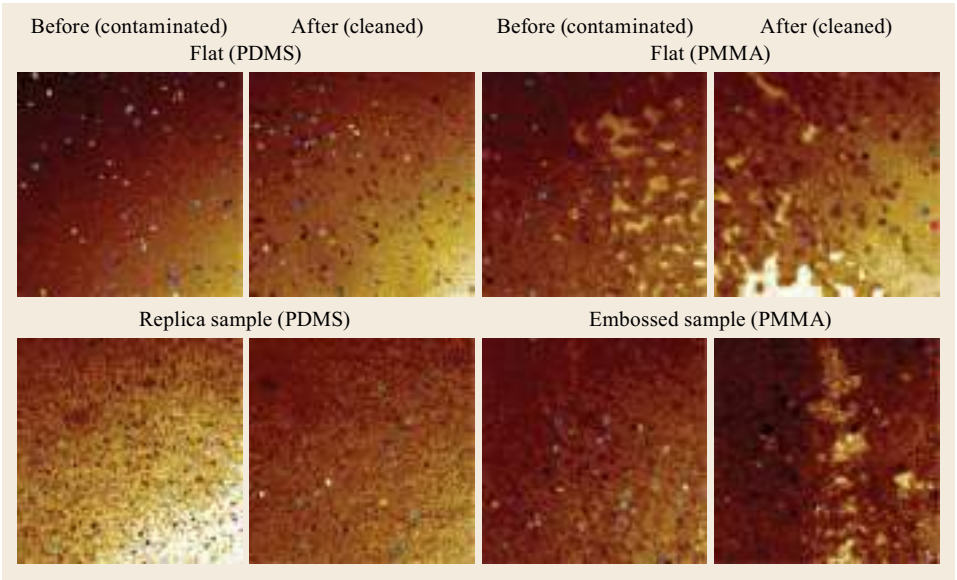

Fig. 37.19 Light microscope images of samples before and after anti-inorganic fouling wash experimentation, with specs representing silicon carbide (SiC) particles [37.92]. Results are presented for flat PDMS and PMMA, the replica sample, and the embossed sample. Self-cleaning analysis was conducted using the images and particle analysis software to quantify particle removal

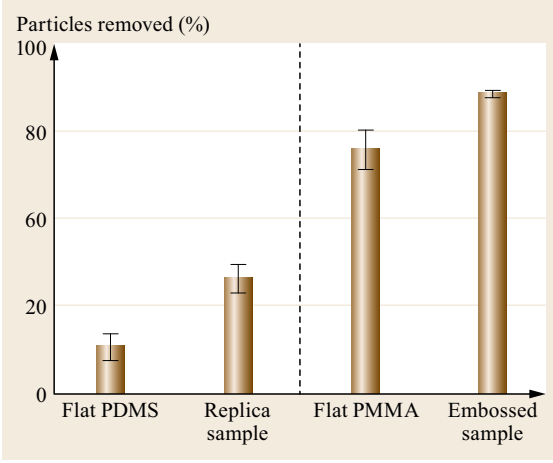

Fig. 37.20 Anti-inorganic fouling wash experimentation results (adapted from [37.92]). Results are presented for the flat PDMS, the replica sample, the flat PMMA sample, and the embossed sample. The embossed sample shows the greatest self-cleaning efficiency followed by the replica sample. Micropatterned samples are superior in self-cleaning efficiency compared to their respective flat samples. Error bars show ±1 standard deviation ◄

shows self-cleaning data for wash experiments. Self-cleaning is more evident with a patterned sample and an embossed sample, as compared to flat samples [37.92]. To understand wettability of samples, *Bixler* and *Bhushan* [37.92] made contact angle measurements. They measured contact angle (CA) and contact angle hysteresis (CAH) values. The replica sample

was found to be superhydrophobic ($\approx 150°$) with low CAH, whereas the embossed sample was hydrophobic ($\approx 101°$). High CA and low CAH is believed to amplify the self-cleaning abilities of the samples, as it is believed that the droplets are able to roll and collect the particles after impact.

37.5.5 Antibiofouling and Anti-inorganic Fouling Mechanisms

Bixler et al. [37.17] presented conceptual models to describe antibiofouling mechanisms. Figure. 37.21 shows schematic illustrations of colonization of microorganisms exposed to flat and patterned samples. Microorganisms are unable to effectively colonize the patterned morphology as well as the flat control sample. If the length of the microorganism is larger than the pillar spacing, they cannot invade the spacing and instead land on top of the pillars. If the length of the microorganism is smaller than the spacing, as is the case with *E. coli*, the sharp edges of the pillars are believed to discourage the settling and eventual colonization of microorganisms on the surface. The edges provide an inconvenient landing zone for settlement, and thus the microorganism must continue the search for an ideal location to colonize. It is believed during this process that many *E. coli* that do not attach remain metabolically active throughout the experiment while others may expire. In many cases, the *E. coli* may be able to settle in clusters and around the bases of the pillars, which provide multiple attachment points of contact.

When the microorganism concentrations are low and the incubation times are short, only a few microorganisms are able to colonize the sample surface. However, when the concentrations are high and the incubation times are long, the microorganisms eventually will cover over the pillars and create a biofilm. Nevertheless, the discontinuities found with the sharp-edged microsized pillars are demonstrated to provide antifouling benefit and extend the time to which a particular surface becomes colonized.

An illustration of anti-inorganic fouling mechanisms is shown in Fig. 37.22 [37.92]. The schematic shows that foulers may be removed from a surface by water droplets or fluid flow when the rice and butterfly wing effect is present. Such a pattern is believed to encourage self-cleaning and directional fluid control, which is believed to provide antifouling benefit.

To summarize, there are a number of examples of micropatterned surfaces in the literature that show that they exhibit antibiofouling if the microsized feature spacing is slightly smaller than the microorganisms. The data presented in this section shows that even if the spacing is larger, they exhibit antibiofouling effects.

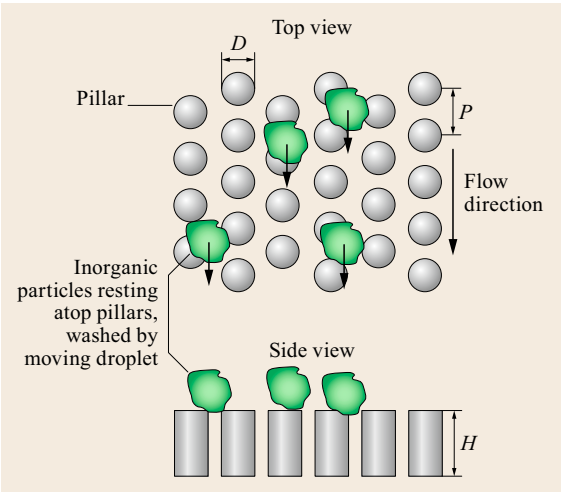

Fig. 37.22 Anti-inorganic fouling mechanisms with rice leaf-inspired samples (adapted from [37.92]. Model shown utilizes uniformly spaced microsized single-height pillars in a hexagonal array. Inorganic fouling may be washed away in fluid flow via self-cleaning

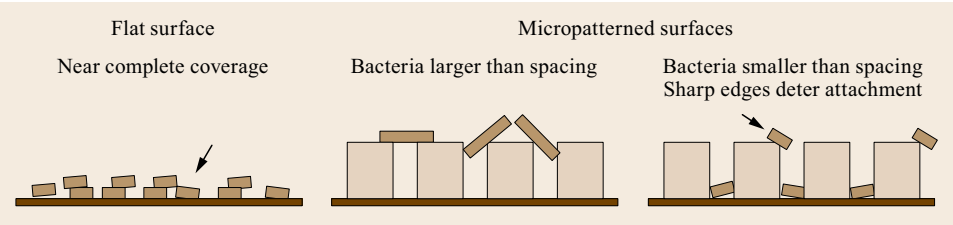

Fig. 37.21 Conceptual models of antibiofouling mechanisms with micropatterned samples. Shown are colonization on flat and micropatterned surfaces. If the length of the microorganism is larger than the pillar spacing, it cannot invade the spacing and instead it lands on top of the pillars. If the length of the microorganism is smaller than the spacing, microstructured discontinuities and sharp edges are believed to discourage colonization – where they may expire in the process of searching for an ideal landing site

37.6 Closure

In this chapter, biofouling and inorganic fouling were introduced. Next, fields susceptible to fouling were summarized, followed by discussion of biofouling and inorganic fouling formation mechanisms, antifouling strategies from living nature, and current prevention and cleaning techniques. Finally, demonstrations of the use of bioinspired rice leaf surfaces for anti-fouling were presented. Data showed that micropatterned surfaces facilitate antifouling.

38. MEMS/NEMS and BioMEMS/BioNEMS: Tribology, Mechanics, Materials and Devices

Bharat Bhushan

A number of micro/nanoelectromechanical systems (MEMS/NEMS) and bioMEMS/bioNEMS are used in commercial applications and/or are under development. Surface area-to-volume ratio in MEMS/NEMS is large, and surface forces such as adhesion, friction, and meniscus and viscous forces become very large compared to inertial and electromagnetic forces. Some devices are designed to execute expected functions with short durations, typically in the millisecond to picosecond range. The expected life of the devices for high-speed contacts can vary from a few hundred thousand to many billions of cycles, e.g., over a hundred billion cycles for digital micromirror devices (DMDs). This puts serious requirements on materials in systems involving relative motion. Thus, there is a need for a fundamental understanding of adhesion, friction/stiction, wear, lubrication, and the role of surface contamination and environment, all on the nanoscale. Most mechanical properties are known to be scale dependent. Therefore, the properties of nanoscale structures need to be measured. For bioMEMS/bioNEMS, adhesion between biological molecular layers and the substrate, and friction and wear of biological layers can be important. Component-level studies are required to provide a better understanding of the tribological phenomena occurring in MEMS/NEMS. This chapter presents an overview of nanoscale adhesion, friction, and wear studies of materials and lubrication for MEMS/NEMS and bioMEMS/bioNEMS, and component-level studies of stiction phenomena in MEMS/NEMS devices.

38.1 MEMS/NEMS Basics

Micro- & nanosystems include micro/nanoelectromechanical systems (MEMS/NEMS). The acronym MEMS originated in the US. The term commonly used in Europe is micro/nanosystem technology (MST/NST), and in Japan it is micro/nanomachines. Another term generally used is micro/nanodevices. Advances in silicon photolithographic process technology since the 1960s led to the development of MEMS in the early 1980s. MEMS combine electrical and mechanical components to create microscopic devices that have a characteristic length between 100 nm and 1 mm. In the early 2000s, with the development of nanofabrication techniques, NEMS were fabricated. NEMS combine electrical and mechanical components to create nanoscopic devices that have a characteristic length of less than 100 nm. In mesoscale devices, if the functional components are on the micro- or nanoscale, they may be referred to as MEMS or NEMS, respectively. These are intelligent miniaturized systems comprised of sensing, processing, and/or actuating functions that combine electrical and mechanical components [38.1]. MEMS/NEMS terms are also now used in a broad sense and include electrical, mechanical, fluidic, optical, and/or biological function. MEMS/NEMS for optical applications are referred to as micro/nanooptoelectromechanical systems (MOEMS/NOEMS). MEMS/NEMS for electronic applications are referred to as radio-frequency-MEMS/NEMS or RF-MEMS/RF-NEMS. MEMS/NEMS for biological applications are referred to as bioMEMS/bioNEMS.

To put the dimensions and weights of nanomaterials, MEMS/NEMS, and bioNEMS in perspective, see Fig. 38.1 and Table 38.1. Examples shown are a single-walled carbon nanotube (SWNT) chemical sensor (adapted from [38.2]), molecular dynamic simulations of carbon-nanotube-based gears (adapted from [38.3]), a quantum-dot transistor (adapted from [38.4]), and a digital micromirror device (adapted from [38.5]). Individual atoms are typically a fraction of a nanometer in diameter, DNA molecules are about 2.5 nm wide, biological cells are in the range of thousands of nm in diameter, and a human hair is about 75 000 nm (75 μm) in diameter. The smaller length of a bioNEMS shown in the figure is about 2 nm. NEMS shown range in size from 10 to 300 nm, and the size of MEMS is on the order of 12 000 nm (12 μm). The weight of a micromachined silicon structure can be as low as 1 nN, and NEMS can be built with weight as low as 10^{-20} N with cross-sections of about 10 nm. In comparison, the weight of a drop of water is about 10 μN, and the weight of an eyelash is about 100 nN.

These devices are fabricated by manufacturing at the nanoscale, referred to as nanomanufacturing. It is accomplished by using either a *bottom-up* or *top-down* approach to the production of nanomaterials, structures, devices, and systems [38.1, 7, 8].

In the bottom-up approach, nanoscale features are mainly built up from their elemental constituents. Elemental constituents are combined using various nanomanufacturing processes including self-assembly, chemical synthesis, molecular beam epitaxy, nanoimprint lithography, roll-to-roll processing, and dip-pen lithography [38.9]. Molecular self-assembly, the spontaneous self-assembly of molecular clusters, can occur from simple reagents in solution or from biological molecules (e.g., DNA) used as building blocks for the production of three-dimensional nanostructures. Chemical synthesis is carried out using gaseous precursors and solvents. These chemicals react to produce nanostructures. A variety of vacuum deposition and nonequilibrium plasma chemistry techniques are then used to produce layered nanocomposites and nanotubes. Molecular beam epitaxy is a method for deposition of thin films with a thickness of one atom on a surface. Nanoprint lithography is used to fabricate nanostructures by stamping or printing them on a surface. Roll-to-roll processing is a high-volume process used to produce nanodevices on a flexible substrate. Dip pen lithography uses an atomic force microscope tip in a fluid to produce nanoscale features on a surface.

The top-down approach uses lithographic and nonlithographic fabrication technologies. Lithographic technology is an underlying technology to make semi-

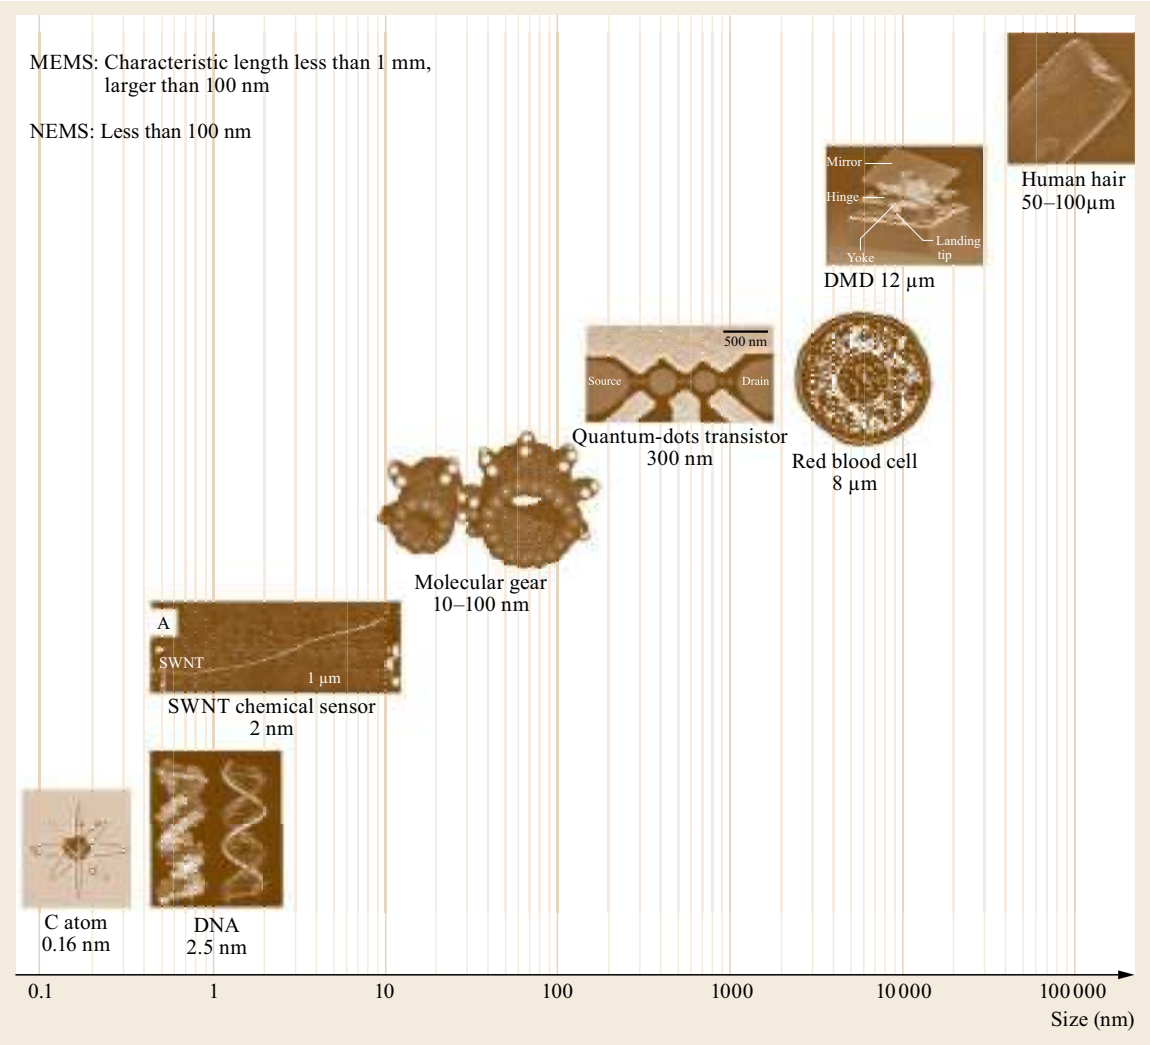

Fig. 38.1 Characteristic dimensions of nanomaterials, MEMS/NEMS, and bioNEMS in perspective (adapted from [38.6]). Examples shown are a single-walled carbon nanotube (SWNT) chemical sensor (adapted from [38.2]), molecular dynamic simulations of carbon-nanotube-based gears (adapted from [38.3]), a quantum-dot transistor (adapted from [38.4]), and a digital micromirror device (adapted from [38.5])

conductor chips and components. Continued improvements in lithography for use in the production of nanocomponents have resulted in line widths as small as 10 nm. The top-down approach is commonly used to fabricate micro- and nanosystem components, which range in size from micro- to nanometers.

MEMS/NEMS and bioMEMS/bioNEMS are beginning to have a major impact on our lives, comparable to that of semiconductor technology, information technology, or cellular and molecular biology in the 20th century. The integration of micro/nanodevices/systems into larger systems has provided breakthrough solutions to many current environmental, medical, and industrial problems including smart materials, nanomanufacturing, electronics, drug delivery, energy, water, biotechnology, information technology, and national security. bioMEMS/bioNEMS are increasingly used in commercial and defense applications. The revenues from nano-enabled products continue growing, with over $200 B in fiscal year 2012 in the US alone, and over $700 B worldwide [38.6]. MEMS/NEMS and bioMEMS/bioNEMS will have a profound impact on our society. They represent a megatrend, bringing disruptive innovation.

Table 38.1 Characteristic dimensions and weights in perspective

Characteristic dimensions in perspective	
NEMS characteristic length	< 100 nm
MEMS characteristic length	< 1 mm and > 100 nm
Single-walled carbon nanotube (SWNT) chemical sensor	≈ 2 nm
Molecular gear	≈ 10 nm
Quantum-dot transistor	300 nm
Digital micromirror	12 000 nm
Individual atoms	Typically a fraction of a nm in diameter
DNA molecules	≈ 2.5 nm wide
Biological cells	In the range of thousands of nm in diameter
Human hair	$\approx 75\,000$ nm in diameter
Weights in perspective	
NEMS built with cross-sections of ≈ 10 nm	As low as 10^{-20} N
Micromachines, silicon structure	As low as 1 nN
Eyelash	≈ 100 nN
Water droplet	$\approx 10\,\mu$N

38.1.1 Introduction to MEMS

The advances in silicon photolithographic process technology since the 1960s led to the development of MEMS in early 1980s. Later, lithographic processes were developed to process nonsilicon materials. The lithographic processes are complemented with nonlithographic processes for the fabrication of components or devices made from plastics or ceramics. Using these fabrication processes, researchers have fabricated a wide variety of devices with dimensions in the range of submicrons to a few thousand microns (see e.g., [38.7, 10–19]). MEMS for mechanical applications include acceleration, pressure, flow, and gas sensors, linear and rotary actuators, and other microstructures or microcomponents such as electric motors, gear chains, gas turbine engines, fluid pumps, fluid valves, switches, grippers, and tweezers. MEMS for chemical applications include chemical sensors and various analytical instruments. MOEMS are the devices that include optical components, such as micromirror arrays for displays, infrared image sensors, spectrometers, bar code readers, and optical switches. RF-MEMS include inductors, capacitors, antennas, and RF-switches. High-aspect-ratio MEMS (HARMEMS) have also been introduced.

A wide variety of MEMS devices have been produced and some are used commercially [38.7, 11, 13–16, 18, 19]. A variety of sensors are used in industrial, consumer, defense, and biomedical applications. The largest *killer* industrial applications include accelerometers, pressure sensors, thermal and piezoelectric-type inkjet printheads, and digital micromirror devices. Integrated capacitive-type silicon accelerometers have been used in airbag deployment in automobiles since 1991 [38.20, 21]. Some 90 million units were installed in vehicles in 2004. Accelerometer technology was over a billion-dollar-a-year industry in 2004, dominated by Analog Devices followed by Freescale Semiconductor (formerly Motorola) and Bosch. It is expected to grow with an annual growth exceeding 30%. Tri-axis accelerometers are needed to describe three-dimensional motion. Multi-axis accelerometers are being used for many other applications such as vehicle stability, rollover control, and gyro sensors for automotive applications. They are used also in various consumer applications including handheld devices, e.g., laptops for free-fall detection (2003), and cellular phones (2004) and tablets for menu navigation, gaming, image rotation, and free-fall detection. Silicon-based piezoresistive pressure sensors were launched in 1990 by GE NovaSensor for manifold absolute pressure (MAP) sensing for engines and for disposable blood pressure sensors, and their annual sales in 2004 were more than 30 million units and more than 25 million units respectively. MAP sensors measure the pressure in the intake manifold, which is fed to a computer that determines the optimum air/fuel mixture to maximize fuel economy. Most vehicles have these as part of the electronic engine control system. Capacitive pressure sensors for tire pressure measurements were launched by Freescale Semiconductor (formerly Motorola) in early 2000, and are also manufactured by Infineon/SensoNor and GE Novasensor (2003). Piezoresistive-type sensors are also used, manufactured by various companies such as EnTire Solutions (2003). The sensing module is located inside the rim of the wheel and relays the information via radio frequency to a central processing

unit (CPU) in order to display it to the driver. In 2005, about 9.2 million vehicles were equipped with sensors, which translated to about 37 million units. Their sales have grown rapidly as they are now required in automobiles in the US (starting in 2008), and it affects 17 million vehicles (one in each tire) sold every year. Pressure sensors can be used to detect altitude by measuring air pressure. For example, global positioning systems (GPS) used for navigation have good lateral resolution but poor vertical resolution, which creates problems in identifying the level in the case of multiple roads stacked up. A pressure sensor is needed to determine the level (altitude) by measuring the air pressure.

Thermal inkjet printers were developed independently by HP and Cannon and were commercialized in 1984 [38.22–25]. Today they are made by Canon, Epson, HP, Lexmark, Xerox, and others. They typically cost less initially than dry-toner laser printers and are the solution of choice for low-volume print runs. Annual sales of thermal inkjet printheads with microscale functional components were more than 500 million units in 2004.

Micromirror arrays are used for digital projection displays. Commercial digital light processing (DLP) equipment, using digital micromirror devices (DMDs), were launched in 1996 by Texas Instruments (TI) for digital projection displays in computer projectors, high-definition television (HDTV) sets, and movie projectors (DLP cinema) [38.5, 26, 27]. Several million projectors had been sold by 2004 (about $700 million revenue by TI in 2004). Electrostatically actuated, membrane-type or cantilever-type microswitches have been developed for direct current (DC), RF, and optical applications [38.28]. There exists two basic forms of RF microswitches: the metal-to-metal contact microswitch (ohmic) and the capacitive microswitch. RF microswitches can be used in a variety of RF applications including cellular phones, phase shifters, smart antennas, multiplexers for data acquisition, and more [38.29]. Optical microswitches are finding applications in optical networking, telecommunications, and wireless technologies [38.28, 30].

Other applications of MEMS devices include chemical, biological, and gas sensors [38.19, 31]; actuators, microresonators, infrared detectors, and focal plane arrays for earth observation, space science, and missile defense applications; picosatellites for space applications; fuel cells; and many hydraulic, pneumatic, and other consumer products. MEMS devices are also being pursued in magnetic storage systems [38.32], where they are being developed for super-compact and ultrahigh-recording-density magnetic disk drives. Several integrated head/suspension microdevices have been fabricated for contact recording applications [38.33]. High-bandwidth servo-controlled microactuators have been fabricated for ultrahigh-track-density applications, which serve as the fine-position control element of a two-stage, coarse/fine servo system, coupled with a conventional actuator [38.34, 35].

Micro/nano-instruments and micro/nanomanipulators are used to move, position, probe, pattern, and characterize nanoscale objects and nanoscale features [38.36]. Miniaturized analytical equipment includes gas chromatography and mass spectrometry. Other instruments include micro-STM, where STM stands for scanning tunneling microscope.

In some cases, MEMS devices are used primarily for their miniature size, while in others, as in the case of the air bags, because of their low-cost manufacturing techniques. This latter fact has been possible since semiconductor-processing costs have reduced drastically over the last decade, allowing the use of MEMS in many fields.

38.1.2 Introduction to NEMS

NEMS are produced by nanomachining in a typical top-down approach (from large to small) and bottom-up approach (from small to large) largely relying on nanochemistry (see e.g., [38.37–43]). The NEMS field, in addition to the fabrication of nanosystems, has provided the impetus to develop experimental and computation tools. Examples of NEMS include microcantilevers with integrated sharp nanotips for STM and atomic force microscopy (AFM) [38.44, 45], quantum corral formed using STM by placing atoms one by one [38.46], AFM cantilever arrays (Millipede) for data storage [38.47], STM and AFM tips for nanolithography, dip-pen nanolithography for printing molecules, nanowires, carbon nanotubes, quantum wires (QWRs), quantum boxes (QBs), quantum transistors [38.4], nanotube-based sensors [38.48, 49], biological (DNA) motors, molecular gears by attaching benzene molecules to the outer walls of carbon nanotubes [38.3], devices incorporating nm-thick films (e.g., in giant magnetoresistive (GMR) read/write magnetic heads and magnetic media for magnetic rigid disk and magnetic tape drives), nanopatterned magnetic rigid disks, and nanoparticles (e.g., nanoparticles in magnetic tape substrates and nanomagnetic particles in magnetic tape coatings) [38.32, 50]. More than two billion read/write magnetic heads were shipped for magnetic disk and tape drives in 2004.

Nanoelectronics can be used to build computer memory using individual molecules or nanotubes to store bits of information [38.51], molecular switches, molecular or nanotube transistors, nanotube flat-panel displays, nanotube integrated circuits, fast logic gates,

switches, nanoscopic lasers, and nanotubes as electrodes in fuel cells.

38.1.3 Introduction to BioMEMS/BioNEMS

The basic building block of all life is the cell [38.52]. Lipid bilayer membranes enclose all animal cells. The internal compartment is a hydrophilic space called cytosol, and is filled with the material necessary to sustain life. The human body consists of on the order of 30 trillion human cells, dominated by red blood cells, and on the order of 40 trillion bacterial cells, dominated by colonic bacteria. Bacteria help digest food, but they can also generate toxins [38.53]. Proteins are large molecules and consist of long chains of amino acids [38.54]. Complete proteins contain all eight essential amino acids. Proteins are a vital part of all living things. They are important to every cell operation, and perform a vast array of functions including catalyzing metabolic reactions, DNA replication, and stimuli response. However, their main function is to heal wounds, fight infection, and build muscle.

BioMEMS/bioNEMS are used for chemical and biochemical analyses (biosensors) in medical diagnostics (e.g., DNA, RNA, proteins, cells, blood pressure and assays, and bacterial pathogens or toxin identification) [38.55, 56], tissue engineering [38.57–59], and implantable pharmaceutical drug delivery [38.60–62]. They are increasingly used in commercial and defense applications (see e.g., [38.56, 63–69]).

Biosensors, also referred to as biochips, deal with liquids and gases. A large variety of biosensors are based on micro/nanofluidics [38.56, 70–73]. Micro/nanofluidic devices offer the ability to work with smaller reagent volumes and shorter reaction times, and perform multiple types of analyses at once. A second type of biosensors includes micro/nanoarrays, which perform one type of analysis thousands of times [38.74–80].

A chip with micro/nanofluidic technology embedded on the disk, called lab-on-a-CD, can test thousands of biological samples rapidly and automatically [38.70]. An entire laboratory can be integrated onto a single chip, called lab-on-a-chip [38.56, 71, 72]. Silicon-based disposable blood-pressure sensor chips were introduced in early 1990s by GE NovaSensor for blood pressure monitoring (about 25 million units in 2004). A blood sugar monitor, referred to as GlucoWatch, was introduced in 2002. It automatically checks blood sugar every 10 minutes by detecting glucose through the skin, without having to draw blood. If glucose is out of the acceptable range, it sounds an alarm so the diabetic can address the problem quickly. A variety of biosensors, many using plastic substrates, are manufactured by various companies including ACLARA, Agilent Technologies, Calipertech, and I-STAT.

Micro/nanoarrays are another type of biochip. They are a tool used in biotechnology research to analyze DNA or proteins to diagnose diseases or discover new drugs. Also called DNA arrays, they can identify thousands of genes simultaneously [38.66, 74]. They include a microarray of silicon nanowires, roughly a few nm in size, to selectively bind and detect even a single biological molecule such as DNA or protein by using nanoelectronics to detect the slight electrical charge caused by such binding, or a microarray of carbon nanotubes to electrically detect glucose.

After the tragedy of September 11, 2001, concern about biological and chemical warfare has led to the development of handheld units with bio- and chemical sensors for detection of biological toxins, chemical or nerve agents, mustard agents, and chemical precursors to protect subways, airports, water supply, and the population at large [38.81].

BioMEMS/bioNEMS are also being developed for minimally invasive surgery including endoscopic surgery, laser angioplasty, and microscopic surgery. Implantable artificial organs can also be produced. Other applications include implantable drug-delivery devices, e.g., micro/nanoparticles with drug molecules encapsulated in functionalized shells for site-specific targeting applications; a silicon capsule with a nanoporous membrane filled with drugs for long-term delivery [38.60, 82–84]; nanodevices for sequencing single molecules of DNA in the Human Genome Project [38.56]; cellular growth using carbon nanotubes for spinal cord repair; and nanotubes for nanostructured materials for various applications such as spinal fusion devices, organ growth, and growth of artificial tissues using nanofibers.

38.2 Nanotribology and Nanomechanics Issues in MEMS/NEMS and BioMEMS/BioNEMS

Tribological issues are important in MEMS/NEMS and bioMEMS/bioNEMS requiring intended and/or unintended relative motion. Nanomechanical properties are scale dependent [38.85]; therefore, these should be measured at relevant scales. In these devices, various forces associated with the device scale down as size decreases. When the length decreases from 1 mm to 1 μm, the surface area decreases by a factor of a million, and the volume decreases by a factor of a billion. As a result, surface forces such as adhesion, friction,

meniscus forces, and viscous forces that are proportional to surface area, become a thousand times larger than the forces proportional to the volume, such as inertial and electromagnetic forces. In addition to the consequences of large surface-to-volume ratios, the small tolerances that these devices are designed for make physical contacts more likely, which makes them particularly vulnerable to adhesion between adjacent components. Slight particulate or chemical contamination present at the interface can be detrimental. Further, the small startup forces and the torques available to overcome retarding forces are small, and the increase in resistive forces such as adhesion and friction become a serious tribological concern that limits the durability and reliability of MEMS/NEMS [38.1, 13, 44, 86–88]. A large lateral force required to initiate relative motion between two surfaces, large static friction, is referred to as *stiction*, which has been studied extensively in the tribology of magnetic storage systems [38.32, 44, 88–92]. The source of stiction is generally liquid-mediated adhesion with the source of liquid being process fluid or capillary condensation of the water vapor from the environment. Adhesion, friction/stiction, wear, and surface contamination affect MEMS/NEMS and bioMEMS/bioNEMS performance, and in some cases can even prevent the devices from working. Adhesion between a biological molecular layer and the substrate (referred to as *bioadhesion*), reduction of friction and wear of biological layers, biocompatibility, and biofouling in bioMEMS/bioNEMS can be important [38.75, 93]. Some examples of devices that experience nanotribological problems follow.

38.2.1 MEMS

Figure 38.2 shows examples of several microcomponents that can encounter tribological problems. The polysilicon electrostatic micromotor has 12 stators and a four-pole rotor, and is produced by surface micromachining. The rotor diameter is 120 μm, and the air gap between the rotor and stator is 2 μm [38.94]. It is capable of continuous rotation up to speeds of 100 000 RPM. The intermittent contact at the rotor–stator interface and physical contact at the rotor–hub flange interface result in wear issues, and high stiction between the contacting surfaces limits the repeatability of operation or may even prevent the operation altogether. Next, a bulk micromachined silicon stator/rotor pair is shown with bladed rotor and nozzle guide vanes on the stator with dimensions less than 1 mm [38.95, 96]. These are being developed for a high-temperature microgas turbine engine with rotor dimension of 4–6 mm in diameter, and an operating speed of up to one million RPM (with a sliding velocity in excess of 500 m/s, comparable to velocities of large turbines operating at high velocities) to achieve high specific power, up to a total of about 10 W. Erosion of blades and vanes and design of the microbearings required to operate at extremely high speeds used in the turbines are some of the concerns. Ultrashort, high-speed microhydrostatic gas journal bearings with a length-to-diameter ratio (L/D) of less than 0.1 are being developed for operation at surface speeds on the order of 500 m/s, which offer unique design challenges [38.97]. Microfabrica, Inc. in the US, is developing microturbines with an outer diameter as low as 0.9 mm to be used as power sources for medical devices. They use precision ball bearings.

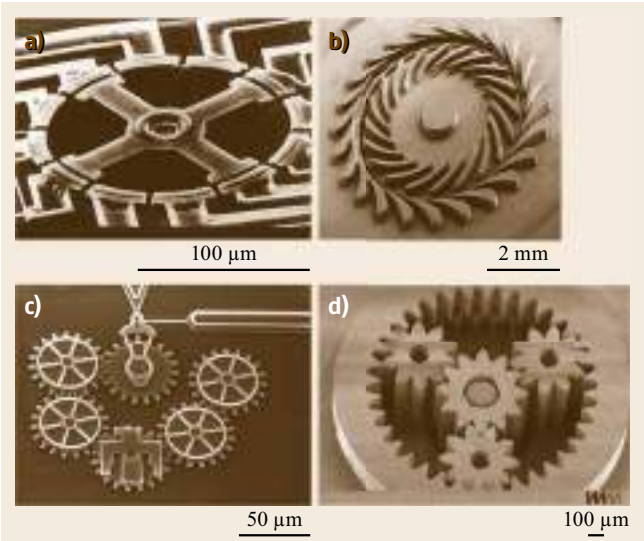

Fig. 38.2a–d Examples of MEMS components that experience tribological problems. **(a)** Electrostatic micromotor (after [38.94]). **(b)** Microturbine bladed rotor and nozzle vanes on the stator (after [38.95]). **(c)** Six-gear chain (Sandia). **(d)** Ni/Fe Wolfrom-type gear system produced by LIGA (after [38.98])

Next in Fig. 38.2 is a scanning electron microscopy (SEM) micrograph of a surface micromachined polysilicon six-gear chain from Sandia National Lab. (For more examples of early version, see [38.99].) As an example of nonsilicon components, a milligear system produced using the Lithographie, Galvanoformung, Abformung (LIGA) process for a DC brushless permanent magnet millimotor (diameter = 1.9 mm, length = 5.5 mm) with an integrated milligear box [38.98, 100, 101] is also shown. The gears are made of metal (electroplated Ni-Fe) but can also be made from injected polymer materials (e.g., polyoxy-methylene or POM) using the LIGA process (described in Appendix 38.A). Even though the torque transmitted at the gear teeth is small, on the order of a fraction of nN m, because of the small dimensions of gear teeth, the bending stresses are

large where the teeth mesh. Tooth breakage and wear at the contact of gear teeth is a concern.

Figure 38.3 shows an optical micrograph of a microengine driven by an electrostatically activated comb drive connected to the output gear by linkages. The microengine operates in the kHz frequency range, and can be used as a general drive and power source to drive micromechanisms [38.102]. Its parts are fabricated from polysilicon. A microgear unit is used to convert reciprocating motion from a linear actuator into circular motion. Another drive linkage oriented at 90° to the original linkage, driven by another linear actuator, allows maintenance of continuous motion. The linkages are connected to the output gear through pin joints that allow relative motion.

One inset shows a polysilicon, multiple microgear speed reduction unit and its components after laboratory wear tests conducted for 600 000 cycles at 1.8% relative humidity (RH) [38.103]. Wear of various components is clearly observed in the figure. Humidity was shown to be a strong factor in the wear of rubbing surfaces. In order to improve the wear characteristics of rubbing surfaces, a 20 nm-thick tungsten (W) coating was deposited at 450 °C using the chemical vapor deposition (CVD) technique [38.104]. Tungsten-coated microengines tested for reliability showed improved wear characteristics with longer lifetimes than polysilicon microengines. However, these coatings have poor yield. Instead, vapor deposited self-assembled monolayers of fluorinated (dimethylamino) silane have been used [38.105]. The second inset shows a comb drive with a deformed frame, which results in some fingers coming in contact. The contacting fingers can result in stiction.

Figure 38.4 shows a micromachined flow modulator. Several micromachined flow channels are integrated in series with electrostatically actuated microvalves [38.106]. The flow channels lead to a central gas outlet hole drilled in the glass substrate. Gas enters the device through a bulk micromachined gas inlet hole in the silicon cap. The gas, after passing through an open microvalve, flows parallel to the glass substrate through flow channels and exits the device through an outlet. The normally open valve structure consists of a freestanding double-end-clamped beam, which is positioned beneath the gas inlet orifice. When electrostatically deflected upwards, the beam seals against the inlet orifice and the valve is closed. In these microvalves used for flow control, the mating valve surfaces should be smooth enough to seal while maintaining a minimum roughness to ensure low adhesion [38.86, 88, 89, 91, 92, 107].

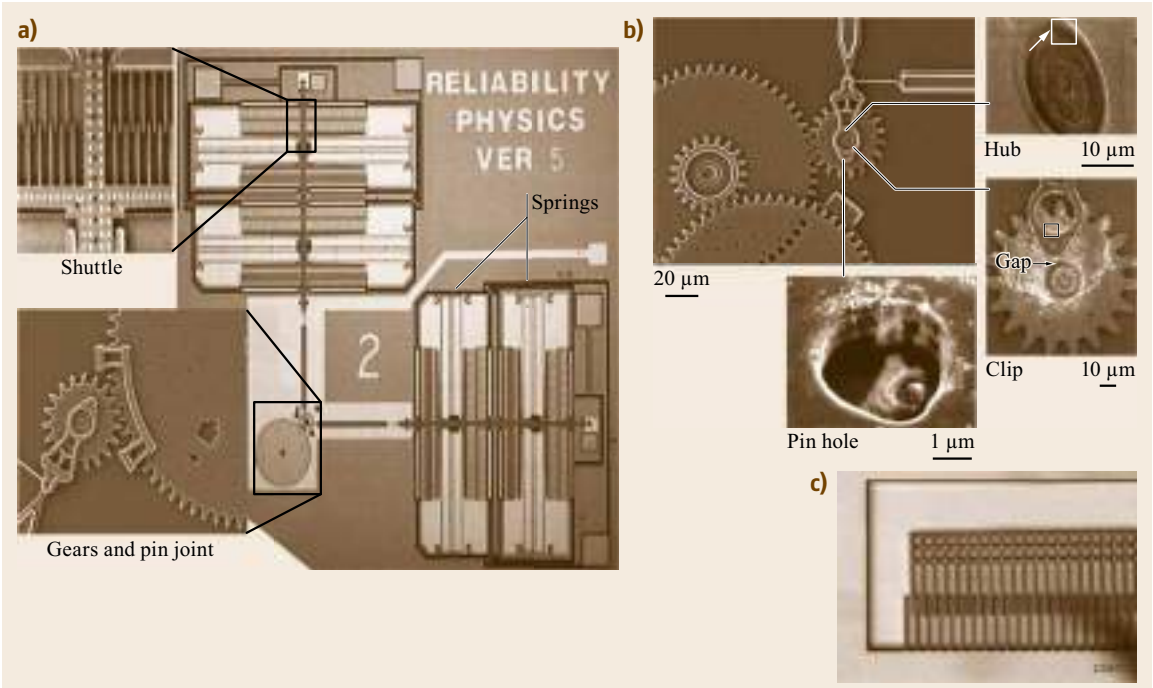

Fig. 38.3 **(a)** Optical micrograph of a microengine driven by an electrostatically actuated comb drive (microengine) fabricated by Sandia Summit Technologies (after [38.102]). **(b)** shows polysilicon microgear speed reduction unit after laboratory wear test for 600 000 cycles at 1.8% relative humidity (after [38.103]). **(c)** shows a stuck comb drive (CSEM)

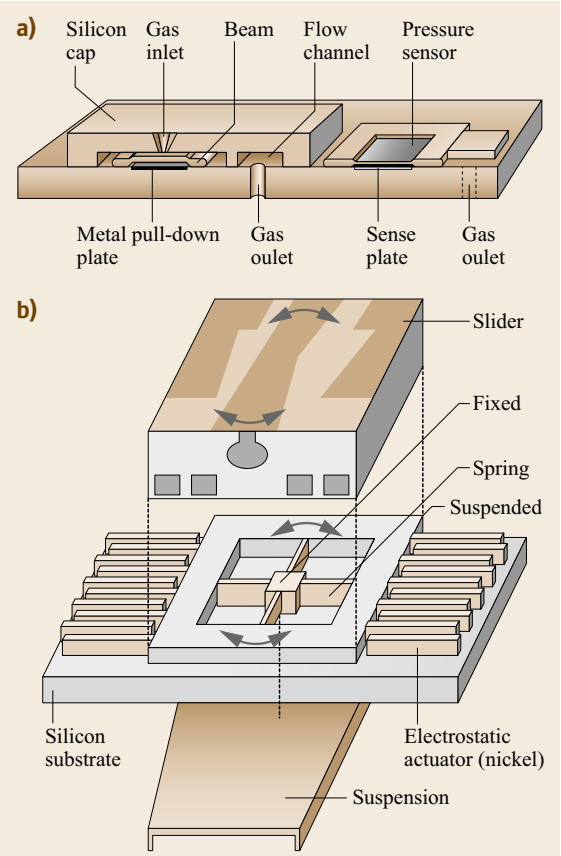

Fig. 38.4a,b Examples of MEMS devices that experience tribological problems. **(a)** Low-pressure flow modulator with electrostatically actuated microvalves (after [38.106]). **(b)** Electroplated-nickel rotary microactuator for magnetic disc drives (after [38.35])

A second MEMS device shown in Fig. 38.4 is an electrostatically driven rotary microactuator for a magnetic disk drive, surface micromachined by a multilayer electroplating method [38.35]. This high-bandwidth servo-controlled microactuator, located between a slider and a suspension, is being developed for ultrahigh-track-density applications, which serves as the fine-position and high-bandwidth control element of a two-stage, coarse/fine servo system when coupled with a conventional actuator [38.34, 35]. A slider is placed on top of the central block of a microactuator, which gives rotational motion to the slider. The bottom of the silicon substrate is attached to the suspension. The radial flexure beams in the central block give the rotational freedom of motion to the suspended mass (slider), and the electrostatic actuator drives the suspended mass. Actuation is accomplished via interdigitated, cantilevered electrode fingers, which are alternately attached to the central body of the moving part and to the stationary substrate to form pairs. A voltage applied across these electrodes results in an electrostatic force, which rotates the central block. The interelectrode gap width is about 2 μm. Any unintended contacts between the moving and stationary electroplated-nickel electrodes may result in wear and stiction.

Commercially available MEMS devices also exhibit tribological problems. Figure 38.5 shows an integrated capacitive-type silicon accelerometer fabricated using surface micromachining by Analog Devices, a couple of mm in dimension, which is used for the deployment of airbags in automobiles, and for various other devices in the consumer electronics market [38.20, 108]. The central suspended beam mass (about 0.7 μg) is supported on the four corners by spring structures. The central beam has interdigitated cantilevered electrode fingers (about 125 μm long and 3 μm thick) on all four sides that alternate with those of the stationary electrode fingers as shown, with about a 1.3 μm gap. Lateral motion of the central beam causes a change in the capacitance between these electrodes, which is used to measure the acceleration. Stiction between the adjacent electrodes as well as stiction of the beam structure with the underlying substrate, under isolated conditions, is detrimental to the operation of the sensor [38.20, 108]. Wear during unintended contacts of these polysilicon fingers is also a problem. A molecularly thick diphenyl siloxane lubricant film, resistant to high temperatures and oxidation, is applied by a vapor deposition process on the electrodes to reduce stiction and wear [38.109]. For deposition, a small amount of liquid is dispensed into each package before it is sealed. As the package is heated in the furnace, the liquid evaporates, which coats the sensor surface. As sensors are required to sense low g accelerations, they need to be more compliant and stiction becomes even a bigger concern.

Figure 38.5 also shows a cross-sectional view of a typical piezoresistive-type pressure sensor, which is used for various applications including manifold absolute pressure (MAP) and tire pressure measurements in automotive applications, and disposable blood pressure measurements. The sensing material is a diaphragm formed on a silicon substrate, which bends with applied pressure [38.110, 111]. The deformation causes a change in the band structure of the piezoresistors that are placed on the diaphragm, leading to a change in the resistivity of the material. The MAP sensors are subjected to drastic conditions – extreme temperatures, vibrations, sensing fluid, and thermal shock. Fluid under extreme conditions could cause corrosive wear, while fluid cavitation could cause erosive wear. The protective gel encapsulant generally used can react

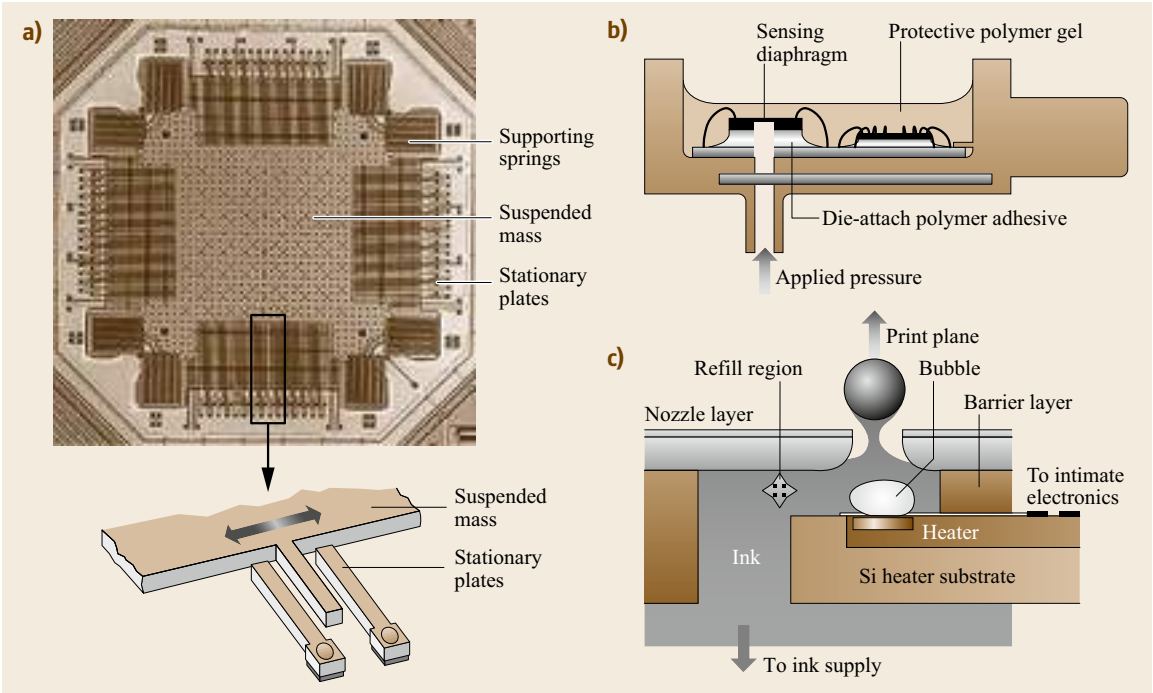

Fig. 38.5a–c Examples of commercial MEMS devices that experience tribological problems. **(a)** Capacitive-type silicon accelerometer for automotive sensory applications (after [38.108]). **(b)** Piezoresistive-type pressure sensor (after [38.110]). **(c)** Thermal inkjet printhead (after [38.24])

with sensing fluid and result in swelling or dissolution of the gel. Silicon cannot deform plastically, therefore any pressure spikes leading to deformation past its elastic limit will result in fracture and crack propagation. Pressure spikes could also cause the diaphragm to delaminate from the support substrate. Finally, cyclic loading of the diaphragm during use can lead to fatigue and wear of the silicon diaphragm or delamination.

The bottom schematic in Fig. 38.5 shows a cross-section of a thermal printhead chip (on the order of 10–50 cm^3 in volume) used in inkjet printers [38.24]. They comprise of a supply of ink and an array of elements with microscopic heating resistors on a substrate mated to a matching array of ink-injection orifices or nozzles (about 70 μm in diameter) [38.22, 23, 25]. In each element, a small chamber is heated by the resistor where a brief electrical impulse vaporizes part of the ink and creates a tiny bubble. The heaters operate at several kHz and are therefore capable of high-speed printing. As the bubble expands, some of the ink is pushed out of the nozzle onto the paper. When the bubble pops, a vacuum is created and this causes more ink from the cartridge to move into the printhead. Clogged ink ports are the major failure mode. There are various tribological concerns [38.22]. The surface of the printhead where the ink is shot out towards the paper can get scratched and damaged as a result of countless trips back and forth across the pages, which are somewhat rough. As a result of repeated heating and cooling, the heated resistors expand and contract. Over time, these elements will experience fatigue and may eventually fail. Bubble formation in the ink reservoir can lead to cavitation erosion of the chamber, which occurs when bubbles formed in the fluid become unstable and implode against the surface of the solid and impose impact energy on that surface. Fluid flow through nozzles may cause erosion and ink particles may also cause abrasive wear. Corrosion of the ink reservoir surfaces can also occur as a result of exposure of ink at high temperatures as well as due to ink pH. The substrate of the chip consists of silicon with a thermal barrier layer followed by a thin film of resistive material and then conducting material. The conductor and resistor layers are generally protected by an overcoat layer of a plasma-enhanced chemical vapor deposition (PECVD) α-SiC:H layer, 200–500 nm thick [38.112].

Figure 38.6 shows two DMD pixels used in DLP technology for digital projection displays in computer projectors, HDTV sets, and movie projectors [38.5, 26, 27]. The entire array (chip set) consists of a large number of oscillating aluminum alloy micromirrors as digital light switches, which are fabricated on top of

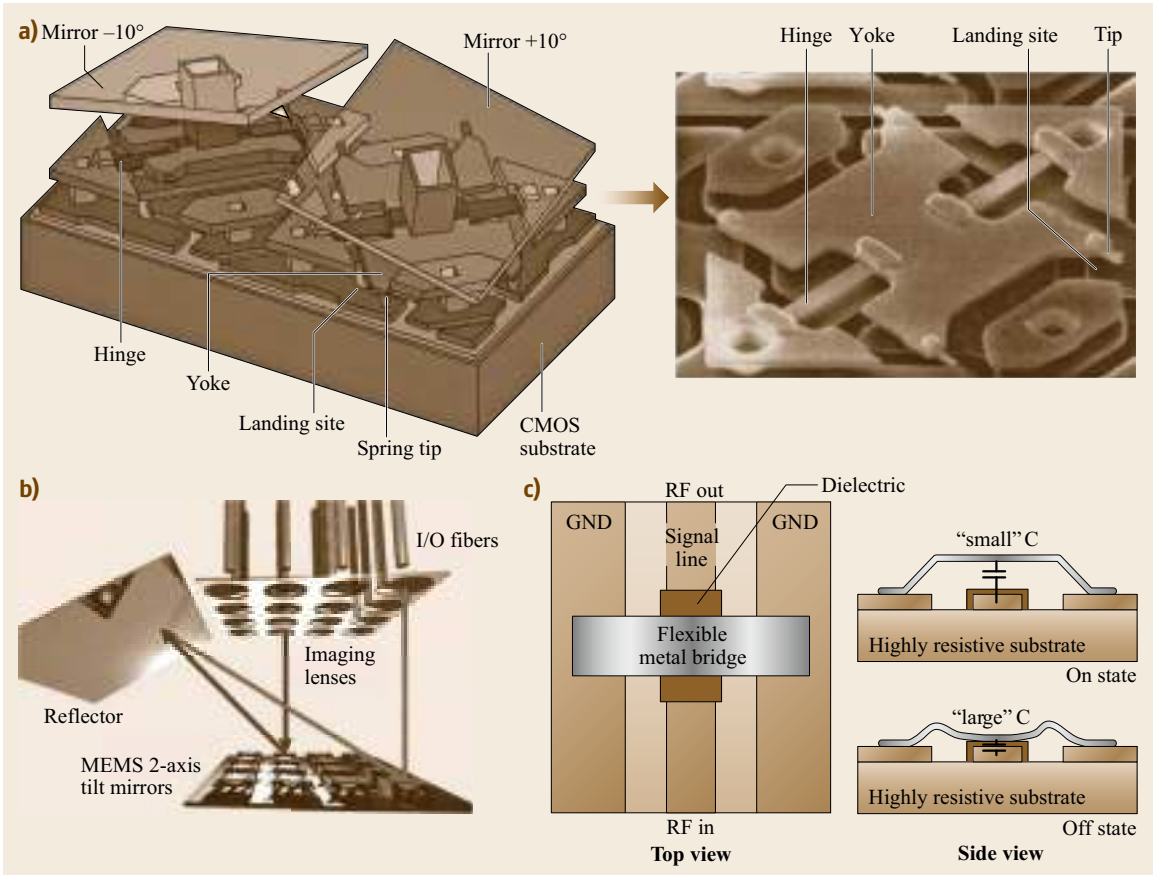

Fig. 38.6a–c Examples of two commercial MOEMS (**a**,**b**) and one RF-MEMS device (**c**) that experience tribological problems. (**a**) Digital micromirror device for displays (after [38.5]). (**b**) Tilt mirror arrays for switching optical signal input and output fiber arrays in optical cross-connect for telecommunications (after [38.113]). (**c**) RF microswitch (© IMEC, Belgium)

a complementary metal–oxide–semiconductor (CMOS) static random access memory integrated circuit. The surface micromachined array consists of half a million to more than two million of these independently controlled reflective micromirrors. Each micromirror is about 12 μm square and with 13 μm pitch, and flip backward and forward at a frequency on the order of 5–7 kHz as a result of electrostatic attraction between the micromirror structure and the underlying electrodes. For binary operation, the micromirror/yoke structure mounted on torsional hinges is oscillated ±10° (with respect to the plane on the chip set), and is limited by a mechanical stop. Contact between cantilevered spring tips at the end of the yoke (four present on each yoke) with the underlying stationary landing sites is required for true digital (binary) operation. Stiction and wear during contact between aluminum alloy spring tips and landing sites, hinge memory (metal creep at high operating temperatures), hinge fatigue, shock and vibration failure, sensitivity to particles in the chip package, and operating environment are some of the important issues affecting the operation reliability of a micromirror device [38.114–118]. A vapor-phase deposited self-assembled monolayer of the fatty acid perfluorodecanoic acid (PFDA) on the surfaces of tip and landing sites is used to reduce stiction and wear [38.119, 120]. However, these films are susceptible to moisture, and to keep moisture out and create a background pressure of PFDA, a hermetic chip package is used. The spring tip uses the stored spring energy to pop up the tip during pull-off. A lifetime estimate of over 100 000 operating hours with no degradation in image quality is typical. At a mirror modulation frequency of 7 kHz, each micromirror element needs to switch about 2.5 trillion cycles.

Figure 38.6 also shows a schematic of a 256×256-port large optical cross-connect, introduced in 2000 by Glimmerglass, Hayward, California, for optical

telecommunication networks in order to be able to rapidly manipulate a larger number of optical signals [38.113]. This optical microswitch uses 256 or more movable mirrors on a chip for switching a light beam from an input fiber to a few output fibers. The mirrors are made of gold-coated polysilicon and are about 500 μm in diameter. Reliability concerns are the same as those described for DMDs. To minimize stiction, the chip set is hermetically sealed in dry nitrogen (90% N_2, 10% He).

Figure 38.6 also shows a schematic of an electrostatically actuated, capacitive-type RF microswitch for switching of RF signals at microwave and low frequencies [38.121]. It is a membrane-type microswitch, and consists of a flexible metal (Al) bridge that spans the RF transmission line in the center of a coplanar waveguide. When the bridge is up, the capacitance between the bridge and RF transmission line is small, and the RF signal passes without much loss. When a DC voltage is applied between the RF transmission line and the bridge, the latter is pulled down until it touches a dielectric isolation layer. Thus, the large capacitance created shorts the RF signal to the ground. The failure modes include creep in the metal bridge, fatigue of the bridge, charging and degradation of the dielectric insulator, and stiction of the bridge to the insulator [38.28, 121–123]. Stiction occurs due to capillary condensation of water vapor from the environment, van der Waals forces, and/or charging effects [38.90–92]. If the restoring force in the bridge of the switch is not large enough to pull the bridge up again after the actuation voltage has been removed, the device fails due to stiction. Humidity-induced stiction can be avoided by hermetically sealing the microswitch. Some roughness of the surfaces reduces the probability of stiction. Selected actuation waveforms can be used to minimize charging effects.

38.2.2 NEMS

Probe-based data recording technologies have been explored for ultrahigh areal density recording where the probe tip (with a radius of about 5 nm) is expected to be scanned at velocities up to 100 mm/s. Major techniques include thermomechanical [38.47], phase change [38.124], and ferroelectric recording [38.125, 126]. We discuss the tribological issues with two of the widely pursued techniques [38.127].

Figure 38.7a shows the thermomechanical recording system that uses arrays of 1024 silicon microcantilevers (*Millipede*) and playback on a ≈ 40 nm-thick polymer medium with a harder Si substrate [38.47]. The cantilevers consist of integrated tip heaters with tips of nanoscale dimensions. Sharp tips themselves are also examples of NEMS. Thermomechanical recording is a combination of applying a local force to the polymer layer and softening it by local heating. The tip, heated to about 400 °C, is brought in contact with the polymer

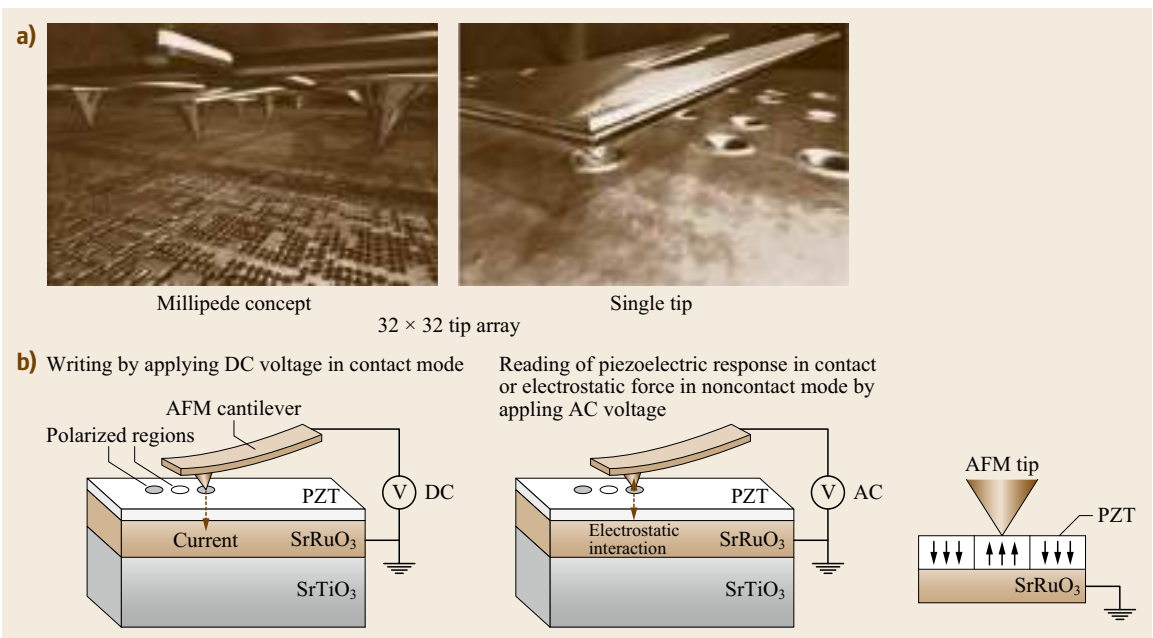

Fig. 38.7a,b Two example of NEMS devices – **(a)** thermomechanical recording, and **(b)** ferroelectric recording – that experience tribological problems

for recording. Readings are done using the heater cantilever, originally used for recording, as a thermal readback sensor by exploiting its temperature-dependent resistance. The principle of thermal sensing is based on the fact that the thermal conductivity between the heater and the storage substrate changes according to the spacing between them. When the spacing between the heater and sample is reduced as the tip moves into a bit, the heater's temperature and hence its resistance will decrease. Thus, changes in temperature of the continuously heated resistor are monitored while the cantilever is scanned over data bits, providing a means of detecting the bits. Erasing for subsequent rewriting is carried out by thermal reflow of the storage field by heating the medium to 150 °C for a few seconds. The smoothness of the reflown medium allows multiple rewriting of the same storage field. Bit sizes ranging between 10 and 50 nm have been achieved by using a 32×32 (1024) array write/read chip (3 mm × 3 mm). It has been reported that tip wear occurs due to contact between the tip and the Si substrate during writing. Tip wear is a major concern for device reliability.

Figure 38.7b shows the schematic of domain writing and reading in a ferroelectric film. The electrically conductive AFM tips are placed in contact with a piezoelectric (lead zirconate titanate, PZT), film-coated medium [38.125, 126]. Ferroelectric domains on PZT film are polarized by applying short voltage pulses (≈ 10 V, $\approx 100\,\mu$s) that exceed the coercive field of the PZT layer, resulting in local, nonvolatile changes in the electronic properties of the underlying film. The temperature rise during recording is expected to be on the order of 80 °C. Reading out of the polarization states in the ferroelectric film can be carried out using two different methods. In one method, the static surface charge, proportional to the normal component of polarization, can be detected by electrostatic force microscopy in the noncontact mode. In the second method, an AFM is operated in the contact mode and piezoresponse force is measured by applying an alternating-current (AC) voltage. Wear of the conducting tip and the PZT layer at high scanning velocities is a major concern for device reliability. Various lubricant films are being developed to minimize wear [38.124–130].

In magnetic data storage, magnetic recording is accomplished by relative motion between the magnetic head slider and a magnetic rigid disk [38.32]. Magnetic rigid disks and heads used today for magnetic data storage consist of nanostructured films a few nm thick. Figure 38.8a shows the sectional view of a conventional magnetic rigid disk. The superparamagnetic effect poses a serious challenge for the ever-increasing areal density of disk drives. One of the promising methods to circumvent the density limitations imposed by this effect is the use of a nanopatterned disk (Fig. 38.8b). In a conventional disk, the thin magnetic layer forms a random mosaic of nanometer-scale grains, and each recorded bit consists of many tens of these random grains. In a patterned disk, the magnetic layer is created as an ordered array of highly uniform islands, each island capable of storing an individual bit. These islands may be one or a few grains, rather than a collection of random decoupled grains. This increases the density by a couple of orders of magnitude. Figure 38.8c shows a schematic of an inductive write GMR read head structure. These are

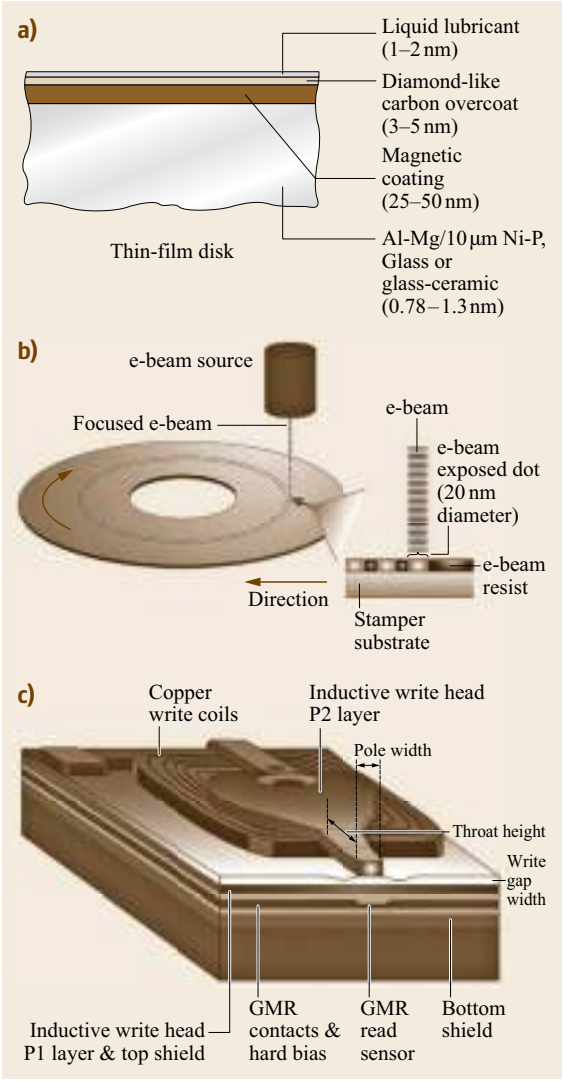

Fig. 38.8a–c Schematic of (a) sectional view of a conventional magnetic rigid disk, (b) nanopatterned magnetic rigid disk, and (c) an inductive write, GMR read magnetic head structure for magnetic data storage (Hitachi)

constructed from a variety of materials: magnetic alloys, metal conductors, ceramic, and polymer insulators in a complex three-dimensional structure. The multilayered thin-film structures used to construct the sensor and individual films are only a few nm thick. The head slider surface, which flies on the disk surface, is coated with about 3 nm thick of diamond-like carbon coatings to protect the thin-film structure from electrostatic discharge. Any isolated contacts between the disk and sensor and lubricant pickup pose tribological concerns [38.32].

Nano-objects are used in various applications where they come into sliding contact with each other and the surfaces where they are used, which can lead to nano-object deformation [38.8]. Some examples of these applications include drug delivery for cancer treatment (to be presented in the bioNEMS section), oil detection, contaminant removal, catalysis, and tribology on the macro- to nanoscale. For oil detection applications, as in the example shown in Fig. 38.9a, oxidized carbon black nanoparticles with a polyvinyl alcohol shell are coated with an oil-detecting agent. This agent is released on contact with hydrocarbons in oil, and its absence on recovery and analysis of the nano-objects is an indication of the presence of oil [38.131]. Agglomeration of nano-objects can prevent flow through porous media, which results in losses and prevents eventual recovery of the nano-objects [38.132]. Friction on surfaces and during flow in liquids can also hinder recovery. Low friction of nano-objects over surfaces and within liquids is of interest.

In contaminant removal, magnetic shell cross-linked knedel-like nanoparticles (MSCKs) are of interest. These are composites of polymer layers on iron oxide nanoparticles. In Fig. 38.9b, the MSCKs are added to polluted water (left), where they selectively absorb oil (center) and are finally removed by introducing a neodymium magnet [38.133]. Reducing agglomeration and fluid friction is important for efficient manipulation of nano-objects through liquids to contaminated sites.

In applications involving catalysis for hydrogen evolution recovery (HER), nanowires have been used to aid in the catalytic activity, as shown in Fig. 38.9c. The nanowires consist of an inner molybdenum trioxide (MoO_3) core and outer molybdenum disulfide (MoS_2) shell. The core is used for transporting electrons to edge sites of the outer MoS_2 shell, which is catalytically active. This is preferred over bulk MoS_2, which has a limited number of edge sites for the same volume of material compared to the nanowires. At these sites, the transfer of electrons necessary for the recovery of hydrogen from water is enhanced by the MoS_2, which improves HER efficiency [38.134]. Low friction of water moving over the nanowires is important for efficient flow over edge sites and conversion to hydrogen.

Nano-objects have demonstrated the ability to reduce friction and wear in applications on the macroscale. For applications on the micro/nanoscale, increasing the lifetime and efficiency of individual components of systems is crucial to the commercialization of micro/nanosystems. Adhesive and friction forces can hinder device operation and reliability [38.88, 91, 92]. In these environments, nano-objects can be deformed locally or the entire nano-object can be compressed. Knowledge of the mechanical behavior during loading and unloading in these environments is essential for sustained use. Studies in friction, wear, and deformation behavior are critical to successful integration of nano-objects for the various applications.

38.2.3 BioMEMS

Biosensors are devices typically used to detect target biomolecules such as proteins, enzymes, or nucleic acids, as well as chemical contaminants. Biosensors can be classified into two broad categories: microarray type, which typically consist of (1) microfluidic and nanofluidic sensors that usually involve manipulation of small fluidic volumes (microliters to nanoliters), leading to optical methods for detection, and (2) cantilever or field-effect devices with adsorption of target analytes to sensing elements as the main transduction mechanism.

Advances in micro- and nanofabrication have led to the development of integrated micro- and nanofluidic biosensors that bring together several operations, e.g., sample extraction, purification, sensing, etc., on a simple platform. These sensors are designed either to detect a single biochemical or a class of (bio)chemicals, or for system-level analytical capabilities for a broad range of (bio)chemical species, known as a micro-total analysis system (μTAS). Detection is generally performed using optical methods in micro- and nanofluidic biosensors and mechanical or electrical methods in microarray-type biosensors [38.73]. Optical methods include fluorescence, optical cavity resonator, and surface plasmon resonance. Various methods are used for driving the fluid flow in micro- and nanochannels. Mechanical methods include mechanical changes induced by adsorption of target molecules or analytes to cantilevers or nanowires. Electrical methods include changes to inherent biomolecular charge in the case of field-effect transistors or electrochemical changes. In micro- and nanofluidic biosensors, two methods are commonly used to drive the fluid flow – pressure-driven and electric field-driven or electrokinetic.

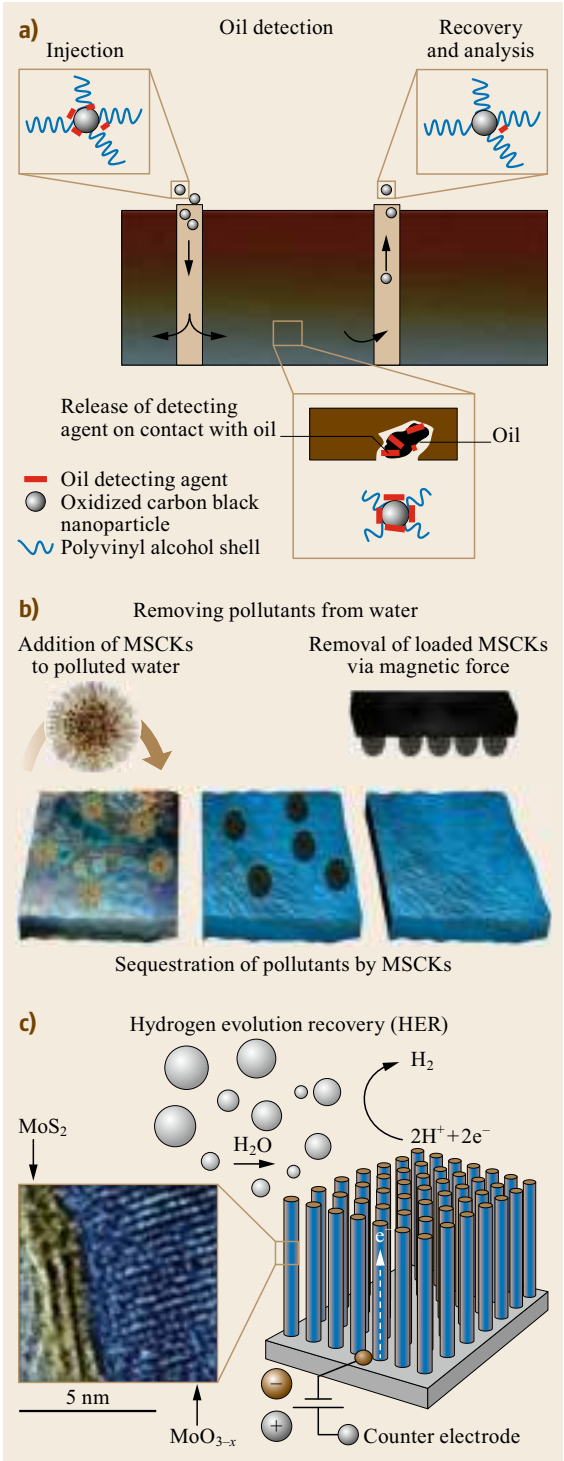

Fig. 38.9a–c Examples of nano-objects in applications in: **(a)** Oil detection, where carbon black nano-objects are coated with an oil detecting agent. After injection into the ground, the agent is released on contact with hydrocarbons, and this is used as an indication of the presence of oil on recovery and analysis of the nanoparticle. An example of a wristwatch-type biosensor based on microfluidics referred to as lab-on-a-chip system is shown in Fig. 38.10a [38.56, 71]. The chip relies on microfluidics and involves manipulation of tiny amounts of fluids in microchannels using microvalves. The test fluid is injected into the chip generally using an external pump or syringe for analysis. Some chips have been designed with an integrated electrostatically actuated diaphragm-type micropump. The sample, which can have volume measured in nanoliters, flows through microfluidic channels via an electric potential and capillary action using microvalves (having various designs including membrane type) for various analyses. The fluid is preprocessed and then analyzed using a biosensor. Another example of a biosensor is the cassette-type biosensor used for human genomic DNA analysis, and integrated biological sample preparation is shown in Fig. 38.10b [38.72]. The implementation of micropumps and microvalves allows for fluid manipulation and multiple sample processing steps in a single cassette. Blood or other aqueous solutions can be pumped into the system where various processes are performed.

Microvalves, which are found in most microfluidic components of biosensors, can be classified in two categories: active microvalves (with an actuator) for flow regulation in microchannels, and passive microvalves integrated with micropumps. Active microvalves consist of a valve seat and a diaphragm actuated by an external actuator [38.55, 135, 136]. Different types of actuators are based on piezoelectric, electrostatic, thermopneumatic, electromagnetic, and bimetallic materials, shaped memory alloys, and solenoid plungers. An example of an electrostatic cantilever-type active microvalve is shown in Fig. 38.11 [38.135]. Passive

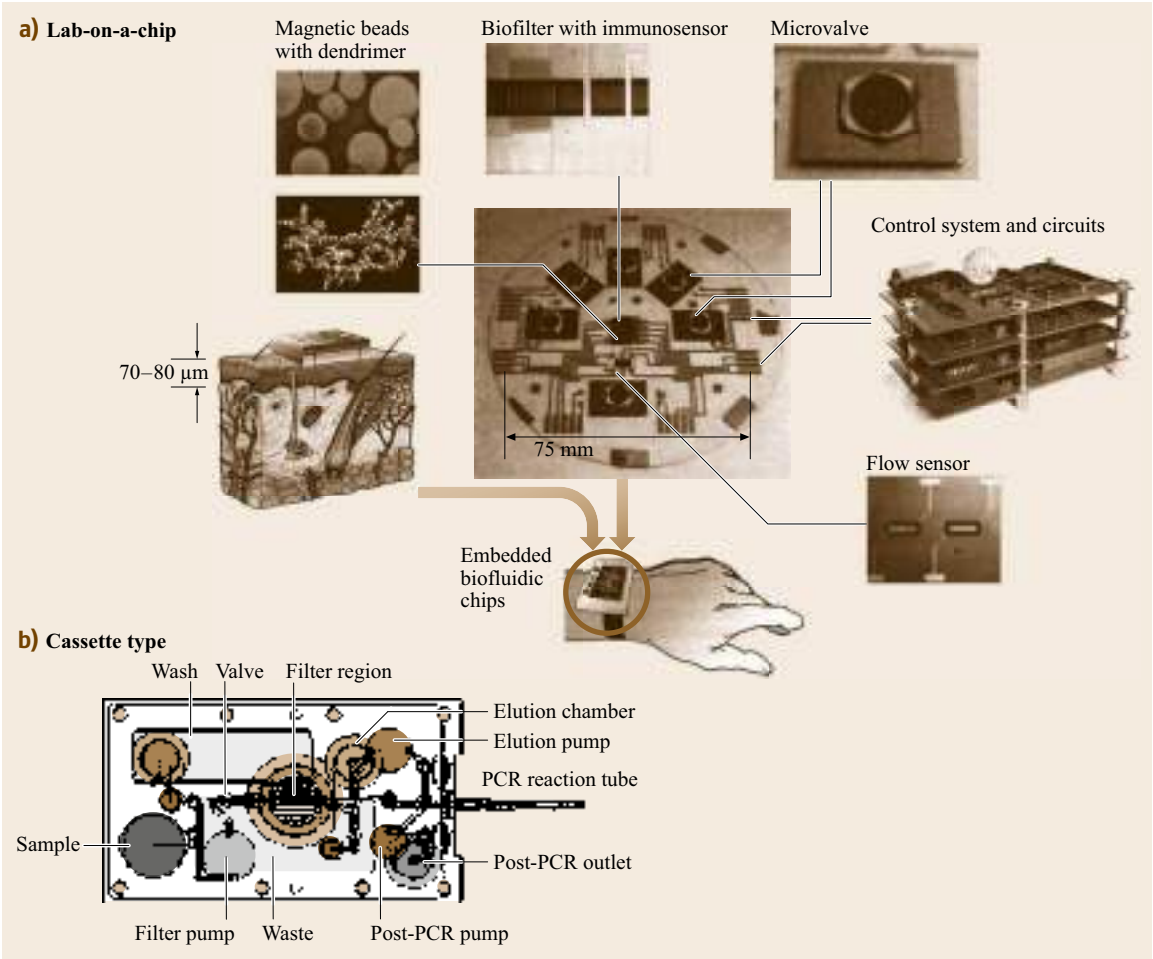

Fig. 38.10 **(a)** MEMS-based biofluidic chip, commonly known as a lab-on-a-chip, that can be worn like a wristwatch (after [38.71]). **(b)** Cassette-type biosensor used for human genomic DNA analysis (after [38.72]) (PCR: polymerase chain reaction)

microvalves used in micropumps include mechanical check valves and a diffuser/nozzle [38.55, 136–139]. Check valves consist of a flap or membrane that is capable of opening and closing with changes in pressure; see Fig. 38.11 for schematics. A diffuser/nozzle uses an entirely different principle and only works with the presence of a reciprocating diaphragm. When one convergent channel works simultaneously with another convergent channel oriented in a specific direction, a change in pressure is possible.

There are four main types of mechanical micropumps: a diaphragm micropump involving mechanical check valves; electrostatic micropumps; valveless rectification pumps with or without diffuser/nozzle type valves; and rotary micropumps [38.55, 136–139]. A diaphragm micropump consists of a reciprocating diaphragm that can be piezoelectrically driven, working in synchronization with two check valves (Fig. 38.11) [38.138]. Electrostatic micropumps have a diaphragm as well, but are driven using two electrodes (Fig. 38.11) [38.140]. Valveless micropumps also consist of a diaphragm that is piezoelectrically driven, but does not incorporate passive mechanical valves. Instead, these pumps use an elastic buffer mechanism or a variable gap mechanism. Finally, a rotary micropump has a rotating rotor that simply adds momentum to the fluid by the fast moving action of the blades (Fig. 38.11) [38.141, 142]. Rotary micropumps can be driven using an integrated electromagnetic motor or by the presence of an external electric field. All of these micropumps can be made of silicon or a polymer material.

During the operation of the microvalves and micropumps discussed above, in which contacts occur due

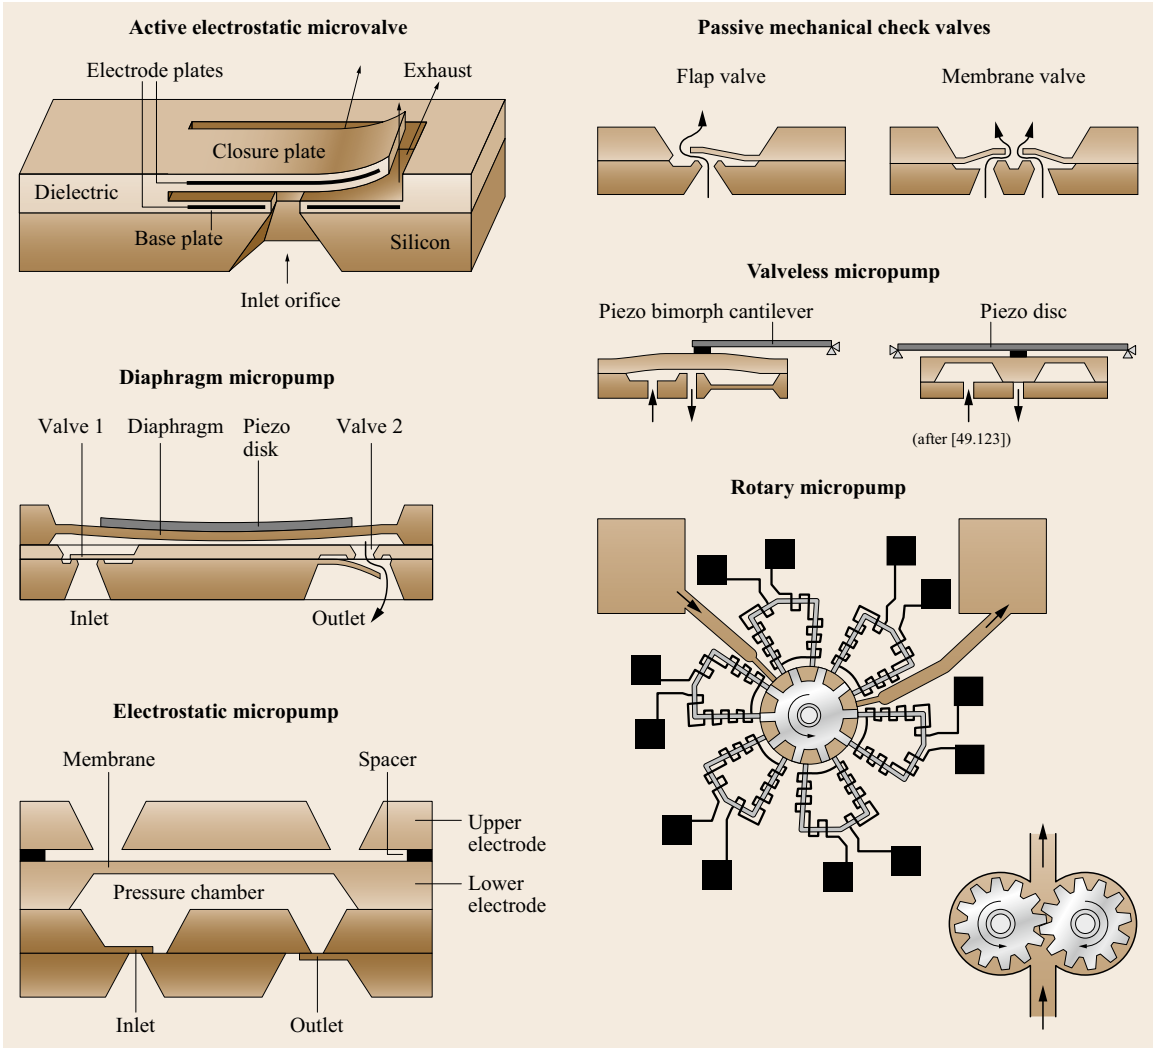

Fig. 38.11 Multiple examples of valves and pumps found in microfluidic devices. Mechanical check valves, diaphragm micropump, valveless micropump, and rotary micropump

to relative motion, adhesion and friction properties become important. During operation, active mechanical microvalves have an externally actuated diaphragm that comes into contact with a valve seat to restrict the fluid flow. Adhesion between the diaphragm and valve seat will affect the operation of the microvalve. In the diaphragm micropumps, two passive mechanical check valves are incorporated into the design. Passive mechanical check valves also exhibit adhesion when the flap or membrane comes into contact with the valve seat when fluid flow is removed. Adhesion also occurs during the operation of valveless micropumps when the diaphragm, which is piezoelectrically driven, comes into contact with the rigid outlet. Finally, adhesion and friction can also be seen during the operation of rotary micropumps when the gears rotate and come into contact and rub against one another.

If the adhesion between the microchannel surface and the biofluid is high, the biomolecules will stick to the microchannel surface and restrict flow. In order to facilitate flow, microchannel surfaces with low bioadhesion are required. Fluid flow in polymer channels can produce triboelectric surface potential, which may affect the flow. Polymers are known to generate surface potential, and the magnitude of the potential varies from one polymer to another [38.143–145]. Conductive surface layers on the polymer channels can be deposited to reduce triboelectric effects.

As mentioned earlier, the microfluidic biosensor shown in Fig. 38.10a required the use of micropumps

and microvalves. As an example, a microdevice with 1000 channels requires 1000 micropumps and 2000 microvalves, which makes it bulky and poses reliability concerns. To overcome this problem, two methods can be used for driving the flow of fluids in microchannels: pressure-driven and electrokinetic. Electrokinetic flow is based on the movement of molecules in an electric field due to their charges. There are two components to electrokinetic flow: electrophoresis, which results from the accelerating force due to the charge of a molecule in an electric field, and electroosmosis, which uses electrically controlled surface tension to drive the uniform liquid flow. Biosensors based on electrokinetic flow have also been developed. In so-called *digital-based microfluidics*, based on the electroosmosis process, electrically controlled surface tension is used to drive liquid droplets, thus eliminating the need for valves and pumps [38.146, 147]. These microdevices consist of a rectangular grid of gold nanoelectrodes instead of micro/nanochannels. An externally applied electric field enables manipulation of few-nanoliter samples through the capillary circuitry.

An example of a microarray-type biosensor, based on a field-effect transistor (FET), is shown in Fig. 38.12a [38.75, 78–80, 148]. FETs are sensitive to the electrical field produced by the charge at the surface of the gate insulator. In this sensor, the gate metal electrode of a metal–oxide–semiconductor field-effect transistor (MOSFET) is removed and replaced with a protein (receptor layer) whose cognate is the analyte (e.g., virus or bacteria) that is meant to be sensed. Various proteins may have 1–25 (positive or negative) charges per molecule. The binding of the receptor layer with the analyte produces a change in the effective charge, creating a change in the electrical field. This electrical field change may produce a measurable change in the current flow through the device. Adhesion between the protein layer and silica substrate affects the reliability of the biosensor. In the case of implanted biosensors, the biosensors come in contact with the exterior environment, such as tissues and fluids, and any relative motion of the sensor surface with respect to that exterior environment may result in surface damage. A schematic of the generation of friction and wear points when an implanted biosensor surface comes in contact with a living tissue is shown in Fig. 38.12b [38.93]. The friction, wear, and adhesion of the biosensor surface may be critical in these applications [38.75, 93, 149, 150].

Polymer bioMEMS have been designed to measure cellular surfaces. For two examples, see Fig. 38.13 [38.151]. The device on the left has cantilevers anchored at the periphery of the circular structure, while the device on the right has cantilevers

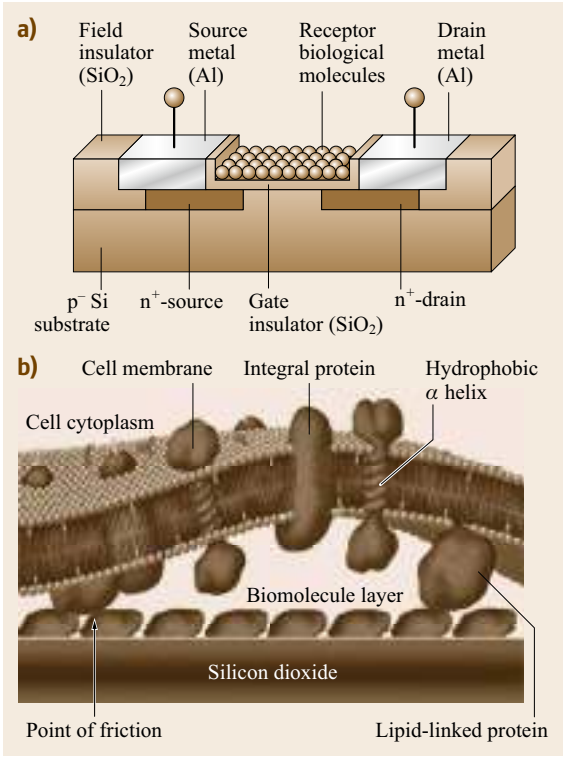

Fig. 38.12 **(a)** Schematic of a bioFET sensor (after [38.75]), and **(b)** schematic showing the generation of friction and wear points due to interaction of an implanted biomolecule layer on a biosensor with living tissue (after [38.93])

anchored at the two corners on the top and the bottom. The cell adheres to the center of the structure, and the contractile forces generated in the cell's cytoskeleton causes the cantilever to deflect. The deflection of the compliant polymer cantilevers is measured optically and related to the magnitude of the forces generated by the cell. Adhesion between cells and the polymer beam is desirable. In order to design the sensors, micro- and nanoscale mechanical properties of polymer structures are needed.

38.2.4 BioNEMS

Micro/nanofluidic devices provide a powerful platform for electrophoretic separations for a variety of chemical and biochemical analyses. Electrophoresis is a versatile analytical method that is used for separation of small ions, neutral molecules, and large biomolecules. Figure 38.14 shows an interdigitated micro/nanofluidic silicon array with nanochannels for separation processes. Figure 38.15 shows a schematic of an implantable, immunoisolation submicroscopic biocapsule

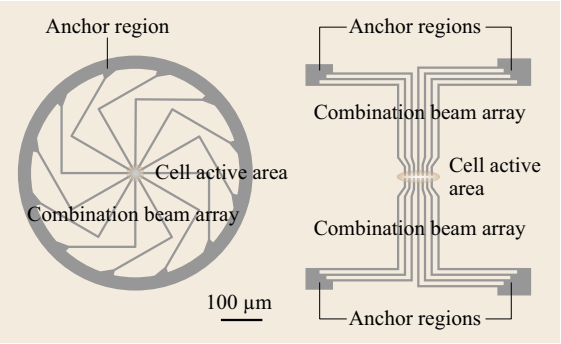

Fig. 38.13 Schematic of two designs for polymer bioMEMS structures to measure cellular forces (after [38.151])

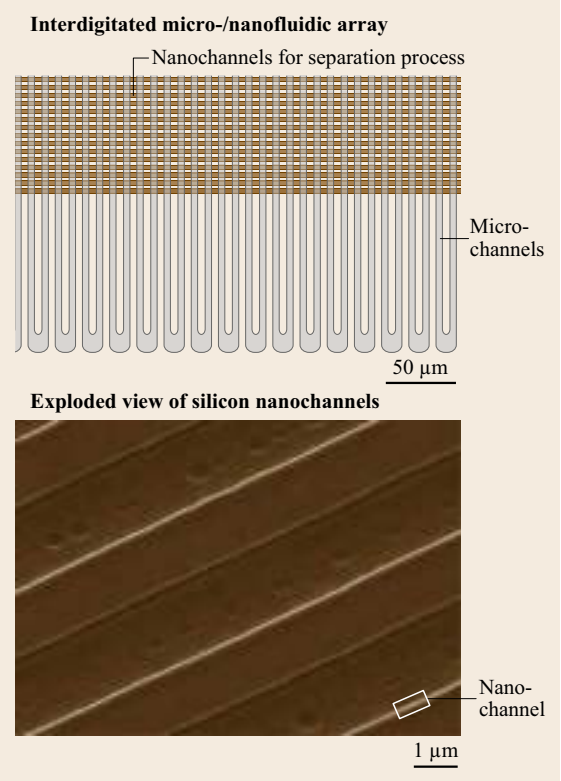

Fig. 38.14 Interdigitated micro/nanofluidic silicon array for separation processes (after [38.83])

for drug delivery treating significant medical conditions such as Type I diabetes [38.82, 83]. The purpose of the immunoisolation biocapsule is to create an implantable device capable of supporting foreign living cells that can be transplanted into humans. It is a silicon capsule consisting of two nanofabricated membranes bonded together with the drug (e.g., encapsulated insulin-producing islet cells) contained within the

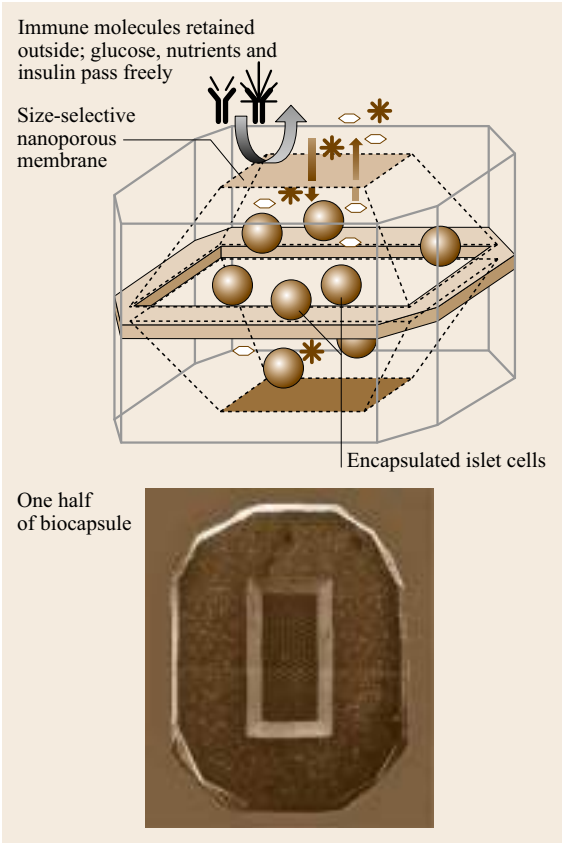

Fig. 38.15 Schematics of implantable, immunoisolation submicroscopic biocapsules (drug-delivery devices) (after [38.83])

cavities for long-term delivery. The pores or nanochannels in a semipermeable membrane as small as 6 nm are used as flux regulators for the long-term release of drugs. The nanomembrane also protects therapeutic substances from attack by the body's immune system. The pores are large enough to provide the flow of nutrients (e.g., glucose molecules) and drugs (e.g., insulin). However, they are small enough to block natural antibodies, which can penetrate any orifice larger than 18 nm. Pores in silicon can be etched using sacrificial layer lithography, described in Appendix 38.A [38.83].

The main reliability concerns in micro/nanofluidic silicon arrays and implantable biocapsules are biocompatibility and potential biofouling (undesirable accumulation of microorganisms) of the channels/membrane by means of protein and cell adsorption from biological fluids. Biofouling can also result in the clogging of the nanochannels/nanopores, which potentially could render the device ineffective. The adhesion of proteins and cells to an implanted device can also cause detrimental results such as inflammation and excessive

fibrosis. Deposition of the self-assembled monolayers of selected organic molecules on the channels implants, which makes them hydrophobic, presents an innovative solution to combat the adverse effects of the biological fluids [38.152–155].

Figure 38.16 shows a conceptual model of a targeted intravascular drug-delivery device using nanoparticles to search and destroy disease (tumor) cells [38.84]. The tumor cells have a 1–2 orders of magnitude higher density of receptors than the normal cells and a lower pH. Some receptors are only expressed on tumor cells. Nanoparticles made of various materials including gold (Au), graphene, iron oxide, polymer, and silica have been studied in targeted drug delivery for cancer treatment [38.156–162]. With lateral dimensions of 1 μm or less, the particles are smaller than any blood cells. These particles can be injected into the bloodstream and travel freely through the circulatory system. In order to direct these drug-delivery nanoparticles to cancer sites, their external surfaces are chemically modified to carry molecules that have lock-and-key binding specificity with molecules that support a growing cancer mass. As the particles come in close proximity with the diseased cells, the ligands on the particle surfaces attach to the receptors on the cells. As soon as the particles dock on the cells, a compound is released that forms a pore on the membrane of the cells, which leads to cell death and, ultimately, death of the cancer mass that was being nourished by the blood vessel. The adhesive interactions are regulated by specific (ligand-receptor binding) and nonspecific (short-range van der Waals, electrostatic, steric) interactions [38.163]. Adhesion between nanoparticles and disease cells is required. Furthermore, the particles should travel close to the endothelium lining of vascular arteries to facilitate the interaction between the particles and diseased cells. Human capillaries can have radii as small as 4–5 μm. *Decuzzi* et al. [38.163] analyzed the margination of a particle circulating in the bloodstream and calculated the speed and time for margination (drifting of particles towards the blood vessel walls) as a function of density and diameter of particle, based on various forces present between the circulating particle and the endothelium lining. They reported that the particles used for drug delivery should have a radius smaller than the critical value (in the range of 100 nm). Studies show that a lateral force on the particles assists them in faster margination towards the endothelium walls. Thus, nonspherical particles are more desirable. In addition, reducing agglomeration and friction of nano-objects moving through a liquid and in contact with surfaces is important for efficient transport to diseased sites.

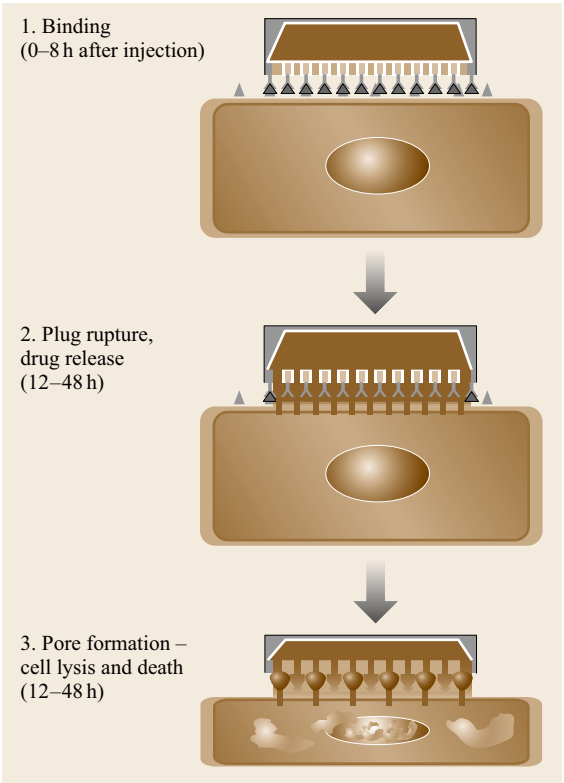

Fig. 38.16 Intravascular nanoparticles to search and destroy diseased blood cells. Life cycles include (1) target binding, (2) drug release, and (3) cell death (after [38.84])

Because of their unique mechanical and electrical properties, single-walled and multiwalled carbon nanotubes (SWNT and MWNT) are being used for thermal management of high-power devices, reinforced composites and super-strong fiber and sheets, chemical and biological sensors, electromechanical devices, field emission devices, molecular electronics and computing [38.49, 164]. Figure 38.17 shows a SWNT biosensor [38.2]. The conductance of carbon nanotube (CNT) devices changes when proteins adsorb on the surface. The change in electrical resistance is a measure of protein adsorption. For high performance, adhesion should be strong between the adsorbent and SWNT.

In summary, adhesion, stiction/friction, and wear clearly limit the lifetimes and compromise the performance and reliability of MEMS/NEMS and bioMEMS/bioNEMS. Figure 38.18 summarizes tribological problems encountered in some of the MEMS, MOEMS, RF-MEMS, and bioMEMS devices just discussed.

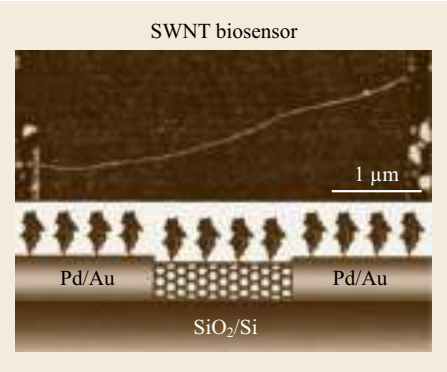

Fig. 38.17 SEM micrograph of SWNT biosensor; *bottom schematic* shows the adsorption of protein molecules to the SWNT (after [38.2])

38.2.5 Microfabrication Processes

In addition to in-use stiction, stiction issues are also present in some processes used for the fabrication of MEMS/NEMS. For example, the last step in surface micromachining involves the removal of sacrificial layer(s) called release, since the microstructures are released from the surrounding sacrificial layer(s). The release is accomplished by an aqueous chemical etching, rinsing, and drying processes. Due to meniscus effects as a result of wet processes, the suspended structures can sometimes collapse and permanently adhere to the underlying substrate, as shown in Fig. 38.19 [38.165]. Adhesion is caused by water molecules adsorbed on the adhering surfaces and/or because of formation of adhesive bonds by silica residues that remain on the surfaces after the water has evaporated. This so-called release stiction is overcome by using dry release methods, such as CO_2 critical point drying or sublimation drying [38.166]. CO_2 at high pressure is in a supercritical state and becomes liquid. Liquid CO_2 is used to remove wet etchant, and then it is converted back to the gas phase.

38.2.6 Tribological Needs

Various MEMS/NEMS are designed to perform expected functions in the millisecond to picosecond range. The life expectancy of devices for high-speed contacts can vary from a few hundred thousand to many billions of cycles, e.g., over a hundred billion cycles for DMDs, which puts stringent requirements on materials [38.13, 103, 167–170]. Adhesion between a biological molecular layer and the substrate (referred to as *bioadhesion*), reduction of friction and wear of biological layers, biocompatibility, and biofouling for

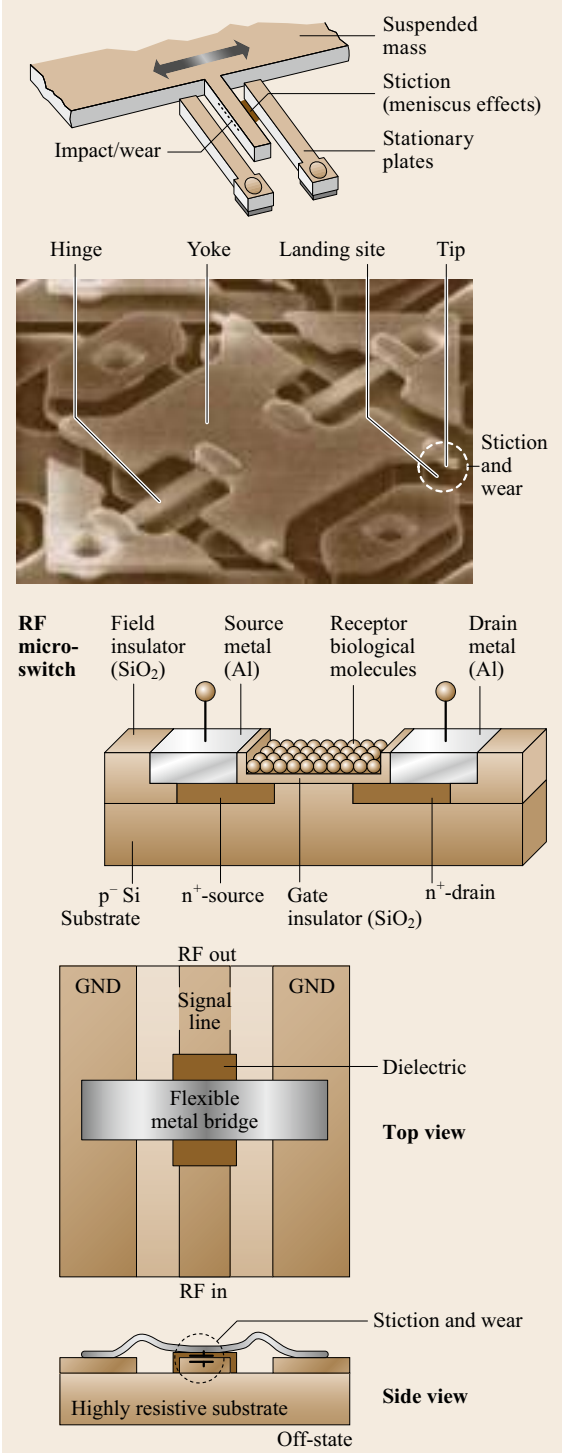

Fig. 38.18 Summary of tribological issues in MEMS, MOEMS, RF-MEMS and bioMEMS device operation (after [38.75, 152])

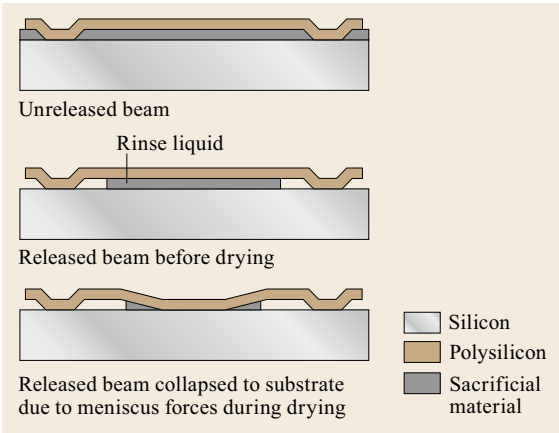

Fig. 38.19 Tribological issues in microfabrication via surface micromachining

bioMEMS/bioNEMS are important [38.75, 93]. Most mechanical properties are known to be scale dependent [38.85]. Therefore, the properties of nanoscale structures need to be measured [38.171]. There is a need to develop a fundamental understanding of adhesion, friction/stiction, wear, and the role of surface contamination, and environment [38.13]. MEMS/NEMS materials need to possess good mechanical and tribological properties on the micro/nanoscale. There is a need to develop lubricants and identify lubrication methods that are suitable for MEMS/NEMS devices and applications. Methods need to be developed to enhance adhesion between biomolecules and the device substrate (bioadhesion). Component-level studies are required to provide a better understanding of the tribological phenomena occurring in MEMS/NEMS.

The fields of nanotribology and nanomechanics, and atomic force microscopy-based techniques, have provided researchers with a viable approach to address these problems [38.44, 45, 86–88, 172, 173]. The following is an overview of nanoscale adhesion, friction and wear studies of materials and lubrication for MEMS/NEMS and bioMEMS/bioNEMS, and component-level studies of stiction phenomena, in MEMS/NEMS devices.

38.3 Nanotribology and Nanomechanics Studies of Silicon and Related Materials

The materials of most interest for planar fabrication processes using silicon as the structural material are undoped and boron-doped (p^+-type) single-crystal silicon for bulk micromachining, and doped and undoped phosphorus (n^+-type) low-pressure chemical vapor deposition (LPCVD) polysilicon films for surface micromachining. Since silicon-based devices lack high-temperature capabilities with respect to both mechanical and electrical properties, SiC is being developed as a structural material for high-temperature microsensor and microactuator applications [38.174–177]. SiC can also be desirable for high-frequency micromechanical resonators, in the GHz range, because of its high modulus of elasticity-to-density ratio and, consequently, high resonance frequency. Table 38.2 compares selected bulk properties of SiC and Si(100). Researchers have found low-cost techniques for producing single-crystalline 3C-SiC (cubic or β-SiC) films via epitaxial growth on large-area silicon substrates for bulk micromachining [38.178] and polycrystalline 3C-SiC films on polysilicon and silicon dioxide layers for surface micromachining of SiC [38.179]. Single-crystalline 3C-SiC piezoresistive pressure sensors have been fabricated using bulk micromachining [38.176, 177]. Surface-micromachined polycrystalline SiC micromotors have been fabricated and reported to provide satisfactory operation at high temperatures [38.180]. Because of their importance to MEMS/NEMS applications, the tribology of these materials must be examined and optimized.

In this section, both macroscale and microscale tribological properties of virgin and treated/coated silicon, polysilicon films, and SiC are presented. As will be shown, bare silicon exhibits inadequate tribological performance and needs to be coated with a solid and/or liquid overcoat or be surface treated (e.g., oxidation and ion implantation, commonly used in semiconductor manufacturing), which reduces friction and wear. SiC films exhibit good tribological performance.

38.3.1 Virgin and Treated/Coated Silicon Samples

Nanotribological and Nanomechanical Properties of Silicon and Effect of Ion Implantation

Friction and wear of single-crystalline and polycrystalline silicon samples have been studied, and the effect of ion implantation with various doses of C^+, B^+, N_2^+, and Ar^+ ion species at 200 keV energy to improve their friction and wear properties has been studied [38.183–185]. The coefficient of macroscale friction and the

[a] Unless otherwise stated, data shown were obtained from [38.181]
[b] Obtained from [38.182]

wear factor of virgin single-crystal silicon and C^+-implanted silicon samples as a function of ion dose are presented in Fig. 38.20 [38.183]. The macroscale friction and wear tests were conducted using a ball-on-flat tribometer. Each data bar represents the average value of four to six measurements. The coefficient of friction and wear factor for bare silicon are very high and decrease drastically with ion dose. Silicon samples bombarded above the ion dose of $10^{17}\,C^+\,cm^{-2}$ exhibit extremely low values of coefficients of friction (typically 0.03–0.06 in air) and wear factors (reduced by as much as four orders of magnitude). *Gupta* et al. [38.183] reported that a decrease in the coefficient of friction and wear factor of silicon as a result of C^+ ion bombardment occurred because of formation of silicon carbide rather than amorphization of silicon. *Gupta* et al. [38.184] also reported an improvement in friction and wear with B^+ ion implantation.

Microscale friction measurements were performed using an atomic force/friction force microscope (AFM/FFM) [38.44, 45, 86, 88, 173]. Table 38.3 shows values of surface roughness and coefficients of macroscale and microscale friction for virgin and doped silicon. There is a decrease in the coefficients of microscale and macroscale friction values as a result of ion implantation. When measured for small contact areas and very low loads used in microscale studies, indentation hardness and elastic modulus are higher than those at the macroscale. This, added to the effect of the small apparent area of contact reducing the number of trapped particles on the interface, results in less plowing contribution and lower friction in the case of microscale friction measurements. Figures 38.21a and 38.21b show results of microscale wear resistance studies of ion-implanted silicon samples studied using a diamond tip in an AFM [38.186]. For tests conducted at various loads on Si(111) and C^+-implanted Si(111), it is noted that the wear resistance of the implanted sample is slightly poorer than that of virgin silicon up to about 80 μN. Above 80 μN, the wear resistance of implanted Si improves. As one continues to run tests at 40 μN for a larger number of cycles, the implanted sample, which forms hard and tough silicon carbide, exhibits higher wear resistance than the unimplanted sample. Damage from the implantation in the top layer results in poorer wear resistance; however, the implanted zone at the subsurface is more wear resistant than the virgin silicon.

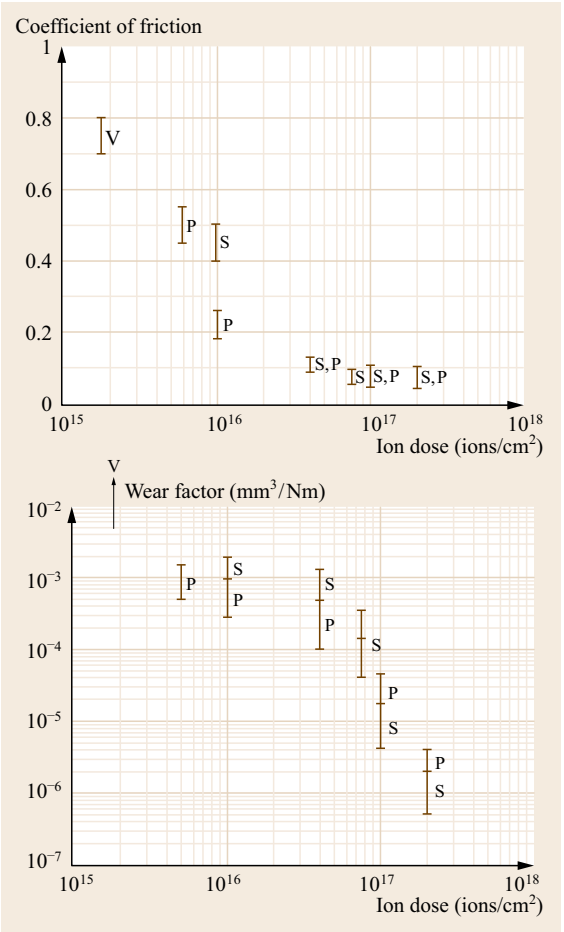

Fig. 38.20 Influence of ion doses on the coefficient of friction and wear factor on C^+ ion bombarded single-crystal and polycrystalline silicon slid against an alumina ball. V corresponds to virgin single-crystal silicon, while S and P denote tests that correspond to doped single- and polycrystalline silicon respectively (after [38.183])

Table 38.3 Surface roughness and micro- and macroscale coefficients of friction of selected samples

Material	RMS roughness (nm)	Coefficient of microscale friction[a]	Coefficient of macroscale friction[b]
Si(111)	0.11	0.03	0.33
C^+-implanted Si(111)	0.33	0.02	0.18

[a] Versus Si_3N_4 tip, tip radius of 50 nm in the load range of 10–150 nN (2.5–6.1 GPa) at a scanning speed of 5 μm/s over a scan area of 1 μm × 1 μm in an AFM
[b] Versus Si_3N_4 ball, ball radius of 3 mm at a normal load of 0.1 N (0.3 GPa) at an average sliding speed of 0.8 mm/s using a tribometer

Hardness values of virgin and C^+-implanted Si(111) at various indentation depths (normal loads) are presented in Fig. 38.21c [38.186]. The hardness at a small indentation depth of 2.5 nm is 16.6 GPa, and it drops to a value of 11.7 GPa at a depth of 7 nm and a normal load of 100 μN. Higher hardness values obtained in low-load indentation may arise from the observed pressure-induced phase transformation during the nanoindentation [38.187, 188]. Additional increases in the hardness at an even lower indentation depth of 2.5 nm reported here may arise from the contribution of complex chemical films (not from native oxide films) present on the silicon surface. At small volumes there is a lower probability of encountering material defects (dislocations, etc.). Furthermore, according to the strain gradient plasticity theory advanced by *Fleck* et al. [38.189], large strain gradients inherent in small indentations lead to accumulation of geometrically necessary dislocations that cause enhanced hardening. These are some of the plausible explanations for an increase in hardness at smaller volumes. If the silicon material were to be used at very light loads, such as in microsystems, the high hardness of surface films would protect the surface until it is worn.

From Fig. 38.21c, the hardness value of C^+-implanted Si(111) at a normal load of 50 μN is 20.0 GPa with an indentation depth of about 2 nm, which is comparable to the hardness value of 19.5 GPa at 70 μN; whereas the measured hardness value for virgin silicon at an indentation depth of about 7 nm (normal load of 100 μN) is only about 11.7 GPa. Thus, ion implantation with C^+ results in an increase in hardness in silicon. Note that the surface layer of the implanted zone is much harder compared with the subsurface, and may be brittle, leading to higher wear on the surface. The subsurface of the implanted zone (SiC) is harder than the virgin silicon, resulting in higher wear resistance, which is also observed in the results of the macroscale tests conducted at high loads.

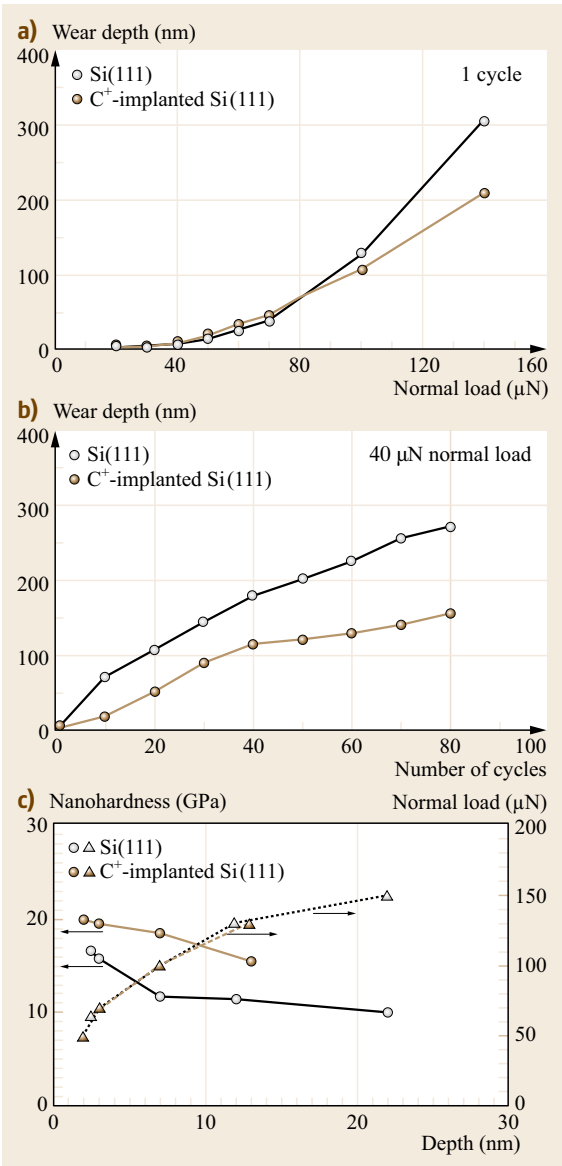

Fig. 38.21a–c Wear depth as a function of **(a)** load (after one cycle), and **(b)** cycles (normal load = 40 mN) for Si(111) and C^+-implanted Si(111). **(c)** Nanohardness and normal load as function of indentation depth for virgin and C^+-implanted Si(111) (after [38.186]) ◀

Effect of Oxide Films on Nanotribological Properties of Silicon

Macroscale friction and wear experiments have been performed using a magnetic disk drive with bare, oxidized, and implanted pins sliding against amorphous-carbon-coated magnetic disks lubricated with a thin layer of perfluoropolyether lubricant [38.190–193]. Representative profiles of the variation of the coefficient of friction with a number of sliding cycles for an Al_2O_3-TiC slider and bare and dry-oxidized silicon pins are shown in Fig. 38.22. For bare Si(111), after an initial increase in the coefficient of friction, it drops to a steady state value of 0.1, as seen in Fig. 38.22. The rise in the coefficient of friction for the Si(111) pin is associated with the transfer of amorphous carbon from the disk to the pin, and oxidation-enhanced fracture of pin material followed by tribochemical oxidation of the transfer film, while the drop is associated with the formation of a transfer coating on the pin. Dry-oxidized Si(111) exhibits excellent characteristics and no significant increase was observed over 50 000 cycles (Fig. 38.22). This behavior has been attributed to the chemical passivity of the oxide and lack of transfer of diamond-like carbon (DLC) from the disk to the pin. The behavior of PECVD-oxide (data are not presented here) was comparable to that of dry oxide, but for the wet oxide there was some variation in the coefficient of friction (0.26–0.4). The difference between the dry and wet oxide was attributed to increased porosity of the wet oxide [38.190]. Since tribochemical oxidation was determined to be a significant factor, experiments were conducted in dry nitrogen [38.191, 192]. The variation of the coefficient of friction for a silicon pin sliding against a thin-film disk in dry nitrogen is shown in Fig. 38.22. It is seen that in a dry nitrogen environment, the coefficient of friction of Si(111) sliding against a disk decreased from an initial value of about 0.2 to 0.05 with continued sliding. Based on SEM and chemical analysis, this behavior has been attributed to the formation of a smooth amorphous-carbon/lubricant transfer patch and suppression of oxidation in a dry nitrogen environment. Based on macroscale tests using disk drives, it was found that the friction and wear performance of bare silicon is not adequate. With dry-oxidized or PECVD SiO_2-coated silicon, no significant friction increase or interfacial degradation was observed in ambient air.

Table 38.4 and Fig. 38.23 show surface roughness, microscale friction and scratch data, and nanoindentation hardness for the various silicon samples [38.186]. Scratch experiments were performed using a diamond tip in an AFM. Results on polysilicon samples are also shown for comparison. Coefficients of microscale friction values for all the samples are about the same.

[a] Measured using AFM over a scan size of 10 μm × 10 μm
[b] Measured using AFM/FFM over a scan size of 10 μm × 10 μm
[c] Obtained using a 3 mm-diameter sapphire ball in a reciprocating mode at a normal load of 10 mN and average sliding speed of 1 mm/s after 4 m sliding distance
[d] Measured using AFM at a normal load of 40 μN for 10 cycles, scan length of 5 μm
[e] Measured using AFM at normal load of 40 μN for one cycle, wear area of 2 μm × 2 μm
[f] Measured using a nanoindenter at a peak indentation depth of 20 nm
[g] Measured using a microindenter with Vickers indenter at a normal load of 0.5 N

These samples showed wear scars from scratching with a 10 μN load. Scratch depth increased with normal load. Crystalline orientation of silicon has little influence on scratch resistance because natural oxidation of silicon in ambient air masks the expected effect of crystallographic orientation. PECVD-oxide samples showed the best scratch resistance, followed by dry-oxidized, wet-oxidized, and ion-implanted samples. Ion implantation with C^+ does not appear to improve scratch resistance.

Wear data on the silicon samples are also presented in Table 38.4 [38.186]. PECVD-oxide samples showed superior wear resistance followed by dry-oxidized, wet-oxidized, and ion-implanted samples. This agrees with the trends seen in scratch resistance. In PECVD, ion bombardment during the deposition improves the coating properties such as suppression of columnar growth, freedom from pinhole, decrease in crystalline size, and increase in density, hardness, and substrate-coating adhesion. These effects may help in improving the mechanical integrity of the sample surface. Coatings and treatments improved the nanohardness of silicon. Note that dry-oxidized and PECVD films are harder than wet-oxidized films as these films may be porous. High hardness of oxidized films may be responsible for measured high scratch/wear resistance.

38.3.2 Nanotribological and Nanomechanical Properties of Polysilicon Films and SiC Films

Studies have also been conducted on undoped polysilicon film, heavily doped (n^+-type) polysilicon film, heavily doped (p^+-type) single-crystal Si(100), and 3C-SiC (cubic or β-SiC) film [38.194–196]. The polysilicon films studied here are different from the ones discussed previously.

Table 38.5 presents a summary of the tribological studies conducted on polysilicon and SiC films. Values for single-crystal silicon are also shown for comparison. Polishing of the as-deposited polysilicon and SiC films drastically affects the roughness, as the values reduce by two orders of magnitude. Si(100) appears to be the smoothest followed by polished undoped polysilicon and SiC films, which have comparable roughness. The doped polysilicon film shows higher roughness than the undoped sample, which is attributed to the doping process. The polished SiC film shows the lowest friction followed by polished and undoped polysilicon film, which strongly supports the candidacy of SiC films for use in MEMS/NEMS devices. Macroscale friction measurements indicate that SiC film exhibits one of the lowest friction values as compared to the other samples. The doped polysilicon sample shows low friction on the macroscale as compared to the undoped polysilicon sample possibly due to the doping effect.

Figure 38.24a shows a plot of scratch depth versus normal load for various samples [38.194, 195]. Scratch depth increases with increasing normal load. Figure 38.25 shows AFM three-dimensional (3-D) maps and averaged two-dimensional (2-D) profiles of the scratch marks on the various samples. It is observed that scratch depth increases almost linearly with the normal load. Si(100) and the doped and undoped polysilicon film show similar scratch resistance. From the data, it is clear that the SiC film is much more scratch resistant than the other samples. Figure 38.24b shows results from microscale wear tests on the various films. For all the materials, the wear depth increases almost linearly with increasing number of cycles. This suggests that the material is removed layer by layer in all the materials. Here also, SiC film exhibits lower wear depths than the other samples. Doped polysilicon film wears less than the undoped film. Higher fracture toughness and higher hardness of SiC as compared to Si(100) is

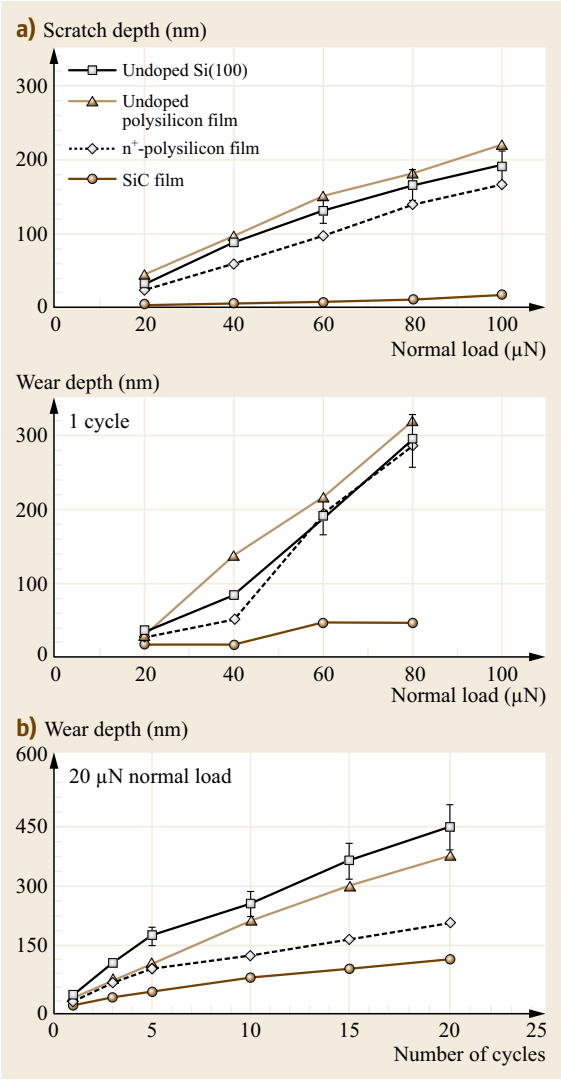

Fig. 38.24 **(a)** Scratch depths for 10 cycles as a function of normal load and **(b)** wear depths as a function of normal load and as a function of number of cycles for various samples (after [38.194])

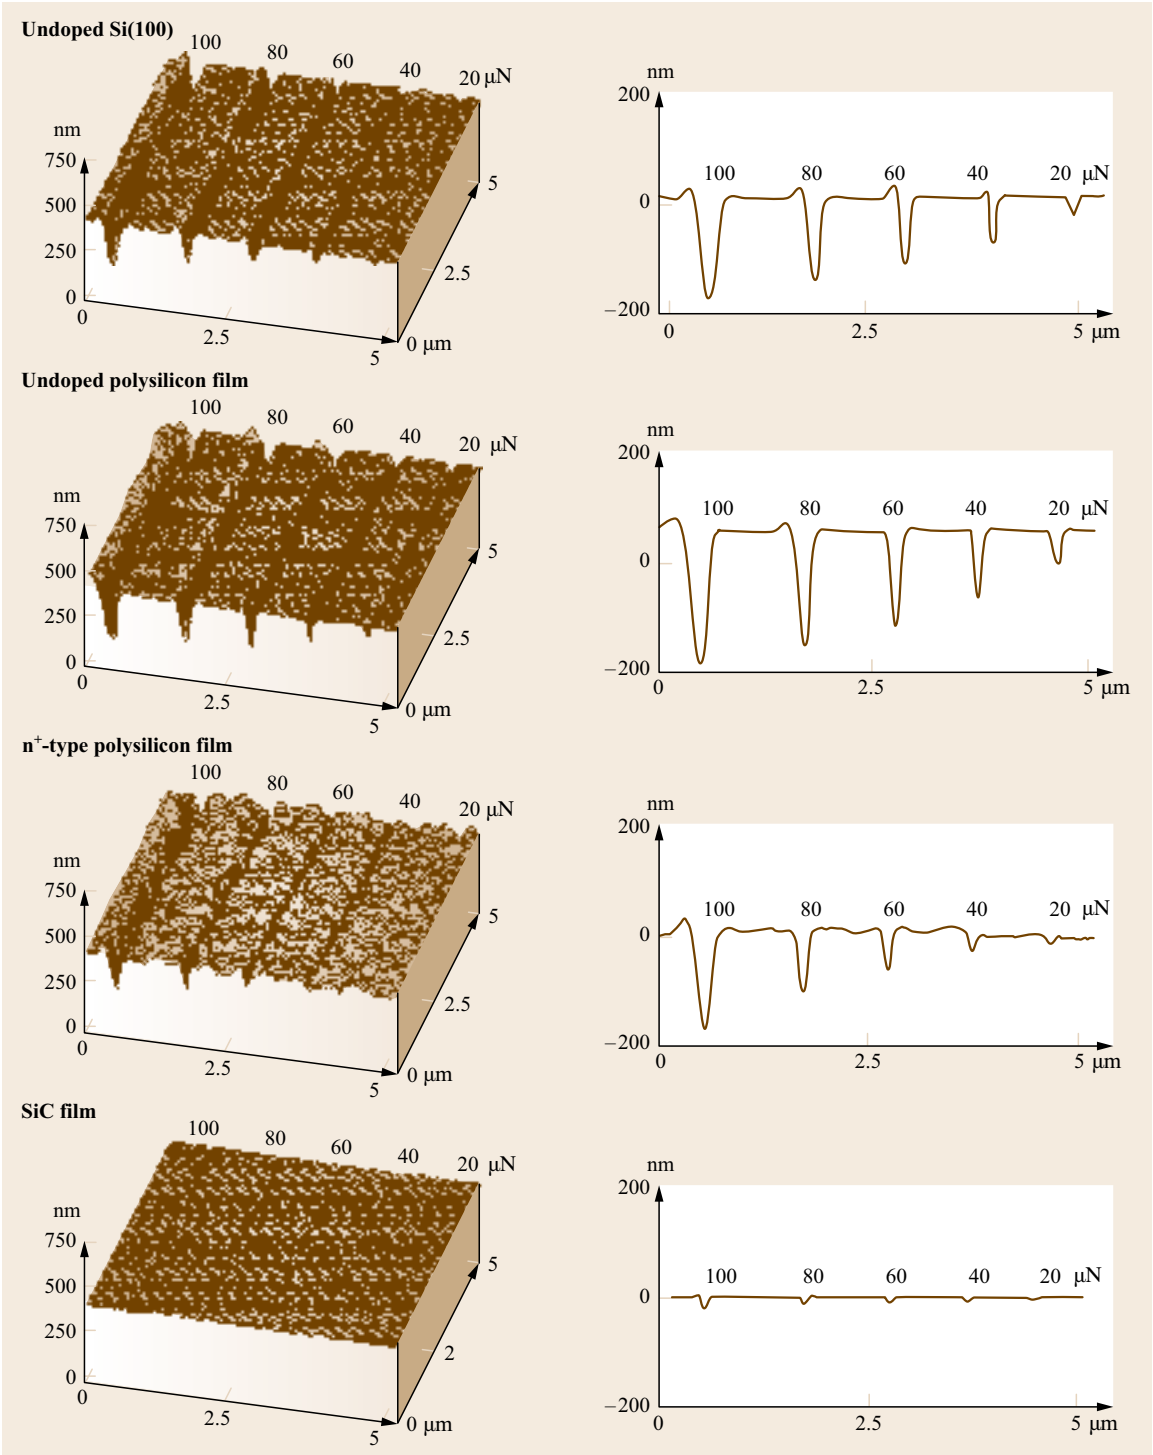

Fig. 38.25 AFM 3-D maps and averaged 2-D profiles of scratch marks on various samples (after [38.194])

responsible for its lower wear. Also, the higher thermal conductivity of SiC (Table 38.2) as compared to the other materials leads to lower interface temperatures, which generally results in less degradation of the surface [38.32, 91, 92]. Doping of the polysilicon does not affect the scratch/wear resistance and hardness much. The measurements made on the doped sample are affected by the presence of grain boundaries. These studies indicate that SiC film exhibits desirable tribological properties for use in MEMS devices.

38.4 Lubrication Studies for MEMS/NEMS

MEMS/NEMS devices may benefit from various lubricants. Several studies of liquid perfluoropolyether (PFPE) lubricant films, self-assembled monolayers (SAMs), and hard diamond-like carbon (DLC) coatings have been carried out for the purpose of minimizing adhesion, friction, and wear [38.44, 45, 86–92, 172, 173, 193]. Many variations of these films are hydrophobic (low surface tension and high contact angle) and have low shear strength, which provides low adhesion, friction, and wear. Relevant details are presented here.

38.4.1 Perfluoropolyether Lubricants

The classical approach to lubrication uses freely supported multimolecular layers of liquid lubricants [38.44, 88, 91, 92]. The liquid lubricants are sometimes chemically bonded to improve their wear resistance. Partially chemically bonded, molecularly thick PFPE lubricants are widely used for lubrication of magnetic storage media because of their thermal stability and extremely low vapor pressure [38.32], and are found to be suitable for MEMS/NEMS devices.

Adhesion, friction, and durability experiments have been performed on virgin Si(100) surfaces and silicon surfaces lubricated with various PFPE lubricants [38.44, 45, 197–203]. Results of two PFPE lubricants will be presented here: Z-15 (with $-CF_3$ nonpolar end groups),

$$CF_3{-}O{-}(CF_2{-}CF_2{-}O)_m{-}(CF_2{-}O)_n{-}CF_3$$

($m/n \approx 2/3$), and Z-DOL (with $-OH$ polar end groups),

$$HO{-}CH_2{-}CF_2{-}O{-}(CF_2{-}CF_2{-}O)_m{-}(CF_2{-}O)_n{-}CF_2{-}CH_2{-}OH$$

($m/n \approx 2/3$). The Z-DOL film was thermally bonded at 150 °C for 30 min, and the unbonded fraction was removed by a solvent (fully bonded) [38.32]. The thicknesses of Z-15 and the Z-DOL (fully bonded) films were 2.8 and 2.3 nm respectively. Nanoscale measurements were made using an AFM. The adhesive forces of Si(100), Z-15, and Z-DOL (fully bonded) measured by force calibration plot, and friction force versus normal load plot are summarized in Fig. 38.26. The results measured by these two methods are in good agreement. Figure 38.26 shows that the presence of mobile Z-15 lubricant film increases the adhesive force as compared to that of Si(100) by meniscus formation [38.91, 92, 204]; whereas, the presence of solid-phase Z-DOL (fully bonded) film reduces the adhesive force as compared that of Si(100) because of the absence of mobile liquid. The schematic (bottom) in Fig. 38.26 shows relative size and sources of meniscus. It is well known that the native oxide layer (SiO_2) on the top of the Si(100) wafer exhibits hydrophilic properties, and some water molecules can be adsorbed onto this surface. The con-

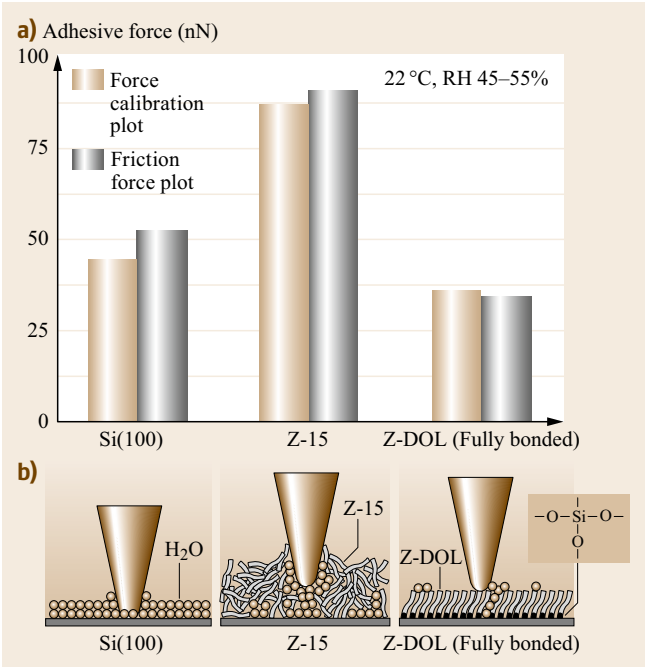

Fig. 38.26 **(a)** Summary of the adhesive forces of Si(100) and Z-15 and Z-DOL (fully bonded) films measured by force calibration plots and friction force versus normal load plots in ambient air. **(b)** Schematic showing the effect of the meniscus, formed between AFM tip and the surface sample, on the adhesive and friction forces (after [38.199])

densed water will form a meniscus as the tip approaches the sample surface. The larger adhesive force in Z-15 is not just caused by the Z-15 meniscus; the nonpolarized Z-15 liquid does not have good wettability and strong bonding with Si(100). Consequently, in the ambient environment, the condensed water molecules from the environment permeate through the liquid Z-15 lubricant film and compete with the lubricant molecules presented on the substrate. The interaction of the liquid lubricant with the substrate is weakened, and a boundary layer of the liquid lubricant forms puddles [38.197, 198]. This dewetting allows water molecules to be adsorbed on the Si(100) surface as aggregates along with Z-15 molecules, and both of them can form a meniscus while the tip approaches the surface. Thus, the dewetting of the liquid Z-15 film results in higher adhesive force and poorer lubrication performance. In addition, as the Z-15 film is soft compared to the solid Si(100) surface, penetration of the tip in the film occurs while pushing the tip down. This leads to a large area of the tip involved in forming the meniscus at the tip–liquid (mixture of Z-15 and water) interface. It should also be noted that Z-15 has a higher viscosity compared to water, therefore the Z-15 film provides higher resistance to lateral motion and coefficient of friction. In the case of the Z-DOL (fully bonded) film, the active groups of Z-DOL molecules are mostly bonded on the Si(100) substrate, thus the Z-DOL (fully bonded) film has low free surface energy and cannot be displaced readily by water molecules or readily adsorb water molecules. Thus, the use of Z-DOL (fully bonded) can reduce the adhesive force.

To study the relative humidity effect on friction and adhesion, the variation of friction force, adhesive force, and coefficient of friction of Si(100), Z-15, and Z-DOL (fully bonded) as a function of relative humidity are shown in Fig. 38.27. It shows that for Si(100) and Z-15 films, the friction force increases with a relative humidity increase up to 45%, and then it shows a slight decrease with further increase in the relative humidity. Z-DOL (fully bonded) has a smaller friction force than Si(100) and Z-15 in the whole testing range, and its friction force shows a relative apparent increase when the relative humidity is higher than 45%. For Si(100), Z-15, and Z-DOL (fully bonded), their adhesive forces increase with relative humidity, and their coefficients of friction increase with a relative humidity up to 45%, after which they decrease with further increasing of the relative humidity. It is also observed that the humidity effect on Si(100) really depends on the history of the Si(100) sample. As the surface of the Si(100) wafer readily adsorbs water in air, without any pretreatment the Si(100) used in our study almost reaches its saturated stage of adsorbed water, and is responsible for less of an effect during increasing relative humidity. However, once the Si(100) wafer was thermally treated by baking at 150 °C for 1 h, a greater effect was observed.

The schematic in Fig. 38.27b shows that Si(100), because of its high free surface energy, can adsorb more water molecules while increasing relative humidity. As discussed earlier, for the Z-15 film in the humid environment, the condensed water competes with the lubricant film present on the sample surface, and interaction of the liquid lubricant film with the silicon substrate is weakened, and a boundary layer of the liquid lubricant forms puddles. This dewetting allows water molecules to be adsorbed on the Si(100) substrate mixed with Z-15 molecules [38.197, 198]. Obviously, more water molecules can be adsorbed on the Z-15 surface with increasing relative humidity. The more adsorbed water molecules in the case of Si(100), along with lubricant molecules in the Z-15 film case, form a bigger water meniscus, which leads to an increase of friction force, adhesive force, and coefficient of friction of Si(100) and Z-15 with humidity. But at a very high humidity of 70%, large quantities of adsorbed water can form a continuous water layer that separates the tip and sample surface, acting as a kind of lubricant, which causes a decrease in the friction force and coefficient of friction. For Z-DOL (fully bonded) film, because of their hydrophobic surface properties, water molecules can be adsorbed at a humidity higher than 45%, and cause an increase in the adhesive force and friction force.

To study the durability of lubricant films at the nanoscale, the friction forces of Si(100), Z-15, and Z-DOL (fully bonded) as a function of the number of scanning cycles are shown in Fig. 38.28. As observed earlier, the friction force of Z-15 is higher than that of Si(100), with the lowest values for Z-DOL (fully bonded). During cycling, the friction force of Si(100) shows a slight decrease during the initial few cycles then remains constant. This is related to the removal of the top adsorbed layer. In the case of the Z-15 film, the friction force shows an increase during the initial few cycles and then approaches higher and stable values. This is believed to be caused by the attachment of the Z-15 molecules onto the tip. The molecular interaction between these attached molecules to the tip and molecules on the film surface is responsible for an increase in friction. However, after several scans, this molecular interaction reaches equilibrium, and after that, friction force and the coefficient of friction remain constant. In the case of the Z-DOL (fully bonded) film, the friction force and coefficient of friction start out low and remain low during the entire test for 100 cycles. It suggests that Z-DOL (fully bonded) molecules do not get attached or displaced as readily as Z-15.

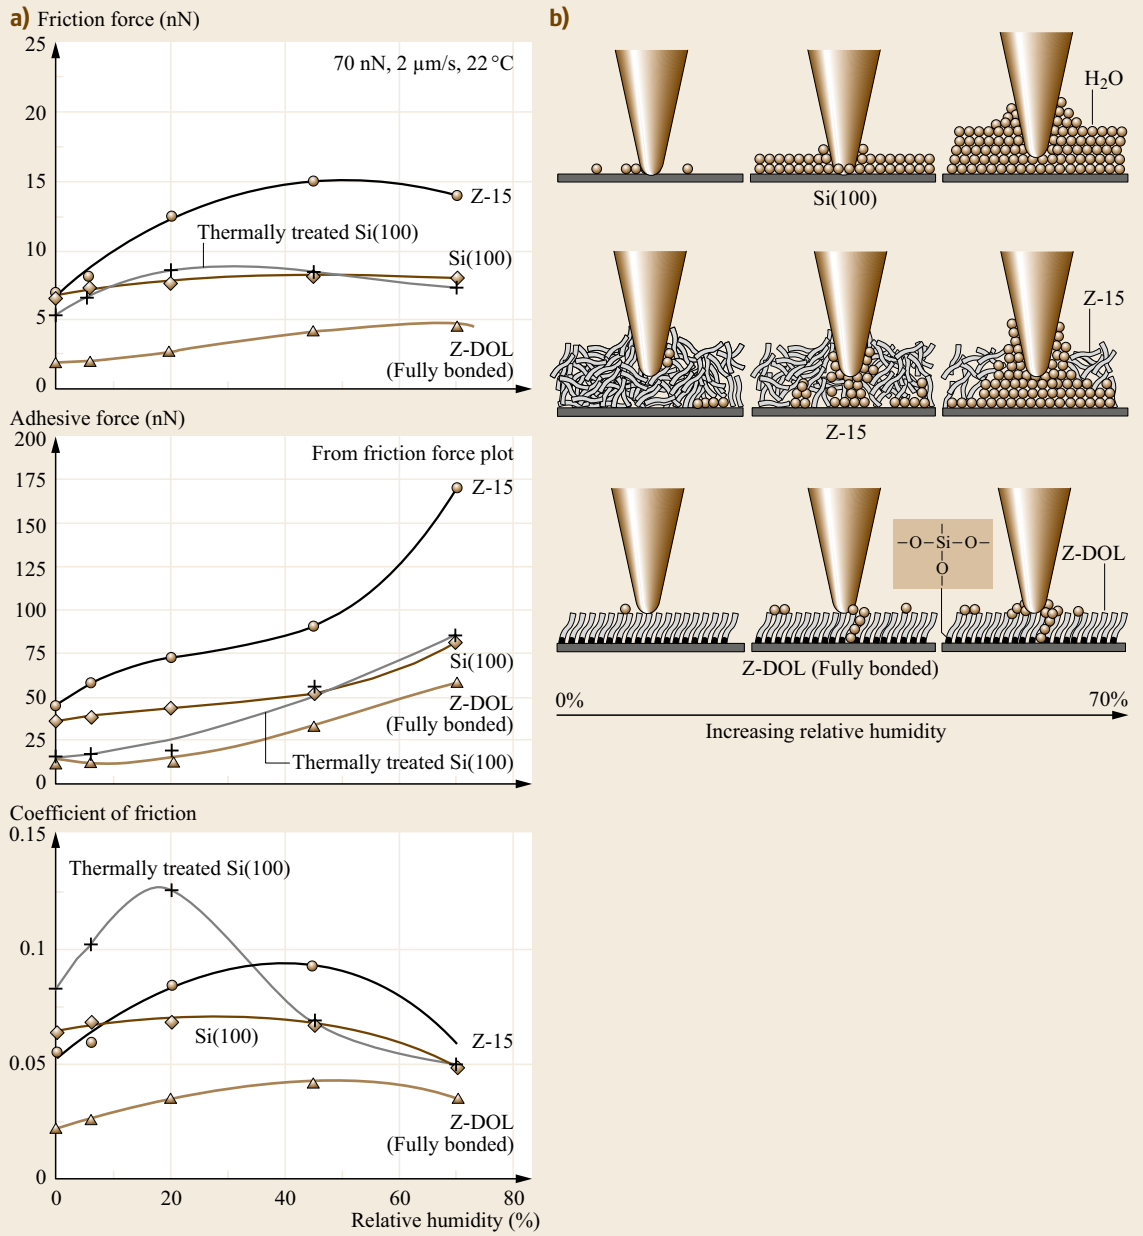

Fig. 38.27 **(a)** The influence of relative humidity of the friction force, adhesive force, and coefficient of friction of Si(100), Z-15 and Z-DOL (fully bonded) films at 70 nN, 2 µm/s, and in 22 °C air. Schematic **(b)** shows the change of meniscus while increasing the relative humidity. In this figure, the thermally treated Si(100) represents the Si(100) wafer that was baked at 150 °C for 1 h in an oven (in order to remove the adsorbed water) just before it was placed in the 0% RH chamber (after [38.199])

38.4.2 Self-Assembled Monolayers (SAMs)

For lubrication of MEMS/NEMS, another effective approach involves the deposition of organized and dense molecular layers of long-chain molecules. Two common methods to produce monolayers and thin films are the Langmuir–Blodgett (L–B) deposition and self-assembled monolayers (SAMs) by chemical grafting of molecules. L–B films are physically bonded to the substrate by a weak van der Waals attraction, while

SAMs are chemically bonded via covalent bonds to the substrate. Because of the choice of chain length and terminal linking group that SAMs offer, they hold great promise for boundary lubrication of MEMS/NEMS.

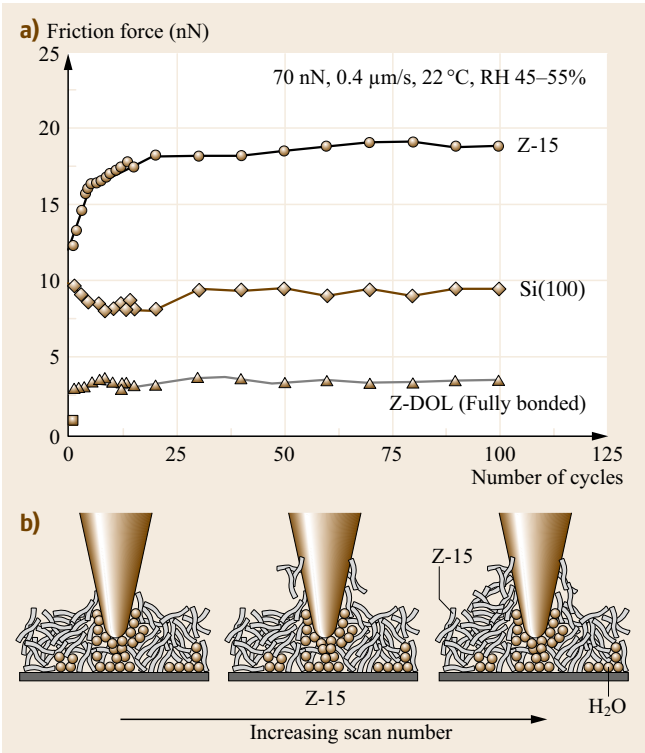

Fig. 38.28 (a) Friction force versus number of sliding cycles for Si(100), Z-15 and Z-DOL (fully bonded) films at 70 nN, 0.4 μm/s, and in ambient air. Schematic (b) shows that some liquid Z-15 molecules can be attached onto the tip. The molecular interaction between the attached molecules onto the tip with the Z-15 molecules in the film results in an increase of the friction force with multiscanning (after [38.199])

A number of studies have been conducted on tribological properties of various SAMs [38.152–155, 205–211].

Bhushan and *Liu* [38.206] studied the effect of film compliance on adhesion and friction. Based on friction and stiffness measurements, SAMs with high-compliance long-carbon chains exhibit low friction; chain compliance is desirable for low friction. The friction mechanism of SAMs is explained by a so-called *molecular spring* model. According to this model, the chemically adsorbed self-assembled molecules on a substrate are just like assembled molecular springs anchored to the substrate. An asperity sliding on the surface of SAMs is like a tip sliding on the top of *molecular springs or brush*. The molecular spring assembly has compliant features and can experience orientation and compression under load. The orientation of the molecular springs or brush under normal load reduces the shearing force at the interface, which in turn reduces the friction force. The orientation is determined by the spring constant of a single molecule as well as the interaction between the neighboring molecules, which can be reflected by packing density or packing energy. It should be noted that the orientation can lead to conformational defects along the molecular chains, which leads to energy dissipation. The SAMs with high-compliance long-carbon chains also exhibit the best wear resistance [38.206, 208]. In wear experiments, the wear depth as a function of normal load curves show a critical normal load. Below the critical normal load, SAMs undergo orientation. At the critical load, SAMs wear away from the substrate due to weak interface bond strengths, while above the critical normal load, severe wear takes place on the substrate.

Bhushan et al. [38.152, 209], *Kasai* et al. [38.154], *Tambe* and *Bhushan* [38.210], and *Tao* and *Bhushan* [38.211] studied various SAMs that were vapor-phase deposited on Si and Al substrates with native oxide films, Fig. 38.29. Perfluorodecyltricholorosi-

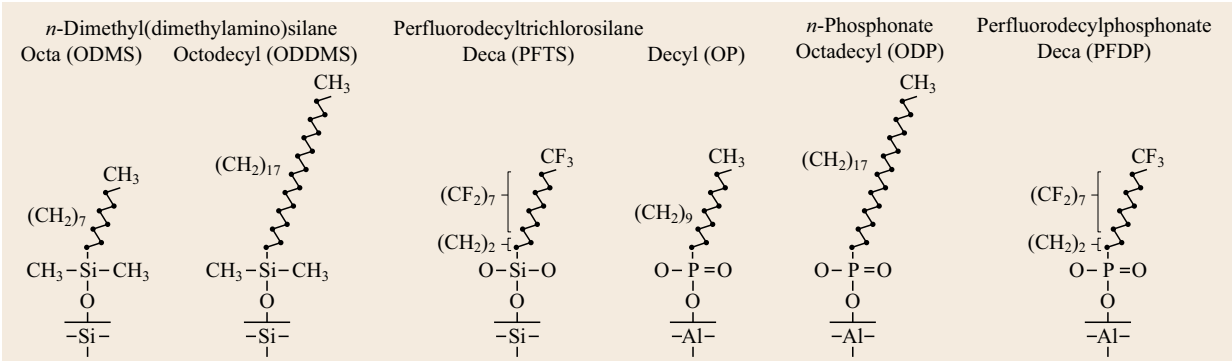

Fig. 38.29 Schematics of the structures of perfluoroalkylsilane and alkylsilane SAMs on Si with native oxide substrates, and perfluoroalkylphosphonate and alkylphosphonate SAMs on Al with native oxide substrates

lane (PFTS), *n*-octyldimethyl (dimethylamino) silane (ODMS) ($n = 7$), and *n*-octadecylmethyl (dimethylamino) silane (ODDMS) ($n = 17$) were deposited on Si substrates. Perfluorodecylphosphonate (PFDP), *n*-decylphosphonate (DP) ($n = 7$) and *n*-octadecylphosphonate (ODP) ($n = 17$) were deposited on Al substrates. Figure 38.30 shows the static contact angles, adhesive forces, friction forces, and coefficients of friction of the two substrates with various SAMs under ambient conditions [38.152, 209]. Based on the data, all films exhibit higher contact angles and lower adhesive forces and coefficients of friction as compared to their corresponding substrates. Among various films, PFTS/Si exhibits a higher contact angle and lower adhesive force as compared to that of ODMS/Si or ODDMS/Si. Longer-chain film ODDMS/Si has superior performance than shorter-chain film ODMS. Trends for films on Al substrates are similar to that on Si substrates. Thus, substrate had little effect. The coefficients of friction for various SAMs are comparable.

The effect of relative humidity on adhesion and friction for various SAMs on Si substrate was studied. Adhesive force, friction force at 5 nN of normal load, coefficient of friction, and microwear data are presented in Fig. 38.31 [38.154, 209]. Adhesive force for silicon showed an increase with relative humidity. This is expected since the surface of silicon is hydrophilic as shown in Fig. 38.30. More condensation of water at the tip–sample interface at higher humidity increases the adhesive force due to the capillary effect. On the other hand, the adhesive force for the SAMs showed a very weak dependency on the change in humidity. This occurs since the surface of the SAMs is hydrophobic. The adhesive force of ODMS/Si and ODDMS/Si showed a slight increase from 75 to 90% RH. Such an increase was absent for PFTS/Si, possibly because of the hydrophobicity of PFTS/Si. The friction force of silicon showed an increase with relative humidity up to about 75% RH and a slight decrease beyond this point. The initial increase possibly results from the increase in adhesive force. The decrease in friction force at higher humidity could be attributed to the lubricating effect of the water layer. This effect is more pronounced in the coefficient of friction. Since the adhesive force increased and the coefficient of friction decreased in this range, those effects cancel out each other, and the resulting friction force showed only slight changes. On the other hand, the friction force and coefficient of friction of SAMs showed very small changes with relative humidity, like that found for adhesive force. This suggests that the adsorbed water layer on the surface maintained a similar thickness throughout the relative humidity range tested. The differences among the SAM types were small, within the measurement error. However a closer look at the coefficient of friction for ODMS/Si showed a slight increase from 75 to 90% RH as compared to PFTS/Si, possibly for the same reason as the adhesive force

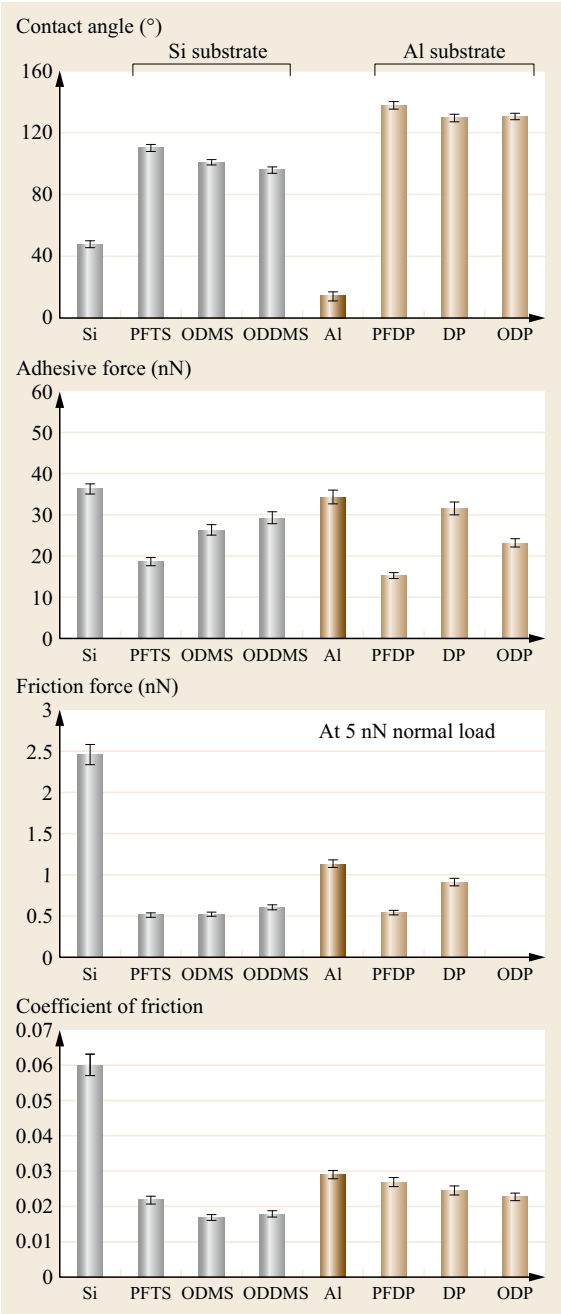

Fig. 38.30 The static contact angle, adhesive force, friction force, and coefficient of friction measured using an AFM for various SAMs on Si and Al substrates (after [38.152, 209])

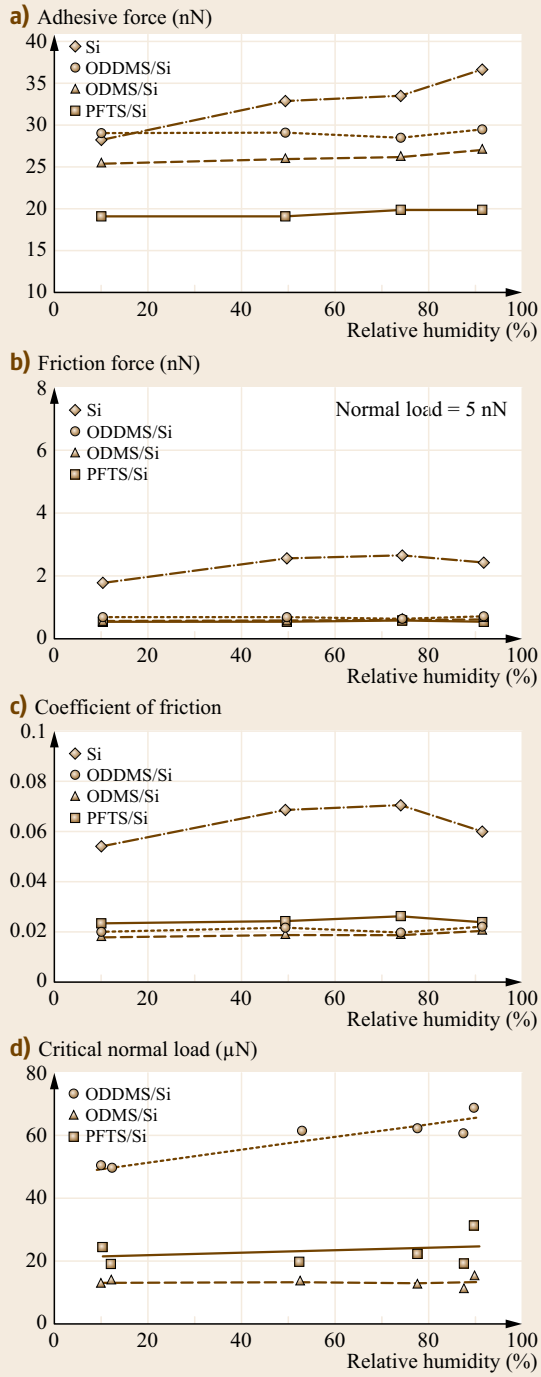

Fig. 38.31a–d Relative humidity effect on (a) adhesive force, (b) friction force, (c) coefficient of friction, and (d) microwear for various SAMs on Si substrates (after [38.154, 209])

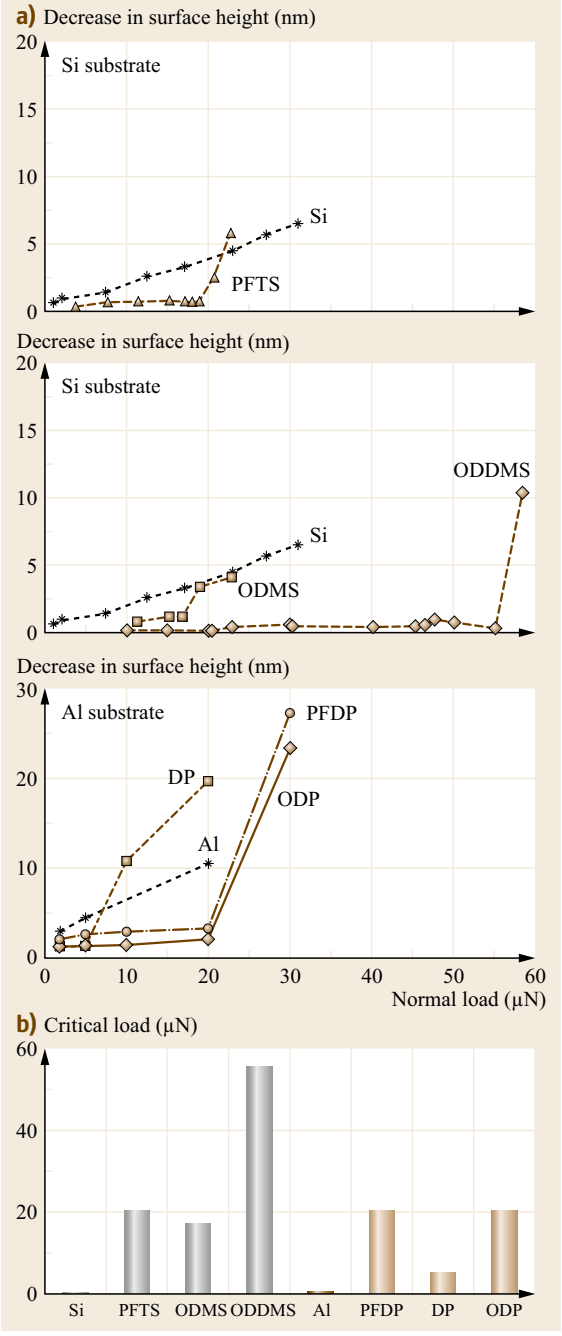

Fig. 38.32 (a) Decrease in surface height as a function of normal load after one scan cycle for various SAMs on Si and Al substrates, and (b) comparison of critical loads for failure during wear tests for various SAMs (after [38.154, 209])

changes. The inherent hydrophobicity of SAMs means that they did not show much relative humidity dependence.

Figure 38.32a shows the relationship between the decrease in surface height as a function of the normal load during wear tests for various SAMs on Si and Al substrates [38.154, 209]. As shown in the figure, the SAMs exhibit a critical normal load beyond the point of which the surface height drastically decreases. Figure 38.32a also shows the wear behavior of the Al and Si substrates. Unlike the SAMs, the substrates show a monotonic decrease in surface height with increasing normal load, with wear initiating from the very beginning, i. e., even for low normal loads. Si (Young's modulus of elasticity, $E = 130$ GPa [38.212], hardness, $H = 11$ GPa [38.193]) is relatively hard in comparison to Al ($E = 77$ GPa, $H = 0.41$ GPa). Hence the decrease in surface height for Al is much larger than that for Si for similar normal loads.

The critical loads corresponding to the sudden failure of SAMs are shown in Fig. 38.32b. Amongst all the SAMs, ODDMS shows the best performance in the wear tests, believed to be due to the longer chain length effect. Fluorinated SAMs – PFTS and PFDP show higher critical load as compared to ODMS and DP with similar chain lengths. ODP shows higher critical load as compared to DP because of its longer chain length. The mechanism of failure of compliant SAMs during wear tests was presented earlier. It is believed that the SAMs fail mostly due to shearing of the molecule at the head group; that is, by means of shearing of the molecules off the substrate.

To study the effect of relative humidity, wear tests were performed at various humidities. The bottom of Fig. 38.31 shows critical normal load as a function of relative humidity. The critical normal load showed weak dependency on relative humidity for ODMS/Si and PFTS/Si, and was larger for ODMS/Si than PFTS/Si throughout the humidity range. This suggests that water molecules could penetrate into the ODDMS, which might work as lubricant [38.208]. This effect was absent for PFTS/Si and ODMS/Si.

Bhushan et al. [38.153] and *Lee* et al. [38.155] studied various fluoropolymer multilayers and fluorosilane monolayers on Si and a selected fluorosilane on poly(dimethylsiloxane) (PDMS) surfaces. For nanoscale devices such as nanochannels, monolayers are preferred. They reported that all fluorosilane films increased the contact angle. The fluorosilane monolayer – 1H, 1H, 2H, 2H – perfluorodecyltriethoxysilane (PFDTES) resulted in a contact angle of about 100°.

Based on these studies, a perfluoro-SAM with a compliant layer should have optimized tribological performance for MEMS/NEMS and bioMEMS/bioNEMS applications.

38.4.3 Hard Diamond-Like Carbon (DLC) Coatings

Coating of hard amorphous carbon (a-C), commonly known as diamond-like carbon (DLC) (implying high hardness), are deposited by a variety of deposition techniques, including filtered cathodic arc (FCA), ion beam, electron cyclotron resonance chemical vapor deposition (ECR-CVD), plasma-enhanced chemical vapor deposition (PECVD), and sputtering [38.181, 193]. These coatings are used in a wide range of applications, including tribological, optical, electronic, and biomedical applications. Ultrathin coatings (3–10 nm thick) are employed to protect against wear and corrosion in magnetic storage applications – thin-film rigid disks, metal evaporated tapes, and thin-film read/write heads, Gillette Mach 3 razor blades, glass windows, and sunglasses. The coatings exhibit low friction, high hardness and wear resistance, chemical inertness to both acids and alkalis, lack of magnetic response, and optical bandgaps ranging from zero to a few eV, depending upon the deposition technique and its conditions. Selected data on DLC coatings relevant for MEMS/NEMS applications is presented in a later section on microtriboapparatus.

38.5 Nanoscale Friction, Wear, and Mechanical Behavior of Nano-Objects

Nano-objects are described as a single material or composite having at least one dimension that is between 1 and 100 nm. They come in a variety of discrete geometries that include spheres, tubes, rods, wires, and pillars. Compared to their bulk material counterparts, many nano-objects exhibit enhanced mechanical, electrical, magnetic, and chemical properties. This makes them attractive for use in many applications on the macro- to nanoscale. Many nano-objects also exhibit low friction and wear properties. These are used in various sliding applications in which they come into sliding contact with each other and the mating surfaces. Contacts can lead to nano-object deformation. For these situations, friction, wear, and nano-object deformation are of interest.

Maharaj and *Bhushan* [38.213] studied Au nanoparticles (NPs) and nanorods (NRs), MoS_2, and WS_2 multiwalled nanotubes (MWNTs), and carbon nanohorns (CNHs). These nano-objects were chosen since they have either been used in applications (discussed earlier), or have been of interest. They also provide an opportunity to explore the relationship between their friction and wear-reduction ability in relation to their geometry, mechanical properties, and deformation mechanisms under different loading conditions. Figure 38.33 shows transmission electron microscopy (TEM) images of spherical Au nanoparticles approximately 50 nm in diameter, and Au nanorods 50 nm in diameter and 200 nm in length. Figure 38.34 shows representative TEM images of the MoS_2 and WS_2 MWNTs and CNHs. Table 38.6 shows the water contact angle of various thin films. Tables 38.7 and 38.8 show nanomechanical properties of various nanoparticles, MWNTs, films, and bulk materials.

Au nano-objects have been used in applications requiring targeted drug delivery due to their chemical inertness and low to zero toxic effects. In tribological studies, their small contact area and mobility due to their spherical shape allows them to roll and slide. This results in reduced friction and wear on the macro- to nanoscale in dry and submerged-in-liquid environments [38.181, 224–228]. Au thin films also have been studied to investigate further scale effects on the nanoscale. Their flat surfaces prevent inaccuracies in measuring mechanical properties due to curvature effects of increasingly smaller nano-objects.

Table 38.6 Water contact angle for thin films of Au, MoS_2, WS_2, and graphene in contact with water (after [38.224])

Films	Water contact angle (°)
Au	50[a]
MoS_2	75[b]
WS_2	93[c]
Graphene	127[d]

[a] [38.214]; [b] [38.215]; [c] [38.216]; [d] [38.217]

MoS_2 and WS_2 have a layered lattice structure with weak bonding between layers, which provides low friction, and these are known solid lubricants [38.91, 92, 181]. MoS_2 and WS_2 MWNTs have also been studied in tribology on the macro- to nanoscale in dry and liquid environments and increasingly in other applications such as catalysis in HER. MoS_2 and WS_2 MWNTs have been shown to reduce friction and wear similar to Au nano-objects. In addition, the exfoliation of the outer layers of the nanotubes and subsequent formation of an easily shearable film aids in friction and wear reduction [38.181, 227, 229].

A single CNH has a structure similar to a single-walled carbon nanotube with one end closed in a cone-shaped cap (horn). These horns agglomerate through van der Waals attractions to form a spherical nano-object with unique morphology. CNHs have been the subject of myriad studies due to their unique surface morphology and the wide-ranging properties of graphene, which include chemical stability, low surface energy [38.230], high thermal [38.231] and electrical conductivity [38.232], and low friction and wear [38.224].

For nano-objects submerged in liquid environments, water, dodecane, and glycerol have been used [38.213]. They have been utilized in friction and wear studies as they are simple liquids without additives, and their properties are well known.

Maharaj and *Bhushan* [38.213] carried out single nano-object contact and multiple nano-object contact studies. In single nano-object contact, Au NPs and NRs,

MoS_2 and WS_2 MWNTs, and CNHs have been studied with an AFM as illustrated in Fig. 38.35 where they are manipulated by lateral pushing. Friction forces were examined in dry and submerged-in-liquid environments. Friction was found to be dependent on size, shape, material, and roughness. Friction was found to be lower in submerged-in-liquid environments compared to dry conditions. These studies provide an understanding of the nature of the friction mechanism of nano-objects at the initiation of sliding.

In multiple nano-object contact studies, the effect of nano-objects on friction and wear reduction was determined. Sliding takes place over several nano-objects, as illustrated in Fig. 38.35. Real area of contact, rolling, sliding, and exfoliation and tribofilm formation were studied for their effect on friction and wear. Results of studies on the macroscale were compared to the nanoscale to understand scale effects of friction.

An overview of friction and wear in dry and liquid environments is presented next, and various mechanisms are presented to explain the friction and wear behavior of nano-objects.

38.5.1 Single Nano-Object Friction

For nano-objects that are spherical in nature, manipulation can involve rolling, sliding, and rotation about the vertical axis. Manipulation can also involve rolling, sliding, and in-plane rotation in the case of the MoS_2 and WS_2 MWNTs. In-plane rotation can occur when the nanotubes are not pushed directly at the center of the MWNT's length.

Figure 38.36a presents the results for the average friction forces for Au 90 NPs, CNHs and MoS_2 and WS_2 MWNTs in dry and submerged-in-liquid environments. The friction force presented is the result of adhesion between the nano-objects and the silicon substrate. The adhesive force can include both van der Waals and meniscus forces for dry environments. However, under submerged-in-liquid environments, meniscus forces are eliminated.

Friction forces for the CNHs and MoS_2 and WS_2 MWNTs compared to Au 90 NPs are lower due to a material effect. For the MWNTs it is not believed that exfoliation and tribofilm formation are respon-

Table 38.8 Nanomechanical properties of MoS_2 MWNTs obtained from the nanoindentation experiments normal to the basal plane. For comparison, mechanical properties of naturally occurring MoS_2 (normal to the basal planes) and single-layer graphene are given (after [38.220])

The vertical scale is magnified for data in liquids. **(c)** Coefficients of friction for both dry and submerged-in-liquid environments, with and without nano-objects. Friction forces and coefficient of friction are lower in submerged-in-water environments (after [38.224])

sible for the lower values, as discussed by *Maharaj* et al. [38.224], since there is no normal load acting on them.

Figure 38.36b presents the friction forces for the nanoparticles and nanotubes submerged in liquid environments. For Au NPs that were already suspended in DI water, experiments were not carried out in dodecane and glycerol. In dodecane and glycerol, similar to water, adhesive forces are due to van der Waals interactions since meniscus forces are eliminated. The lower friction forces in submerged-in-liquid environments compared to the dry environments can be attributed to both elimination of meniscus forces and nano-objects sliding on a low shear-strength surface. The lowest friction forces occur with the CNHs due to the low contact area provided by the roughness of the nanohorns. Here, the material effects due to the work of adhesion do not contribute to friction. The highest friction force occurs in glycerol, which has the highest viscosity and therefore the greatest contribution to viscous drag force. Similar viscosity of dodecane and water accounts for the similarity in friction forces observed for both liquids with and without nano-objects.

The characteristics of the nano-objects discussed in single nano-object contact studies will also be investigated in multiple nano-object contact studies in the context of reducing friction and wear under load. As will be discussed in the next section, new nano-object behavior not previously seen will contribute to friction and wear reduction due to the application of a load.

38.5.2 Multiple Nano-Object Contact

Nanoscale Friction and Wear

In multiple nano-object contact, the effect of normal load acting on the Au 90 NPs, CNHs, and MoS_2 and WS_2 MWNTs between two surfaces is studied to determine the effects on friction and wear. Figure 38.36c summarizes the coefficient of friction for dry and submerged-in-liquid environments. Sliding in multiple nano-object contact results in lower friction forces in all conditions compared to sliding on the bare silicon substrate as discussed by *Maharaj* et al. [38.224]. For Au nano-objects that were already suspended in deionized (DI) water, experiments were not carried out in dodecane and glycerol. In general, the friction forces were lower for sliding in submerged-in-liquid environments as compared to sliding in dry environments for nano-object-coated and uncoated surfaces.

Sliding on multiple asperities on nanopatterned surfaces resulted in lower friction. With the immobile asperities, friction reduction occurs as a result of the reduced contact area. For Au 90 NPs, CNHs, and MoS_2 and WS_2 MWNTs, the friction force reduction can be attributed to nano-object mobility in addition to the reduced contact area. The resulting friction reduction mechanism can be attributed to the reduced contact

area, the sliding over deformed nano-objects, and the individual nano-objects being dragged with the glass sphere as shown in Fig. 38.37b,c. It is also possible that as the glass sphere encounters a greater number of nano-objects, the contact pressure is reduced, allowing undeformed nano-objects to roll between the surfaces as shown in Fig. 38.37a. Exfoliation and tribofilm formation as shown in Fig. 38.37d,e are believed to be possible in dry environments for MoS_2 and WS_2 MWNTs as there is a general trend towards lower friction compared to Au 90 NPs. However this is not very significant due to the limited number of MWNTs that would be able to fit under the 50 μm sphere. In dry environments, the coefficient of friction data for the CNHs and the MoS_2 and WS_2 MWNTs are generally lower than the Au 90 NPs. As previously discussed, with the Au 90 NPs there is a higher meniscus force contribution to friction compared to the CNHs and MoS_2 and WS_2 MWNTs. With the CNHs, the reduced contact area due to the roughness of the nanohorns and low meniscus force contribution are responsible for the low friction forces [38.224].

For nano-objects submerged in liquid environments, the coefficients of friction were lower compared to dry. For water, as the meniscus forces are eliminated, the coefficient of friction data shows very little difference for Au 90 NPs and MoS_2 and WS_2 MWNTs. The CNHs have the lowest coefficient of friction in all liquid environments due to the nanohorn roughness contributing to lower real area of contact. Similar to single nano-object contact, the highest friction force and coefficient of friction occurs in glycerol, which has the highest viscosity and results in a greater contribution from viscous drag force followed by dodecane. The elimination of the meniscus forces, coupled with sliding on a surface of low shear strength results in lower coefficients of friction [38.234].

The nano-objects were also investigated in wear conditions to determine their effectiveness in protecting the underlying surface, which is a crucial feature for a potential lubricant. Figure 38.38 summarizes the wear data for sliding on Si, and Si coated with Au 90 NPs, CNHs, MoS_2 and WS_2 MWNTs, for 1, 10, and 100 cycles at a normal load of 20 μN under dry environments. A 20 μm × 20 μm area is imaged to show wear scars, which are created over a 10 μm × 10 μm area. Topography maps along with corresponding height profiles are also shown.

The surface of the uncoated silicon, after one cycle, appears rough during the early stages of wear

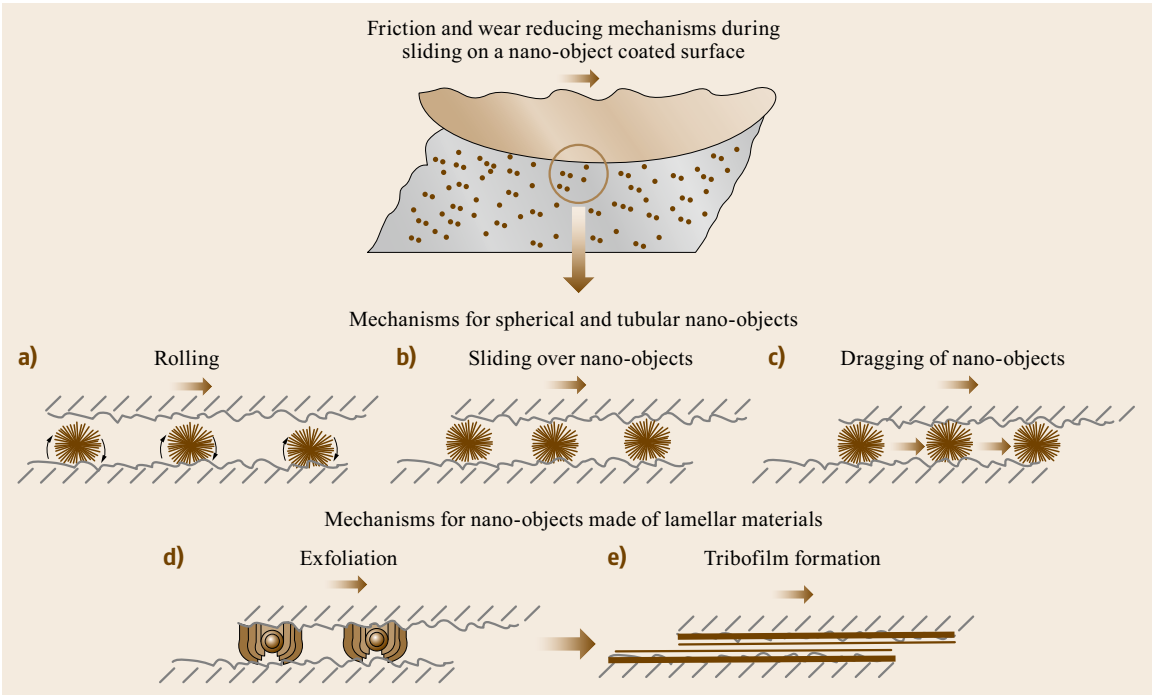

Fig. 38.37a–e Schematic of friction- and wear-reducing mechanism of nano-object-coated surface by **(a)** rolling, **(b)** sliding over nano-objects, **(c)** dragging of nano-objects, **(d)** exfoliation, and **(e)** tribofilm formation. CNHs are used as an example for mechanisms **(a)** through **(c)** and WS_2 and MoS_2 MWNTs are used as an example for mechanisms **(d)** through **(e)** (after [38.224])

as it becomes damaged. For the Au 90 NPs, CNHs, and MoS_2 and WS_2 MWNTs coated surfaces, the nano-objects are just beginning to be pushed out of the wear area after one cycle. After 10 cycles, the topography profile of the uncoated silicon surface appears smoother than after one cycle. This is due to polishing of the surface. The nano-objects are pushed out of the wear area and agglomerate around the edges of the wear scar. After 100 cycles, for the uncoated silicon substrate, a small amount of material is removed, which gives a wear depth of approximately 0.25 nm, as seen in the height profile. For the coated surfaces, a few nano-objects remain in the wear area for MoS_2 and WS_2 MWNTs while they are completely removed for CNHs and Au 90 NPs.

Figure 38.39 shows SEM micrographs of the wear scars in dry environments after 100 cycles (first row). Vertical arrows point to magnified micrographs of the areas within the squares that are shown in the sec-

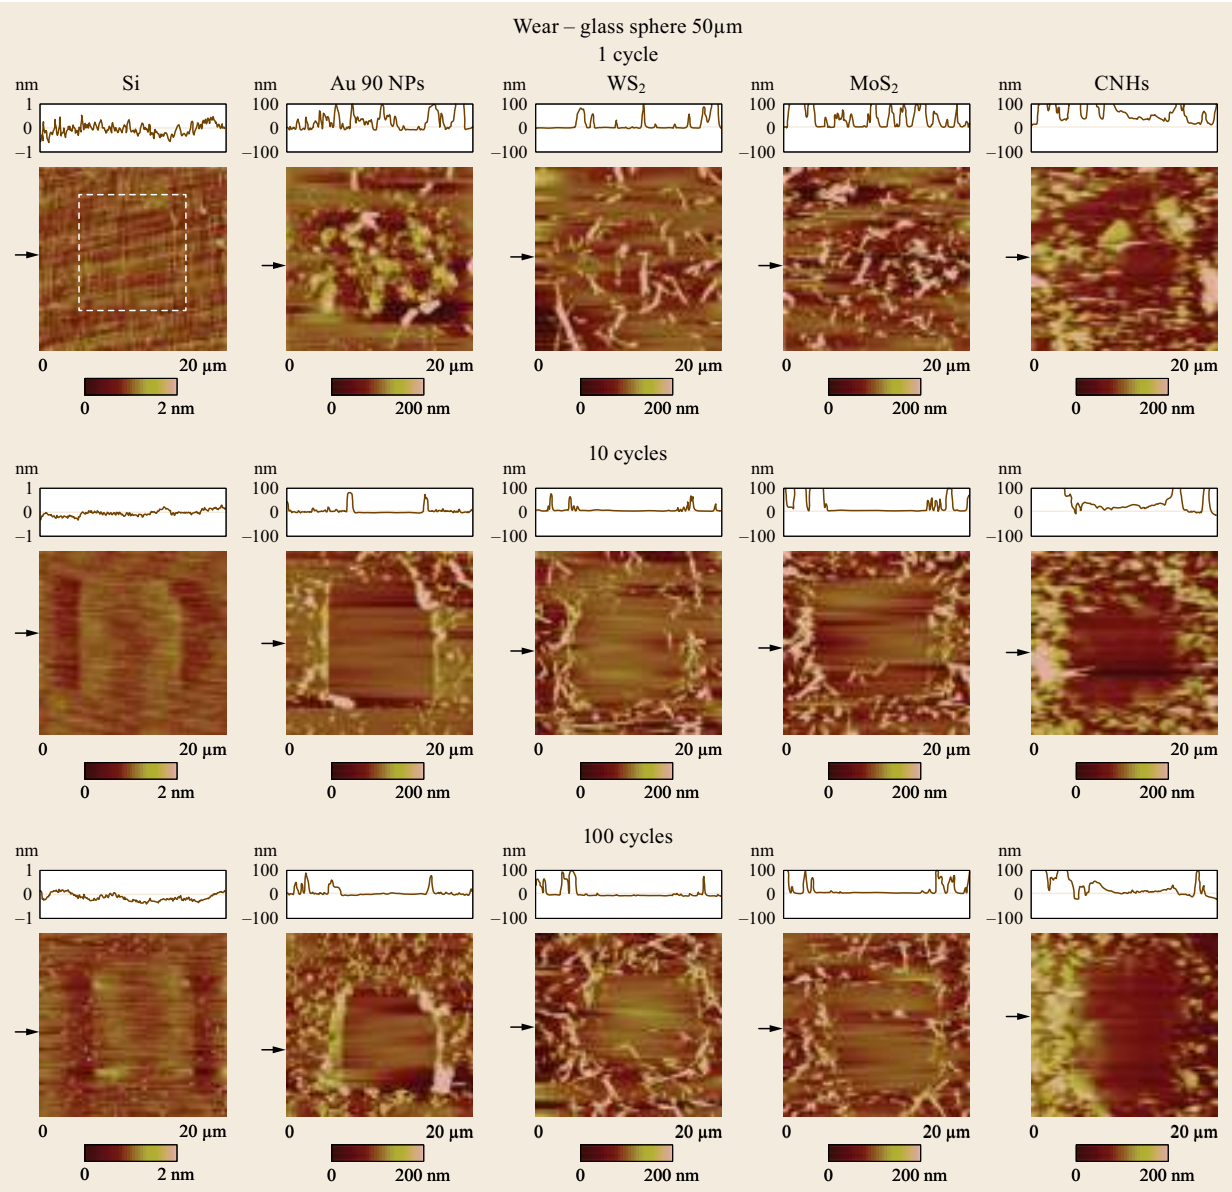

Fig. 38.38 Topography maps and 2-D profiles, at sections shown by the arrows, after sliding at one, 10 and 100 cycles with a normal load of 20 µN on Si and Si coated with Au 90 NPs, CNHs, and MoS_2 and WS_2 nanotubes (after [38.224])

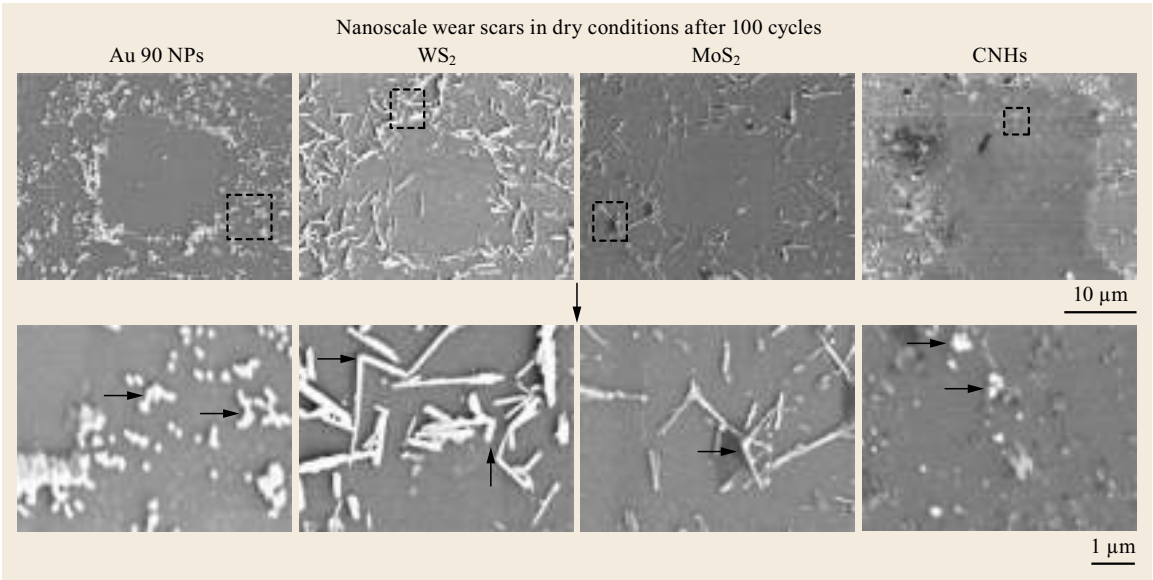

Fig. 38.39 SEM micrographs of nanoscale wear scars for Au 90 NPs, CNHs, and MoS_2 and WS_2 MWNTs in dry conditions after 100 cycles at a normal load of 20 μN (*first row*). The nano-objects within the *squares* are magnified and the *vertical arrows* point to those micrographs in the *second row*. ond row. Agglomerated Au 90 NPs, CNHs, and broken MoS_2 and WS_2 MWNTs are pointed out by arrows within each micrograph. Agglomeration and breaking of the nano-objects can occur during the wear process due to the high loads being applied. In sample preparation of MoS_2 and WS_2 MWNTs, broken nanotubes also can result from sonication as they collide with one another. Since there is no evidence for crushed nanotubes from the SEM micrographs, it is likely that exfoliation of MoS_2 and WS_2 MWNTs would be limited. Protection of the substrate from wear due to tribofilm formation is not expected to be significant.

After one cycle, the damage of the silicon surface is expected to be less than that of an initially uncoated substrate since the Au 90 NPs, CNHs and MoS_2 and WS_2 MWNTs remain in the wear area. In addition to the reduced contact area provided by the nano-objects it is believed that they roll and slide between the glass sphere and the substrate, which promotes facile shearing of the two surfaces, as shown in Fig. 38.37a–c. Further reductions in wear are expected for the CNHs due to roughness, which results in reduced real area of contact. It is expected that the greatest wear occurs on the bare silicon substrate and the presence of nano-objects provides protection of the substrate with the least wear occurring with the CNHs after 100 cycles.

Macroscale Friction and Wear

In macroscale friction and wear tests, a ball on flat tribometer was used. A sapphire ball of 1.5 mm radius was slid over nano-object-coated and uncoated silicon substrates under a normal load of 200 mN for 500 cycles with a stroke length of 10 mm. Figure 38.40 shows optical micrographs of wear scars in dry and liquid environments with and without nano-objects. The widths of the wear scars shown are smaller for sliding in liquid environments compared to sliding in dry environments, as the amount of wear is less. The presence of nano-objects in dry and liquid environments reduces the amount of wear compared to cases without nano-objects.

In liquid environments, as the viscosity of the fluid increases, the width of the wear scar decreases, with the greatest wear protection occurring in glycerol. This is due to the ability of the viscous fluid to support the normal load and not be squeezed out of the contact area.

Optical and SEM micrographs of the wear scars for all cases are shown in Fig. 38.41. Nano-objects can be observed within the wear scars for all cases, as seen in Fig. 38.41a. The presence of the nano-objects after the wear test further confirms that reduction in wear and size of the wear scars are due to addition of the nano-objects. Figure 38.41b shows magnified SEM micrographs of wear scars for Au 90 NPs, CNHs, and

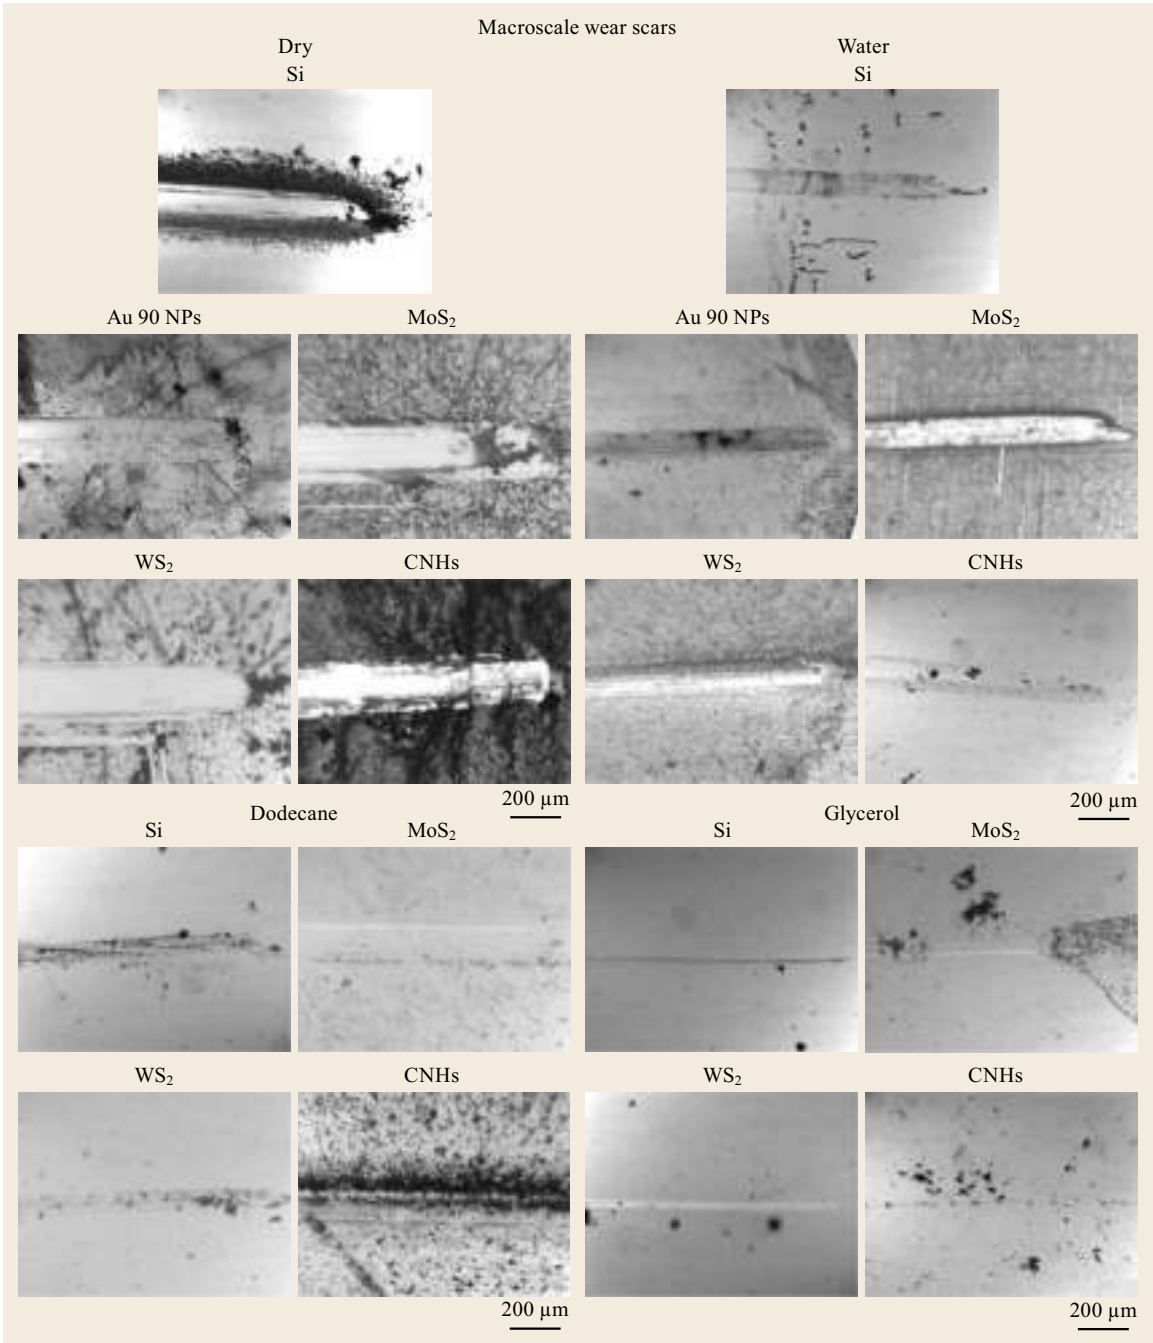

Fig. 38.40 Optical micrographs of macroscale wear scars taken after 500 cycles at a normal load of 200 mN, with 1.5 mm radius sapphire ball sliding in dry, water, dodecane and glycerol conditions with and without Au 90 NPs, CNHs, and MoS_2 and WS_2 MWNTs (after [38.224]). The lowest wear occurs in glycerol with CNHs

MoS_2 and WS_2 MWNTs in dry environments. Agglomerations of nanoparticles within the squares can be observed in the case of the Au 90 NP and CNH wear scar.

Agglomeration occurs during the wear process as nanoparticles are pressed together and are attracted to each other due to van der Waals and at-

tractive meniscus forces. For both MoS_2 and WS_2 wear scars, the SEM micrographs show crushed and broken nanotubes within the squares compared to those in Fig. 38.34a,b, which depicts undeformed nanotubes. It is believed that in the process of being crushed, the outer layers of the nanotubes break apart leading to exfoliation of the nanotubes and tribofilm formation, as discussed by *Maharaj* et al. [38.224].

In liquid environments, the results are similar to the nanoscale, where the coefficients of friction are lower than in dry environments in general, as reported by *Maharaj* et al. [38.224]. This is due to the presence of a surface of low shear strength for sliding. For CNHs submerged in water, the coefficient of friction is the lowest of all four nano-objects due to the reduced contact area provided by the roughness of the nanohorns. For MoS_2 and WS_2 MWNTs after 200 cycles, the coefficient of friction increases and becomes greater than that of the other nano-objects, and reaches that of bare silicon. The increase in friction is due to the oxidation of the MoS_2 and WS_2 MWNTs, as previously discussed. For sliding in dodecane and glycerol, the coefficient of friction is lower sliding on a nano-object-coated surface compared to bare silicon. The coefficient of friction is lower for the CNHs compared to the MWNTs, similar to the submerged-in-water case. After approximately 400 cycles for sliding on nanoparticles and nanotubes in dodecane, the coefficient of friction begins to increase as wear of the substrate takes place. In the case of glycerol there is also an increase in coefficient of friction for the nanotubes after 400 cycles. However, the coefficient remains steady for the CNHs. This is due to the combined effect of the reduced real area of contact for CNHs with the ability of glycerol to better support the load due to its high viscosity, which reduces the wear. The lowest coefficient of friction and least wear takes place in glycerol with CNHs.

38.5.3 Summary

Au NPs, MoS_2 and WS_2 MWNTs, and CNHs were investigated to understand friction and wear mechanisms of nano-objects and their effect on friction and wear in dry and liquid environments in water, dodecane, and glycerol. Studies were conducted in both single and multiple nano-object contacts with the aid of an AFM. In macroscale studies, a ball on flat tribometer was used.

For single nano-object contact, the lowest friction forces occur with the CNHs compared to Au NPs and MoS_2 and WS_2 MWNTs due to the reduced contact area provided by the roughness of the nanohorns and the low meniscus force contribution of the dry environments. Lower friction forces occur in submerged-in-liquid environments compared to dry environments due to elimination of meniscus force and sliding on a low shear-strength surface among the various liquids. The highest friction forces occur in glycerol due to high viscosity.

For multiple nano-object contact, sliding over nano-objects decreased the coefficients of friction compared to sliding on the bare silicon substrate due to reduced contact area and rolling and sliding among the various nano-objects. The lowest coefficient of friction occurs with the CNHs compared to the other nano-objects due to the mechanisms mentioned for single nano-object contact in dry environments. In nanoscale wear experiments in dry environments, the addition of nano-objects reduces the real area of contact and reduces the wear of the substrate through rolling and sliding of the nano-objects.

In macroscale studies, sliding over the various nano-objects reduced friction and wear due to the mechanisms mentioned in multiple nano-object contact on the nanoscale. Additionally, in dry environments, because of exfoliation and tribofilm formation, sliding on the MWNTs decreased the coefficient of friction and reduced wear. The lowest coefficient of friction and least wear in all cases occur with CNHs due to the reduced contact area. The coefficients of friction were also lower in submerged-in-liquid environments compared to dry conditions due to mechanisms mentioned on the nanoscale. The more viscous liquids results in better wear protection and lower coefficient of friction due to their ability to support the load and not be easily squeezed out of the contact area.

38.6 Nanotribological Studies of Biological Molecules on Polystyrene and Silicon Surfaces and Coated Polymer Surfaces

Protein layers are routinely deployed on bioMEMS/NEMS as a functional layer allowing for specific molecular recognition, binding properties, or to facilitate biocompatibility. Examples of these include sensors, immunoisolation capsules, and drug-delivery systems [38.1, 60, 235]. In addition, coating material surfaces with a protein layer facilitates biocompatibility along with implant functionality [38.149, 236]. Both the implanted biomaterial and the layer of protein will experience a range of physical and chemical assaults over the life of the device [38.237]. These include degradation by serum or tissue proteases, biochemical dissociation from surfaces, chemical modification, and abrasion by tissue elements [38.238]. In addition, an implanted biomaterial will experience micromotion over time, leading to wear and degradation of the protein layer [38.75, 93]. These can significantly affect and degrade the performance of the biomaterial, eventually leading to failure [38.237]. Optimizing the adhesion, friction, and wear on the adsorbed protein layer therefore is crucial to prevent device failure.

Protein adsorption, conformation, and adhesion also are of interest in cellular adhesion and growth. *Schricker* et al. [38.239, 240] and *Bhushan* and *Schricker* [38.241] studied protein adhesion on block copolymer-based biomaterials used as a scaffold for dental bone generation.

Bioadhesion refers to the adherence of biological material to a natural or synthetic material. The factors that control bioadhesion or cell adhesion and wear include surface morphology, chemical interactions, physiological factors, physical-mechanical interactions, and fluid environment [38.242, 243]. Bioadhesion for a given biological material to be bonded to an engineering surface and its wear properties need to be optimized.

In some applications, surfaces with low bioadhesion are required. Fluorinated self-assembled layers have been used to reduce bioadhesion of polymer surfaces.

38.6.1 Nanoscale Adhesion, Friction, and Wear of Protein Layers on Polystyrene Surfaces

Bhushan and *Utter* [38.242] studied nanoscale adhesion, friction, and wear behavior of four common proteins – bovine serum albumin (BSA), collagen, fibronectin, and streptavidin (STA) – adsorbed to a spin-coated polystyrene surface using atomic force microscopy. Bovine serum albumin is a homologue of human serum albumin and its primary physiological functions include helping to maintain blood oncotic pressure, the binding and transport of important ligands, and several antioxidant functions [38.244]. Type I collagen is the most abundant protein in the human body and is the primary load-bearing component of connective tissue [38.245]. Fibronectin is a major extracellular component required for clot formation and wound healing found throughout the body [38.246]. Finally, STA is used extensively in the biotechnology field for protein purification, biosensors, and the immobilization of biomolecules due to its interaction with biotin [38.247]. Figure 38.42 shows protein structures. Bovine serum albumin, fibronectin and streptavidin are all globular proteins [38.242]. Collagen is the only protein used in this experiment with a linear structure. Table 38.9 compares and contrasts the masses and isoelectric points of the four proteins used [38.242]. The isoelectric point is

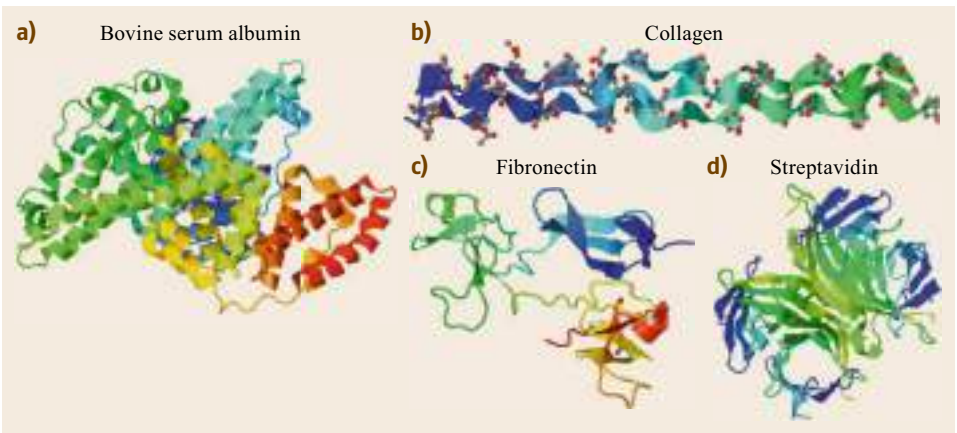

Fig. 38.42a–d Images showing the physical structure of the bovine serum albumin **(a)**, collagen **(b)**, fibronectin **(c)**, and streptavidin **(d)**. Proteins are not shown to scale relative to one another. All figures based on the protein data bank's files (after [38.242])

Table 38.9 Summary of the different protein masses and their isoelectric point [38.242])

Protein	Molecular weight (kDa)	Isoelectric point
Bovine serum albumin	≈ 67[a]	4.7[e]
Collagen	≈ 300[b]	4.7[f]
Fibronectin	≈ 500[c]	5[g]
Streptavidin	≈ 60[d]	5.5[d]

[a] [38.248]; [b] [38.245]; [c] [38.246]; [d] [38.247]; [e] [38.249]; [f] [38.250]; [g] [38.251]

the pH at which the protein will be electrically neutral in solution. Changing the pH of the solution above or below the isoelectric point will change the net charge on each protein. All of the proteins used in this experiment have an acidic isoelectric point giving them a net negative charge in DI water. STA and BSA have masses of 60 and 67 kDa respectively, with fibronectin and collagen being an order of magnitude more massive.

Polystyrene was selected as the substrate surface due to its extensive use in the biotechnology field. 50 µl of protein solution were added to the surface, and the samples were allowed to sit overnight. Before beginning any experiment, the samples were rinsed with DI water to remove the electrolytes and any unbound protein. Phosphate buffered saline (PBS) (pH 7.4) and the two remaining pH levels were created by combining monosodium phosphate (Aldrich) and disodium phosphate (Aldrich) in DI water to create the proper phosphate buffered solution.

Nanoscale adhesion, friction, and wear measurements were made using an AFM in DI and PBS (pH 5.0, 7.4 and 9.0). Adhesion and friction were investigated for all four proteins by varying the concentration of the protein solution from 1 to 100 µg/ml in DI water and PBS (pH 7.4). Nanoscale wear was also studied at a protein concentration of 100 µg/ml in PBS (pH 7.4). In addition, adhesion and friction were investigated by varying the pH and temperature of the liquid medium for both BSA and STA at 100 µg/ml.

Nanoscale Adhesion Measurements

First, the effect of protein concentration on the adhesive force was investigated for all the proteins. Figure 38.43a shows the adhesive force data between the bare silicon nitride AFM tip and each of the various proteins. The adhesive force increases between the protein film and the bare silicon nitride AFM tip as the concentration of protein is increased [38.242]. This increase in adhesive force is believed in part to be due to multiple interactions occurring between the protein film and the AFM tip [38.93]. This is also consistent with the observation that increasing the concentration of protein solution increases the density of the immobilized protein on the polystyrene surface. This increase may also be due to the more hydrophobic domains of the protein interacting with the polystyrene surface, leaving the hydrophilic domains to be exposed to the AFM tip. Other studies have shown that near-maximum binding will occur at roughly two hours, and that more protein will directly adsorb depending on solution concentration [38.252, 253]. It has also been reported that above a concentration of 10 µg/ml, certain proteins will begin to form higher-order structures not present at lower concentrations [38.93].

Figure 38.44 lists the basic interactions that may occur during protein adsorption and is only meant to show some of the interactions that can occur [38.254]. The

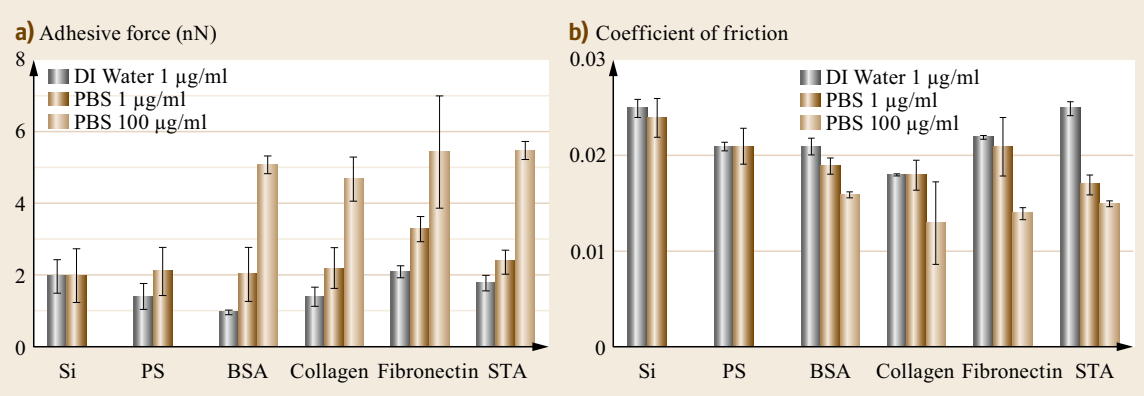

Fig. 38.43a,b Effect of protein concentration on **(a)** the adhesive force and **(b)** the coefficient of friction between the protein film and bare AFM tip. All experiments conducted at ambient temperature 22±1 °C unless otherwise noted. DI water (pH 7.0) and PBS (pH 7.4) were used for all experiments unless otherwise noted. Error bars represent ±1 standard error (after [38.242])

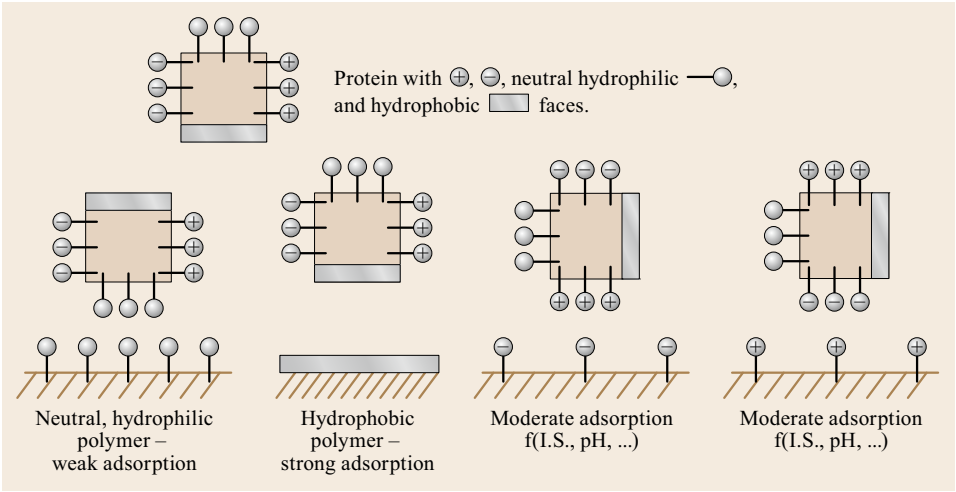

Fig. 38.44 Schematic showing the different protein domains and the potential interactions with the substrate surface (after [38.254])

strongest interaction occurs between the hydrophobic domains of the protein and a hydrophobic surface. Next, moderate adsorption occurs between charged protein domains and charged surfaces. Finally, weak adsorption occurs between hydrophilic protein domains and hydrophilic surfaces. Protein adsorption may involve several of these interactions occurring on the same surface and with the same protein.

Given that polystyrene is a hydrophobic surface, it is to be expected that the hydrophobic domains of the proteins interact with the surface during adsorption. The strength of the hydrophobic interaction is strong enough to induce a conformational change in the protein exposing the inner hydrophobic domains to the surface. This allows for the hydrophilic and charged domains to interact with the solution. It is also well known that by varying the pH of the solution, proteins can be made to denature from their native structure, thus allowing the inner hydrophobic domains to interact with the polystyrene surface. Previous studies have shown that chemically modifying the polystyrene surface has an effect on the amount of adsorbed protein, suggesting that the four proteins used in this study have a higher affinity for hydrophobic surfaces [38.252, 253]. This hydrophobic interaction is believed to be the dominant mechanism for protein adsorption to polystyrene. However, we do not have the data to show the orientation or packing density of the protein films [38.252]. The data from this experiment demonstrates no clear trend to distinguish the proteins from one another. However, what is clear for all of the selected proteins is that an increase in protein concentration leads to an increase in adhesive force between the AFM tip and the protein layer.

Next, the effect of pH on BSA and STA at 100 μg/ml concentration was investigated. Figure 38.45a shows the adhesive force data as a function of pH at 22 °C [38.242]. The general trend is that the adhesive force increases for each protein as the pH of the solution becomes more basic. Both proteins exhibit higher adhesive forces than the polystyrene control surface over the range of pH values. As the protein layer is exposed to a more basic solution, the surface will have a much larger net negative charge. Given that silicon nitride has an isoelectric point of pH 6–7, this may lead to a stronger interaction between the surface and the silicon nitride AFM tip [38.255]. For lower pH values (< pH 7.4), STA displays higher adhesive forces than BSA but this trend does not hold for the most basic solution.

The effect of temperature over the range of pH values also was studied for BSA and STA at 100 μg/ml concentration. Figure 38.45b shows the adhesive force data as a function of pH at 37 °C [38.242]. Adhesive forces for both proteins are much lower than at 22 °C and are not much different than the polystyrene control surface. This decrease in adhesive force at 37 °C may be due in part to the fact that more protein–protein and protein–surface interactions are occurring that result in a lower adhesive force with the AFM tip. The decrease in adhesive force could also be due to a temperature-related conformation change in the protein, which then interacts more weakly with the AFM tip. However, a slight increase occurs for all samples as the solution becomes more basic. This trend is consistent with the data that was obtained at 22 °C. As before, no clear trend is present to distinguish BSA from STA. This may be in part due to their similar protein structure, isoelectric point and mass.

Nanoscale Friction Measurements

The coefficient of friction was measured for all proteins as a function of protein concentration. Figure 38.43b

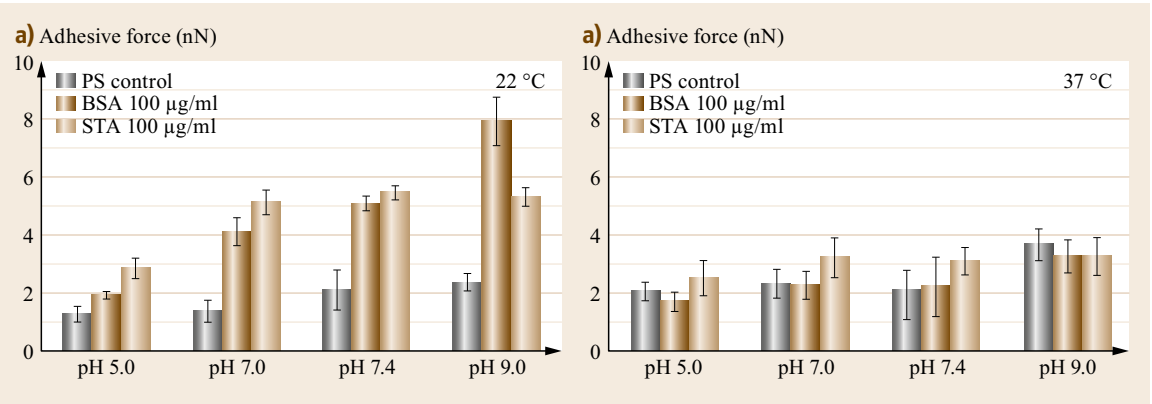

Fig. 38.45a,b Effect of pH on adhesive forces **(a)** at 22 °C and **(b)** 37 °C. Error bars represent ±1 standard error (after [38.242])

shows the coefficient of friction between the bare silicon nitride AFM tip and the various proteins [38.242]. The friction measurements that were taken show a decreasing coefficient of friction as the protein concentration is increased from 1 to 100 µg/ml. This decrease is believed to be due to the proteins acting as a lubricant film between the polystyrene surface and the silicon nitride AFM tip. At a higher protein concentration, a continuous lubrication film is formed due to a more uniform protein layer being formed on the substrate surface [38.93]. Like the adhesion data, there is no clear trend to distinguish the proteins from one another. However, the general trend is that increasing the concentration of these proteins leads to a decrease in the coefficient of friction for each protein tested.

Next, the coefficient of friction was measured for BSA and STA at 100 µg/ml concentration as a function of pH at 22 °C. Figure 38.46a shows the coefficient of friction between the bare silicon nitride AFM tip and two different protein-coated surfaces [38.242]. Both proteins exhibit lower friction than the polystyrene control, but the data appears to show that the coefficient of friction is fairly constant for all of the samples as the pH of the solution is altered. Also, no clear trend is present to distinguish BSA from STA when the pH varied, but the data from this experiment is in good agreement with what was found earlier by varying the protein concentration.

The effect of temperature also was investigated by heating the sample and solution to 37 °C. Figure 38.46b shows the coefficient of friction between the bare silicon nitride AFM tip and two different protein-coated surfaces [38.242]. At an elevated temperature the coefficient of friction increases slightly or stays the same relative to the 22 °C data. Again, the coefficient of friction is lower for the protein-coated samples relative to the polystyrene controls, but the coefficient of friction does not significantly change from one pH level to the next.

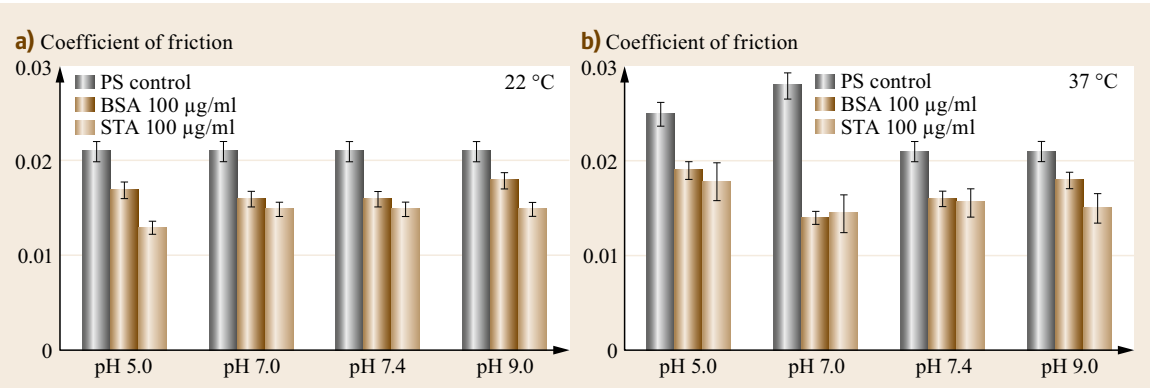

Fig. 38.46a,b Effect of pH on the coefficient of friction **(a)** at 22 °C and **(b)** 37 °C. Error bars represent ±1 standard error (after [38.242])

From these experiments, the coefficient of friction appears to be affected significantly by the concentration of the adsorbed protein film and not by the pH or temperature of the surrounding medium. As reported by *Bhushan* et al. [38.93] and *Fan* et al. [38.256], and confirmed with these experiments, protein concentration appears to be the primary factor in the formation of a continuous lubrication film. Solution pH and temperature appear to have secondary effects on the friction force experienced by the AFM tip.

Nanoscale Wear Tests

Figure 38.47 shows the wear images for each protein and a bare polystyrene control surface [38.242]. Each figure shows the height image and cross-sectional profile of a wear mark after conducting the wear scans. For these tests, the protein concentration was kept constant at 100 μg/ml with the normal load increasing from 3–9 nN. These tests show that the depth of wear increases with an increasing normal load for all of the samples imaged.

Several key differences become apparent on comparing the wear marks between the different protein-coated surfaces. The surface coated with BSA shows the most significant wear relative to all of the other samples. This may be in part due to the smaller mass of BSA and lower isoelectric point. At a pH of 7.4, BSA will have a net negative charge, which will interact more strongly with the AFM tip. When the AFM tip comes into contact with the protein film, the net negative charge and small mass allows for more wear to occur relative to the other samples. Streptavidin has approximately the same mass as BSA, but it does not exhibit the degree of wear that BSA undergoes. Therefore, protein mass appears to have a secondary effect on wear over the range of normal forces tested. As expected, the wear loads are of the same order of magnitude as the adhesive forces found in this experiment.

A trend becomes apparent by comparing the wear of the three globular proteins. As the protein isoelectric point becomes more basic and closer to the pH of saline (pH 7.4), wear marks become smaller. The most significant wear occurs with BSA, which has the lowest isoelectric point (pH 4.7). The surface coated with fibronectin (isoelectric pH 5) displays less wear than the BSA sample, but greater wear than the streptavidin (isoelectric pH 5.5) sample. The difference in wear marks for the globular proteins in part may be due to charge–charge repulsion that occurs when the pH of the solution is different than the isoelectric point of the protein.

However, the most interesting surface of all appears to be the one coated with collagen. This surface appears not to undergo any significant wear as compared to the other surfaces on the length scale in which we are interested. Collagen is the only protein tested that is linear in structure compared to the other proteins, and it has the ability to strongly self-associate [38.257]. Collagen also contains more hydrophobic amino acid groups than other proteins, which results in a stronger interaction with the polystyrene surface [38.258]. As the protein solution is allowed to sit overnight, slow rearrangements take place in the adsorbed collagen, creating a denser mesh with an increased resistance to wear [38.253]. Given that collagen is the primary load-bearing protein in the body and can be found in tissues in which significant mechanical wear can occur, it seems logical that it could be the most wear-resistant protein [38.245]. However, as shown by *Pamuła* et al. [38.253], and confirmed in the study being presented as well, the collagen surface will still undergo slight degradation at higher loads. Although fibronectin has the ability to self-associate, it does not appear to form the wear-resistant mesh that collagen does due to its globular structure.

Figure 38.48 shows a schematic of the hypothetical wear mechanism for the globular proteins at a higher protein concentration [38.242]. Due to the motion of the AFM tip during scanning, the protein molecules displace laterally and begin to interact with the remaining protein molecules. Protein aggregation leads to a pileup formation that keeps the molecules attached to the surface. The increased normal force causes more protein molecules to displace, leading to an increased degradation of the surface.

Summary

Bhushan and *Utter* [38.242] studied the nanoscale adhesion, friction and wear properties of four proteins adsorbed to a spin-coated polystyrene surface using an AFM in DI water and PBS by varying the concentration of the protein solution, pH, and temperature of the liquid medium. They found that under mild operating conditions, all of the proteins had similar adhesion and friction behavior, making a direct comparison between these proteins difficult. They showed that for all four proteins studied, the adhesive force between each protein and the AFM tip increased with increasing protein concentrations. It is believed that this increase in adhesive force in part is due to the formation of multiple interaction sites between the protein film and the AFM tip. Further, as the solution was altered from acidic to basic, adhesive forces also increased for BSA and STA, possibly in part due to the larger net charge of the protein interacting with the AFM tip. Adhesive forces then decreased when the temperature was increased to 37 °C. There was no clear trend present distinguishing BSA from STA, possibly because they have similar structure, isoelectric points, and mass.

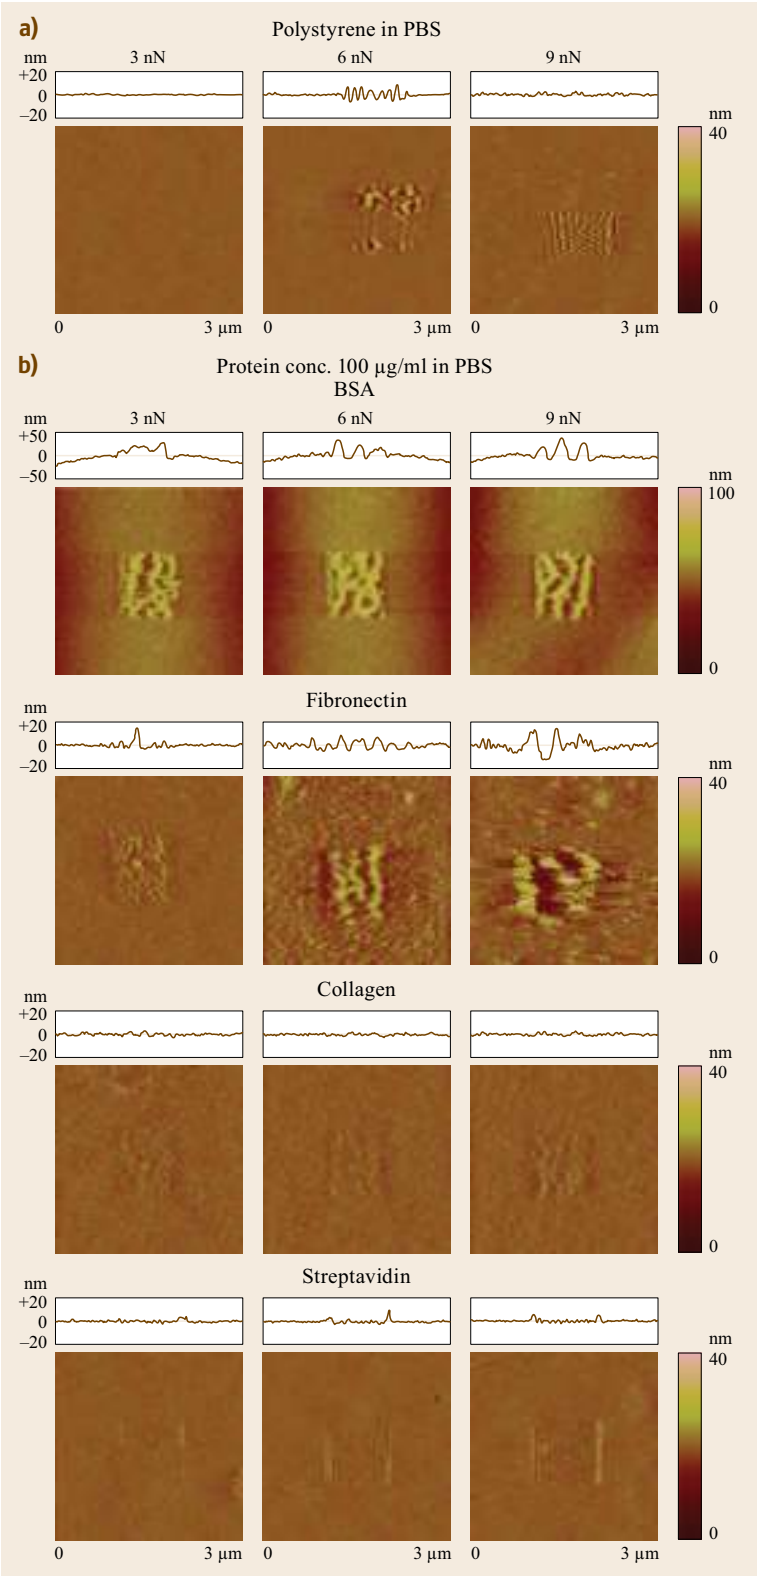

Fig. 38.47a,b AFM height images and corresponding cross-sectional profile of a wear mark in contact mode of **(a)** bare polystyrene and **(b)** four proteins at a concentration of 100 µg/ml in PBS. The normal loads used were 3, 6, and 9 nN. Reprinted from [38.242] with permission from Elsevier

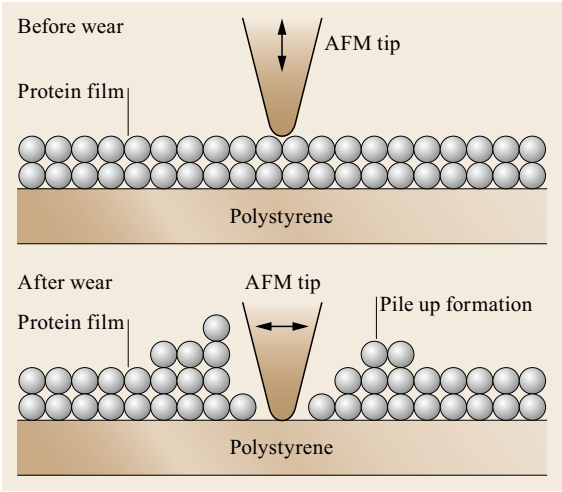

Fig. 38.48 Schematic of hypothetical wear mechanism of the adsorbed protein film at higher concentration (after [38.242])

It was also shown that for all proteins studied in PBS (pH 7.4), the coefficient of friction decreased as the protein concentration increased. It is believed that this is because the protein layer acts as a continuous lubrication film at higher protein concentrations. As compared to the polystyrene control surface, the coefficient of friction also decreased for BSA and STA when each pH level was tested at 22 °C. For each protein studied, the coefficient of friction remained relatively constant across the range of pH values. As compared to the polystyrene control surface, increasing the temperature to 37 °C kept the coefficient of friction relatively constant across the range of pH levels for BSA and STA. It appears that the existence of a lubrication film is the most important factor affecting the coefficient of friction. Solution pH and temperature appear only to have secondary effects on the coefficient of friction. There was no clear trend distinguishing BSA from STA when the pH and temperature of the solution are varied.

Wear is the distinguishing factor for the different proteins. Normal load had an effect on wear. As the normal force was increased, there was increased degradation for all of the samples imaged. For all of the proteins tested, the depth of wear marks increased with increased normal load. The globular proteins degraded in the order of their isoelectric points: bovine serum albumin > fibronectin > streptavidin > collagen. It is possible that collagen is more wear resistant because of its linear structure and ability to self-associate. For the normal forces tested, protein mass appears only to have a secondary effect on wear; the primary wear mechanism results from protein structure and isoelectric point.

38.6.2 Adhesion, Friction, and Wear of Biomolecules on Si-Based Surfaces

Proteins on silicon-based surfaces are of extreme importance in various applications, including silicon microimplants, various bioMEMS such as biosensors, and therapeutics. Silicon is a commonly used substrate in microimplants, but it can have undesired interactions with the human immune system. Therefore, to mimic a biological surface, protein coatings are used on silicon-based surfaces as passivation layers, so that these implants are compatible in the body and avoid rejection. Whether this surface treatment is applied to a large implant or a bioMEMS, the function of the protein passivation is obtained from the nanoscale three-dimensional (3-D) structural conformation of the protein. Proteins are also used in bioMEMS because of their function specificity. For biosensor applications, the extensive array of protein activities provides a rich supply of operations that may be performed at the nanoscale. Many antibodies (proteins) have an affinity to specific protein antigens. For example, pathogens (disease-causing agents, e.g., virus or bacteria) trigger the production of antigens that can be detected when bound to a specific antibody on the biosensor. The specific binding behavior of proteins that has been applied to laboratory assays may also be redesigned for in vivo use as sensing elements of a bioMEMS. The epitope-specific binding properties of proteins to various antigens are useful in therapeutics. Adhesion between the protein and substrate affects the reliability of an application. Among other things, morphology of the substrate affects the adhesion. Furthermore, for in vivo environments, the proteins on the biosensor surface should exhibit high wear resistance during direct contact with the tissue and circulatory blood flow without washing off.

Bhushan et al. [38.75] studied the step-by-step morphological changes and the adhesion of a model protein – streptavidin (STA) – on silicon-based surfaces (see also [38.148, 150, 259]). Figure 38.49a presents a flow chart showing the sequential modification of a silicon surface. In addition to physical adsorption, they also used nanopatterning and chemical linker methods to improve adhesion. A nanopatterned surface contains large edge surface area, leading to high surface energy, which results in high adhesion. In the chemical linker method, sulfo-*N*-hydroxysuccinimido-biotin (sulfo-NHS-biotin) was used as a cross-linker because the bonds between the STA and the biotin molecule are one of the strongest noncovalent bonds known (Fig. 38.49b). Sulfo-NHS-biotin was con-

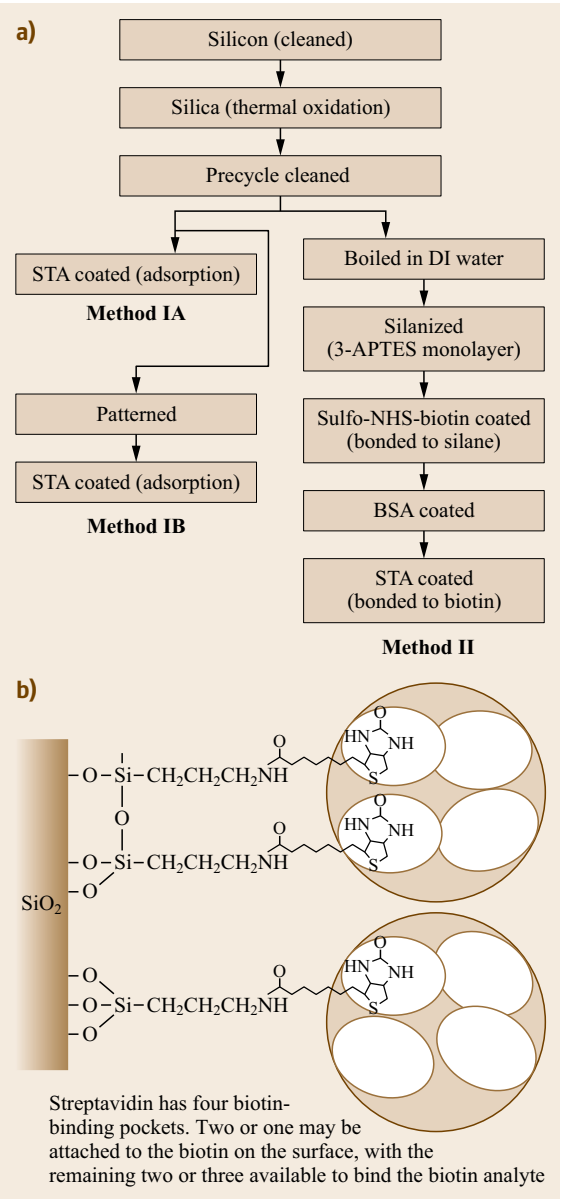

Fig. 38.49 **(a)** Flow chart showing the samples used and their preparation technique, and **(b)** a chemical structure showing streptavidin protein binding to the silica substrate by the chemical linker method

nected to the silica surface through a silane linker, 3-aminopropyltriethoxysilane (3-APTES). In order to make a bond between the silane linker and the silica surface, the silica surface was hydroxylated. Bovine serum albumin (BSA) was used before STA to block nonspecific binding sites of the STA protein with the silica surface. Figure 38.50 shows the step-by-step mor-

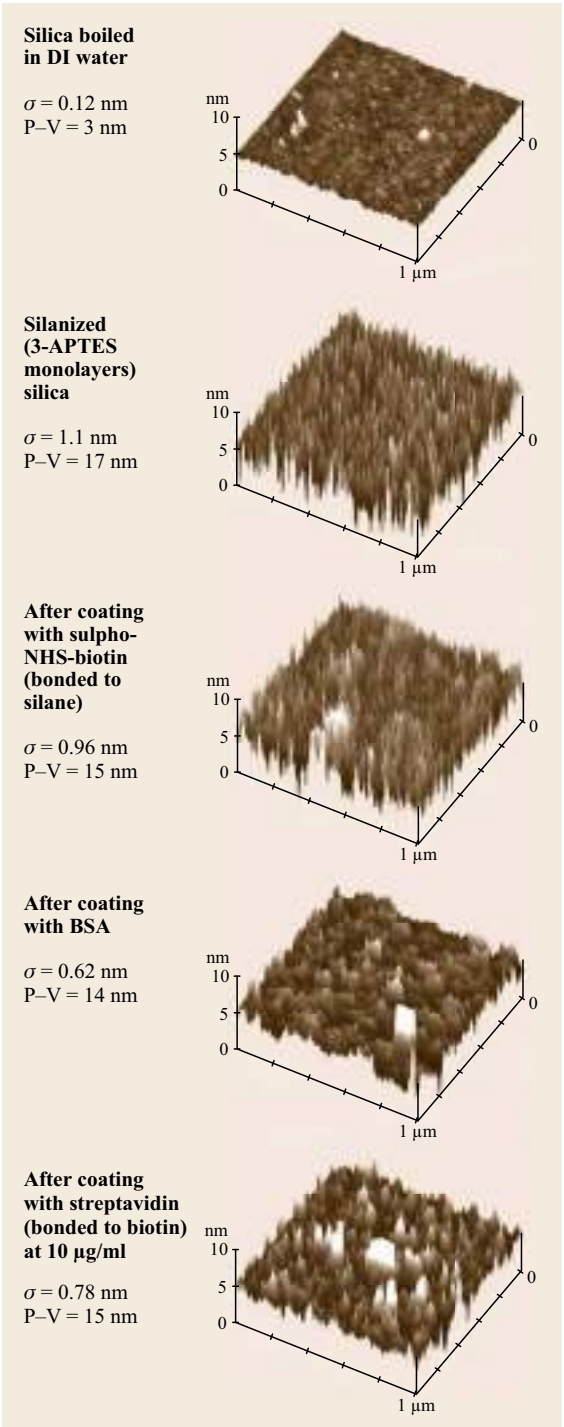

Fig. 38.50 Morphological changes in silica surface during functionalization of silica surface by chemical linker imaged in PBS. Streptavidin is covalently bonded at 10 µg/ml concentration (after [38.75])

phological changes in the silica surface during the deposition process using the chemical linker method. There is an increase in roughness (σ and peak-to-valley (P–V) distance) of the silica surface boiled in deionized (DI) water compared to the bare silica surface. After the silanization process, there are many free silane links on the surface, which cause higher roughness. Once biotin is coated on the silanized surface, the surface becomes smoother. Finally, after the deposition of STA, the surface shows large and small clumps. Presumably, the large clumps represent BSA, and the smaller ones represent STA. To measure adhesion between STA and the corresponding substrates, a STA-coated tip (or functionalized tip) was used and all measurements were made in PBS, a medium commonly used in protein analysis to simulate body fluid. Figure 38.51 shows the adhesion values of various surfaces. The adhesion value between biotin and STA was higher than that for other samples, which is expected. Edges of patterned silica also exhibited high adhesion values. It appears that both nanopatterned surfaces and chemical linker method increase adhesion with STA.

Bhushan et al. [38.93] studied friction and wear of STA deposited by physical adsorption and the chemical linker method (see also [38.150]). Figure 38.52 shows the coefficient of friction between the Si_3N_4 tip and various samples. The coefficient of friction is less for STA-coated silica samples being adsorbed, as compared to an uncoated sample. The STA coating acts as a lubricant film. The coefficient of friction is found to be dependent upon the concentration of STA, and it decreases with an increase in the concentration. *Bhushan* et al. [38.75] have reported that the density and distribution of the biomolecules vary with the concentration. At a higher concentration of the solution, the coating layer is more uniform, and covers more of the silica substrate surface than at a lower concentration. This means that the surface forms a continuous lubricant film at a higher concentration.

In the case of samples prepared by the chemical linker method, the coefficient of friction increases with an increase in the biomolecular chain length due to increased compliance. When normal load is applied to the surface, the surface gets compressed, resulting in a larger contact area between the AFM tip and the biomolecules. Further, the size of STA is much larger than that of APTES and biotin, resulting in a surface tightly packed with biomolecules that results in very little lateral deflection of the sulfo-NHS-biotin linker. Due to the high contact area and low lateral deflection, the friction force increases for the same applied normal load as compared to samples prepared by the physical adsorption method. These tests reveal that the surfaces coated with biomolecules reduce friction, but if the biomolecular coating of the surface is too thick, or the surface has some cushioning effect, as seen in the chemical linker method, the coefficient of friction increases.

Figure 38.53 shows the surface height maps and phase images of wear marks on STA deposited by

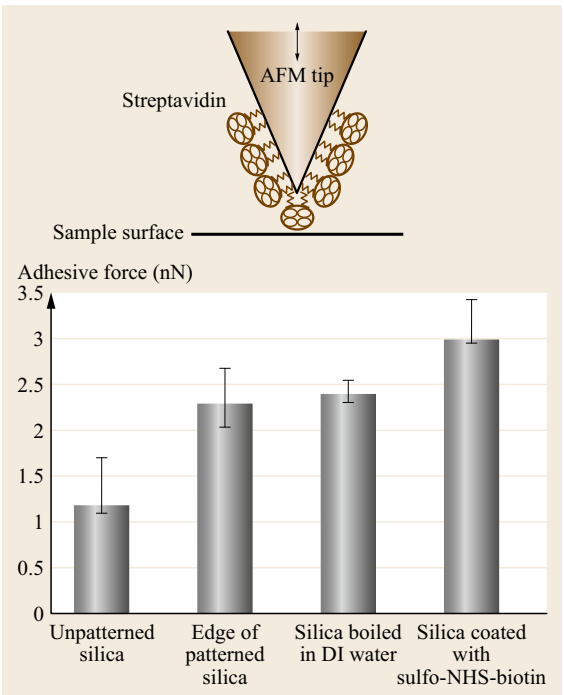

Fig. 38.51 Adhesion measurements of silica, patterned silicon, silica boiled in DI water, and sulfo-NHS-biotin using functionalized (with streptavidin) tips obtained from force–distance curves, captured in PBS

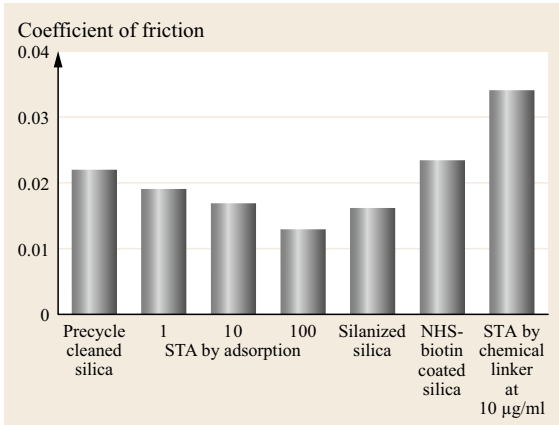

Fig. 38.52 Coefficient of friction for various surfaces with and without biomolecules (after [38.93])

physical adsorption taken after wear tests at three normal loads. The wear depth increases with the increasing normal load. An increase in normal load causes partial damage to the folding structure of the streptavidin molecules. It is unlikely that the chemical (covalent) bonds within the streptavidin molecule are broken, in-

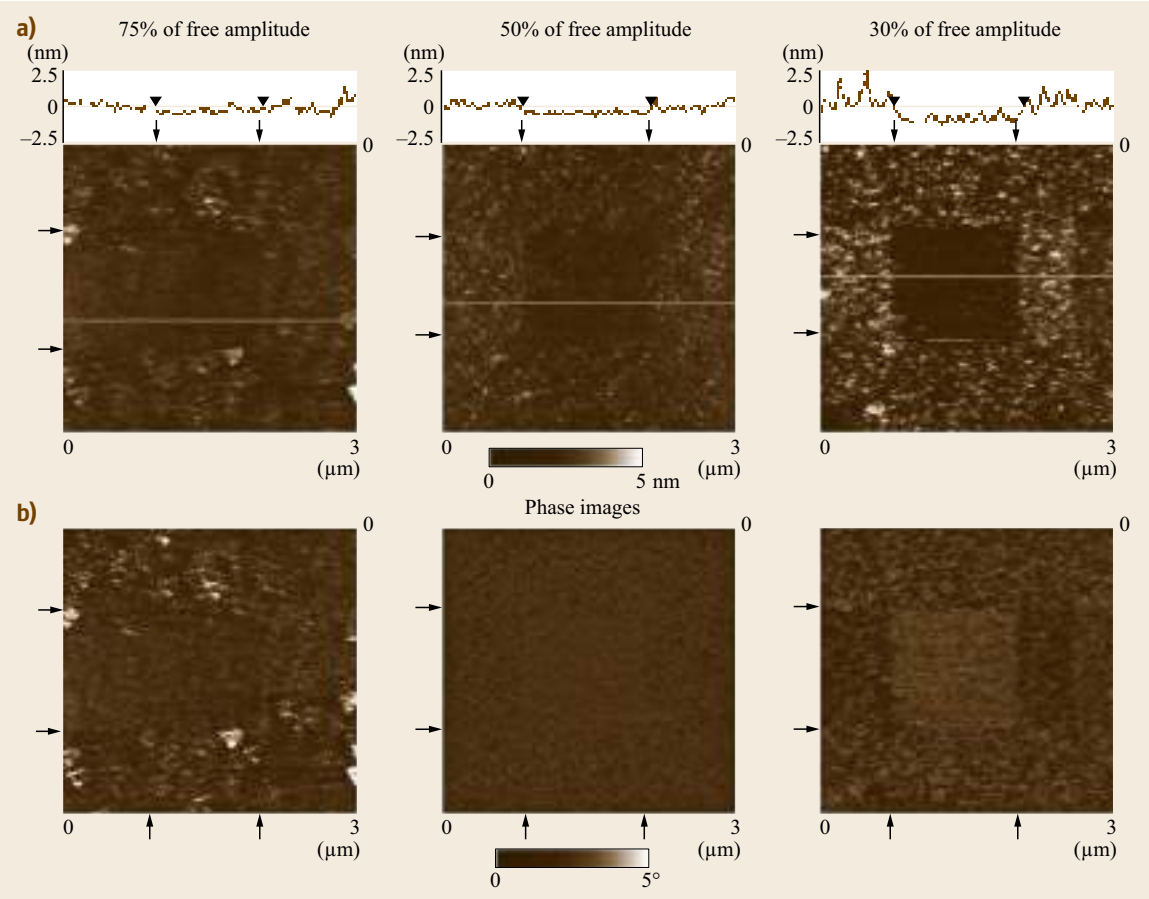

Fig. 38.53a,b Surface height maps and cross-sectional profiles **(a)** and phase images **(b)** of wear marks on precycle cleaned silica coated with streptavidin by physical adsorption after wear tests at three normal loads (increasing from *left* to *right*). The 75, 50, and 30% of free amplitudes correspond to equivalent normal loads of 3, 6, and 8 nN respectively (after [38.93])

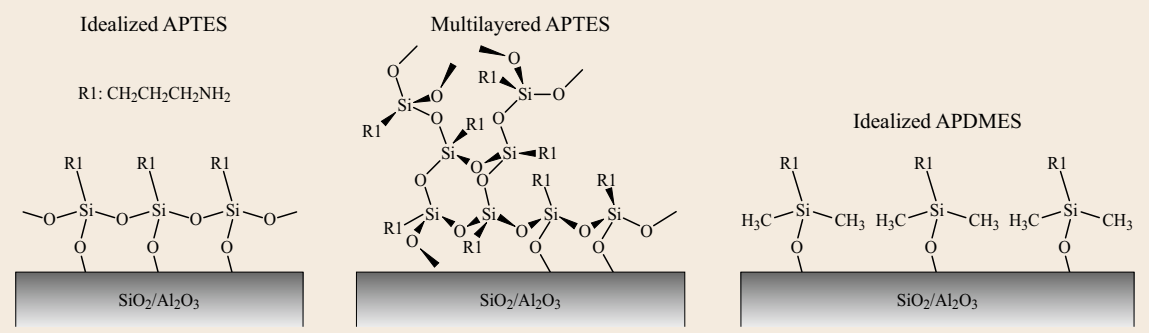

Fig. 38.54 Schematics of idealized and multilayered APTES and idealized APDMES silane polymer films on silicon/SiO_2 and aluminum/Al_2O_3 substrates. Idealized film corresponds to a self-assembled monolayer (after [38.150])

stead, the folding structure is damaged, leading to the wear mark. When the load is high, about 30% of free amplitude (≈ 8 nN), the molecules may be removed by the AFM tip due to the indentation effect. Because of this, there is a significant increase in the wear depth from 50% of free amplitude (≈ 6 nN) to 30% of free amplitude (≈ 8 nN). The data show that biomolecules will be damaged during sliding.

In summary, for the samples prepared using nanopatterning and chemical linker methods, adhesion is higher as compared to the direct adsorption method. The coefficient of friction is smaller for STA-coated silica prepared using the direct adsorption method as compared to an uncoated silica sample. The coefficient of friction decreases with increasing concentration of STA in the solution because the protein acts as a lubricating film. Friction increases for the STA sample prepared using the chemical linker method due to low lateral deformation and the cushioning effect. Wear of STA increases with the increasing load.

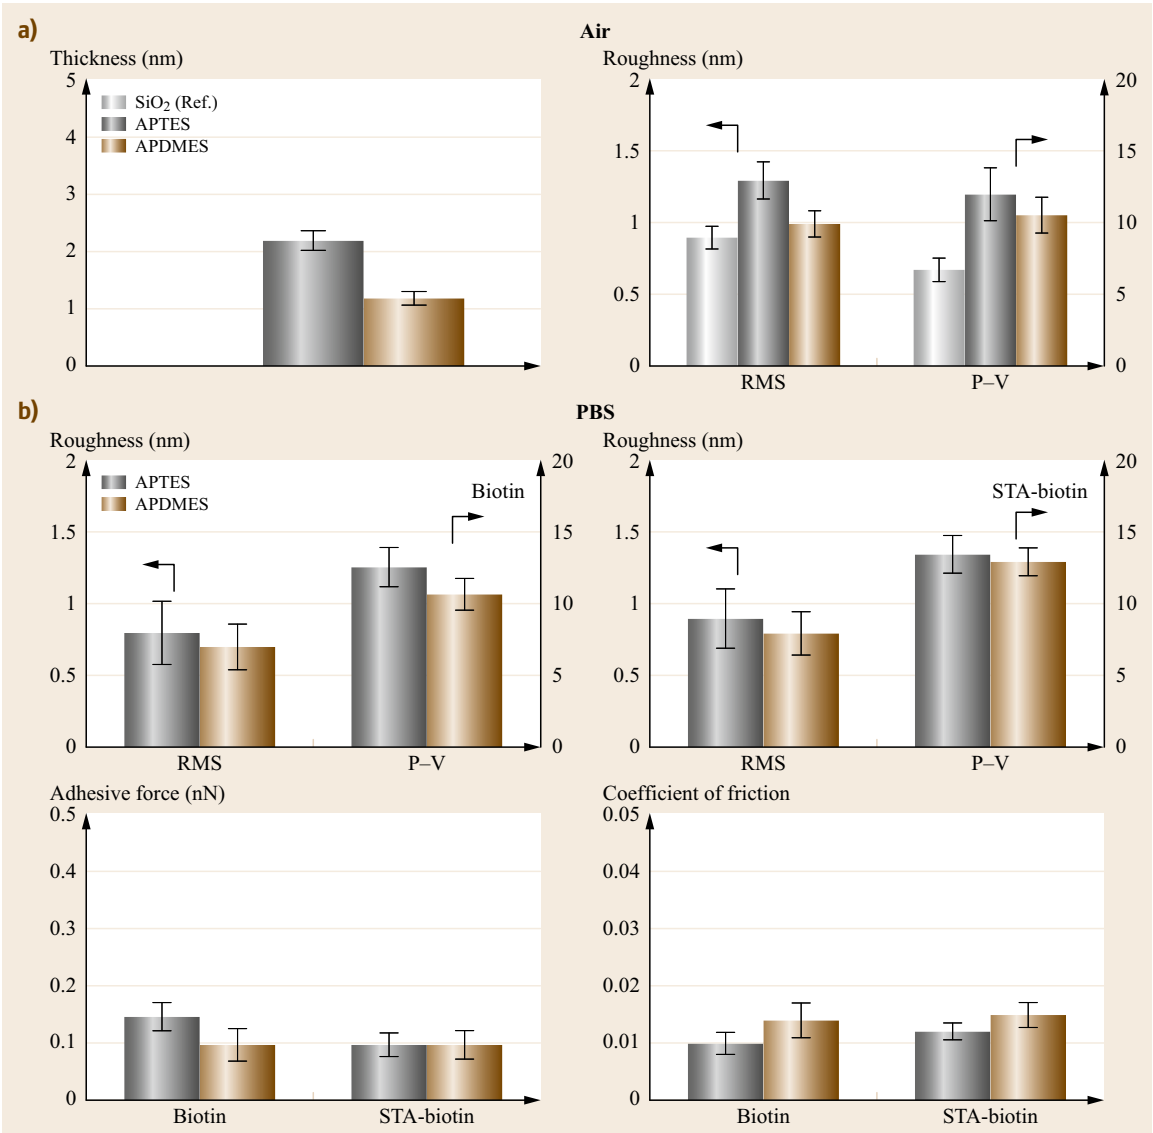

Fig. 38.55 **(a)** Summary of film thickness and surface roughness (RMS and P–V distance) for APTES and APDMES in air, and **(b)** summary of the surface roughness (RMS and P–V distance), adhesive force, and coefficient of biotin and STA-biotin on APTES and APDMES films, all in PBS buffer solution. *Error bars* represent $\pm 1\sigma$ (after [38.150])

APDMES to Improve Adhesion, Friction and Wear of Biomolecular Films

APTES films used in the study reported above were not very smooth, and P–V distances were greater than the summed bond strengths of APTES. Therefore, the biotin/STA deposited on APTES films were not very robust. APTES films are commonly described as SAMs, though this is often inaccurate [38.260–262]. APTES monomers can form infinite, cross-linked siloxane polymer lattices because APTES is a multi-(tri)valent silane. Further, APTES can form a multilayered structure due to intermolecular polymerization with significant cross-linking between monomers. It should consist of sparse cross-links between the polymer and the substrate, Fig. 38.54 [38.150]. The propensity to form multilayers and its low mechanical strength make APTES an undesirable interface material. On the other hand, 3-aminopropyldimethylethoxysilane (APDMES) cannot polymerize into extensive networks because it is monovalent, forming only siloxane dimers or linkages

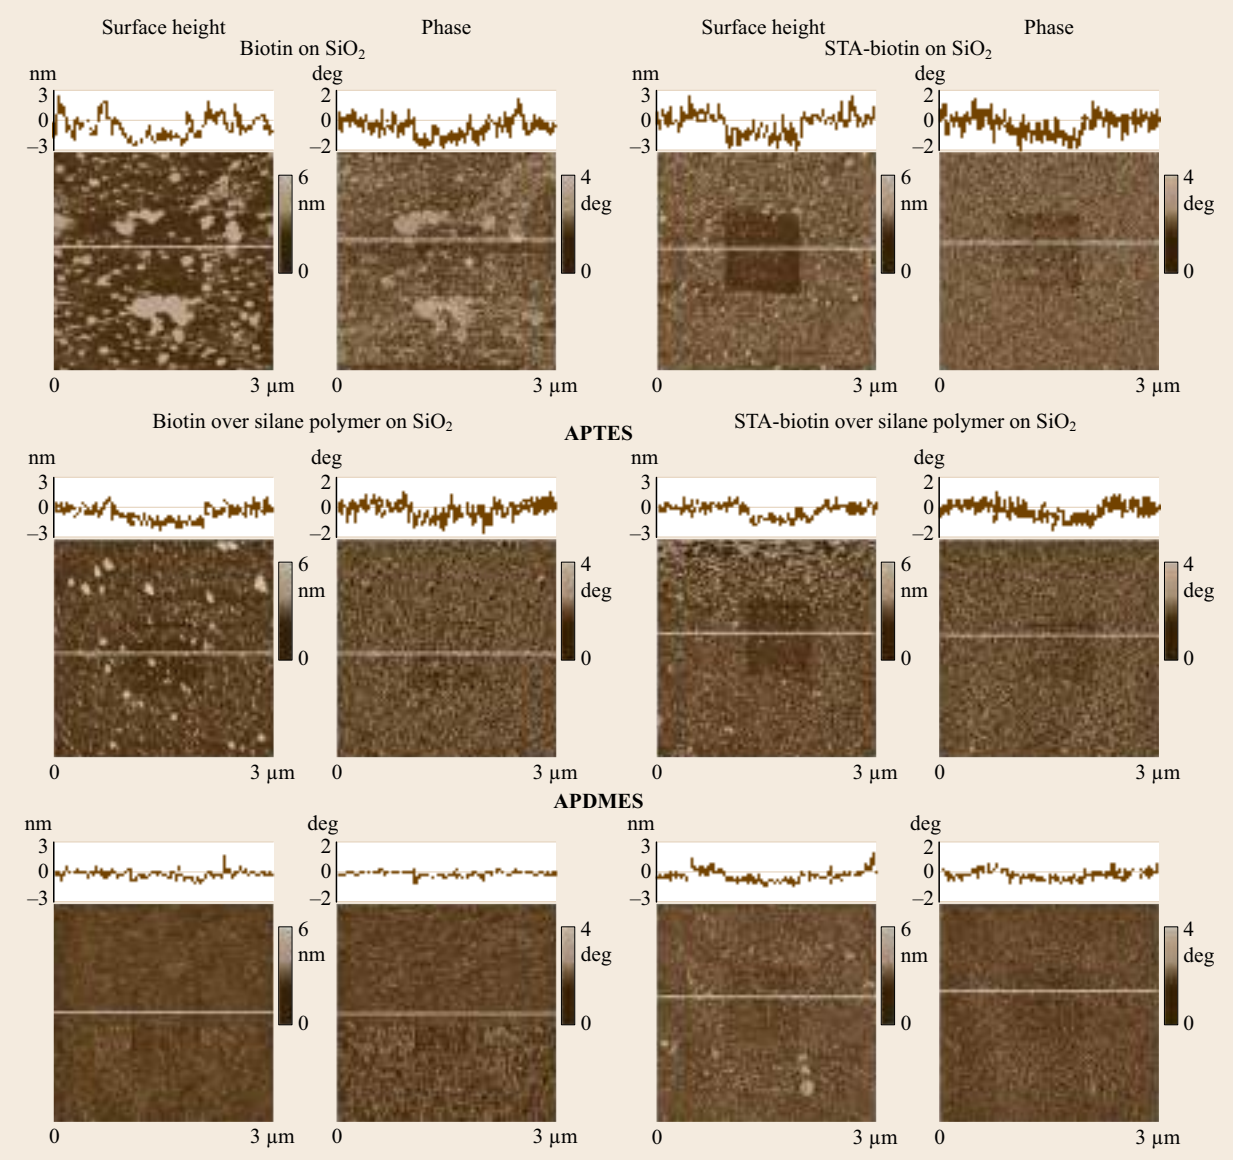

Fig. 38.56 AFM surface height and phase angle images and cross-sectional profiles obtained after wear testing in PBS in tapping mode at 50% of free amplitude (≈ 2 nN) on biotin and STA-biotin on SiO_2 and APTES and APDMES films on SiO_2. The *white lines* indicate the locations of the cross-sections.

to substrate oxides (Fig. 38.54). Therefore, APDMES should produce thinner films of greater mechanical robustness than APTES and provide the robustness to the biomolecular layers deposited on its top. Thinner interfaces theoretically would also increase sensor sensitivity to analytes.

Bhushan et al. [38.150] examined the thickness and durability of APDMES deposited on SiO_2 and Al_2O_3 substrates, with biotin and biotin/STA bound to them. Figure 38.55a shows the thickness and surface roughness (RMS and P–V) of APTES, APDMES, and SiO_2 substrate for reference. Figure 38.55b shows the surface roughness, adhesive force, and coefficient of friction for biotin and STA-biotin deposited on APTES and APDMES films. The data show that the APTES film was not very smooth. It was shown in Fig. 38.50 that biotin and STA deposited on APTES were also not very smooth, with high P–V values. The thickness of the APTES layer was larger than the expected monolayer thickness. The unexpected thickness of the film suggests multilayering by APTES. APDMES films produced the thinner film, with a thickness comparable to the summed bond lengths of the APDMES polymer (Fig. 38.55a). *Bhushan* et al. [38.150] reported that the APDMES film was more uniform, smoother, nearly continuous, and exhibited a higher contact angle and lower adhesive force as compared to the APTES film. The surface roughness and adhesive force of biotin and STA-biotin on APDMES was also slightly lower than that on APTES film. The coefficient of friction on APDMES was slightly higher than that on APTES (Fig. 38.55b).

Bhushan et al. [38.150] also studied wear properties of various films. Contact mode always immediately stripped the surface at low loads; consequently, wear experiments were performed in tapping mode at various loads. AFM surface height and phase angle images and cross-sectional profiles obtained after wear tests for biotin and STA-biotin on APTES and APDMES in PBS are shown in Fig. 38.56. As controls, the wear experiments of biotin and STA-biotin on SiO_2 without SAM were also carried out. The biomolecular films on APDMES were more robust than that on APTES. Given that each molecule of APDMES must be bonded to a surface oxide group and that intrapolymer cross-links are not possible in APDMES, it has the highest density of siloxane linkages to the substrate oxide, making it the more robust. *Bhushan* et al. [38.150] also studied the effect of load on the wear of APDMES and biotin and STA-biotin deposited on APDMES; Fig. 38.57. As expected, wear increased with an increase in the load. The relationship between the average wear depth (and the coefficient of friction) and the average normal load is generally linear. The slope of the wear depth (and coefficient of friction) to load is steepest for the interface to which STA-biotin was bound because of the cushioning effect of the thick film, as suggested earlier.

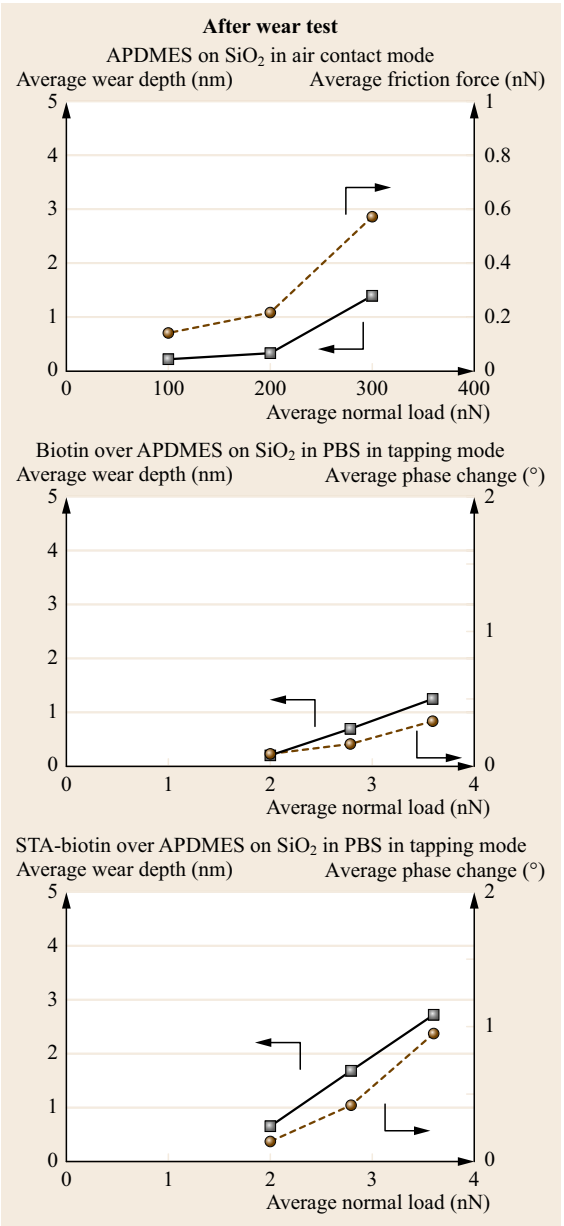

Fig. 38.57 Plot of average wear depth and average friction force/phase angle as a function of average normal load for APDMES on SiO_2 in air in contact mode, biotin over APDMES on SiO_2 in PBS in tapping mode, and on STA-biotin over APDMES on SiO_2 in PBS in tapping mode (after [38.150])

In summary, an APDMES film is more uniform, smoother, and nearly continuous as compared to APTES film. These properties of APDMES provide a good interfacial material for biomolecular films providing a smooth and robust structure.

38.6.3 Adhesion of Coated Polymer Surfaces

As mentioned in Appendix 38.A, poly(methyl methacrylate) (PMMA), PDMS, and other polymers are used in the construction of micro/nanofluidic-based biodevices. Adhesion between the moving parts needs to be minimized. Furthermore, if the adhesion between the microchannel surface and the biofluid is high, the biomolecules will stick to the microchannel surface and restrict flow. In order to facilitate flow, a surface with low bioadhesion is required.

Tambe and *Bhushan* [38.263, 264] and *Bhushan* and *Burton* [38.265] have reported adhesive force data for PMMA and PDMS against an AFM Si_3N_4 tip and a silicon ball. *Tokachichu* and *Bhushan* [38.266] measured contact angle and adhesion of bare PMMA and PDMS and those coated with a perfluoro SAM of perfluorodecyltriethoxysilane (PFDTES). Oxygen plasma treatment was used for hydroxylation of the surface to enhance chemical bonding of the SAM to the polymer surface. They made measurements in ambient conditions, PBS, and fetal bovine serum (FBS); the latter is a blood component. Figures 38.58 and 38.59 show the contact angle and adhesion data. SAM-coated surfaces have high contact angles (Fig. 38.58), as expected. The adhesion value of PDMS in ambient conditions is high because of the electrostatic charge present on the surface. The adhesion values of PDMS are higher than PMMA because PDMS is softer than PMMA (elastic modulus = 5 GPa and hardness = 410 MPa [38.151]), resulting in a higher contact area between the PDMS surface and the AFM tip. Additionally, PMMA does not develop electrostatic charge. When SAM is coated on PMMA and PDMS surfaces the adhesion values are similar, which shows that the electrostatic charge on virgin PDMS plays no role when the surface is coated. In the PBS solution, there is a decrease in adhesion values

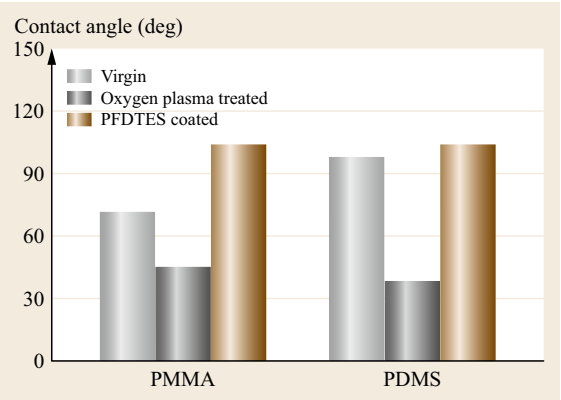

Fig. 38.58 Sessile drop contact angle measurements of virgin, oxygen plasma-treated and PFDTES-coated PMMA and PDMS surfaces. The maximum error in the data is ±2° (after [38.266])

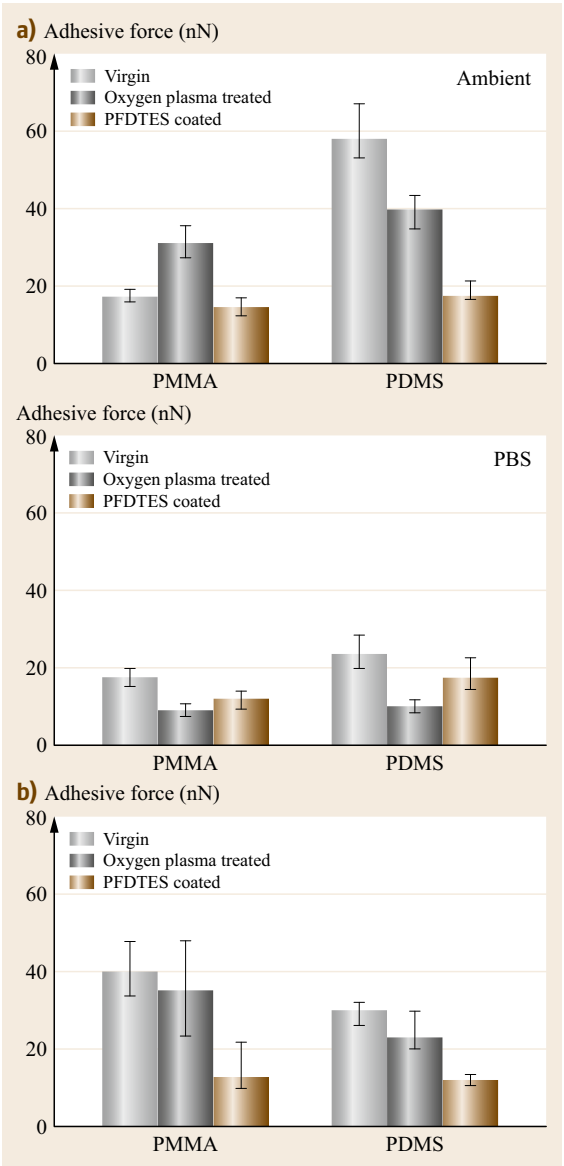

Fig. 38.59a,b Adhesion measurement of virgin, oxygen plasma-treated and PFDTES-coated PMMA and PDMS surfaces **(a)** with bare silicon nitride AFM tip in ambient, and in PBS environment, and **(b)** dip-coated tip with FBS in PBS environment (after [38.266])

because there is no meniscus contribution. The adhesion values for an FBS-coated tip in PBS are generally lower than for an uncoated tip in PBS.

In summary, the adhesion values of SAM-coated surfaces are lower than bare surfaces in various environments.

38.7 Trajectory of Submicron Particles for Therapeutics and Diagnostics

For drug delivery, submicron particles are injected into the bloodstream in human capillaries (as small as 4–5 μm) and employed to deliver drugs to diseased cells, to locate diseased cells or tumoral masses and estimate the state of disease, and to carry diagnostic agents (fluorescent molecules) to diseased cells to enhance imaging [38.163]. Particles exhibiting one of these characteristics are considered smart systems, which can function as purely therapeutic agents or purely diagnostic agents or a combination of both. Small delivery particles include nanocrystals, synthetic vesicles, liposomes, and fabricated silicon.

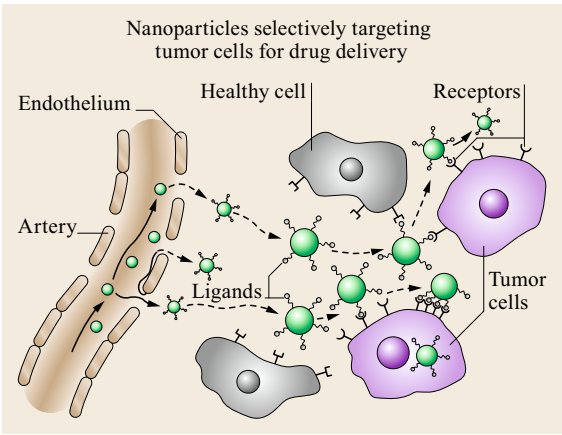

Fig. 38.60 Trajectory of submicron particles injected intravenously for selectively targeting tumor cells for drug delivery (after [38.162]).

A schematic of the trajectory of a submicron particle injected intravenously for selectively targeting tumor cells for drug delivery is shown in Fig. 38.60. Particles are reservoirs containing drug or diagnostic agents. These are covered with a layer of adhesive molecules (ligands) for attaching to selected target sites. When a particle is sufficiently close to select cell surfaces (a few nm), its ligands can interact with the cellular counterpart (receptors), leading to firm attachment. Once the particle is attached to its target, a drug or diagnostic agent is delivered. The speed and the time needed for a particle circulating in the bloodstream to reach the endothelium lining of the human capillary is dependent upon the distance and interactive forces. The particle can interact with the endothelium lining with buoyancy, van der Waals forces, and electrostatic and steric forces. These interactions are a function of the material properties of the particle and any coating on it, in particular, relative density (particle density relative to blood), the electrostatic potential, the dielectric constant, and the particle radius. These properties can be optimized.

The interacting forces are weak, so the particle trajectory should be close to the endothelium lining. Otherwise, the particle may not get attracted to the lining and perform its intended function. *Decuzzi* et al. [38.163] developed an analytical model to predict the trajectory of a particle freely circulating in

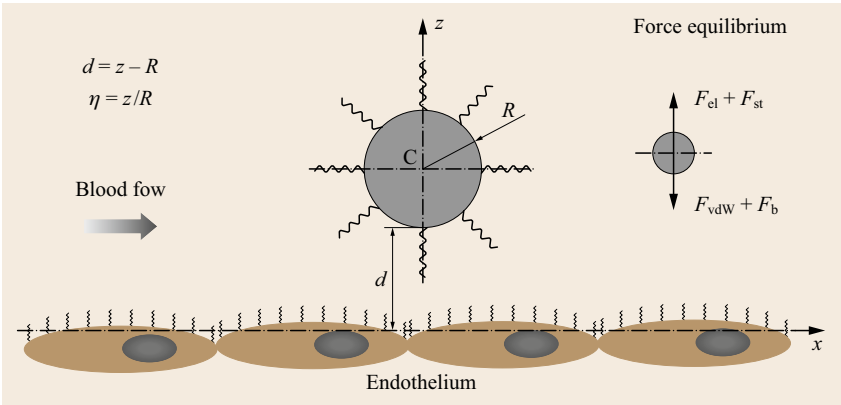

Fig. 38.61 A spherical particle moving close to the endothelium wall in a laminar flow. In the inset, the balance of the forces acting over the particle are sketched. F_{el}, F_{st}, F_{vdW}, and F_b correspond to electrostatic force, steric force, van der Waals force, and buoyancy force respectively (after [38.163])

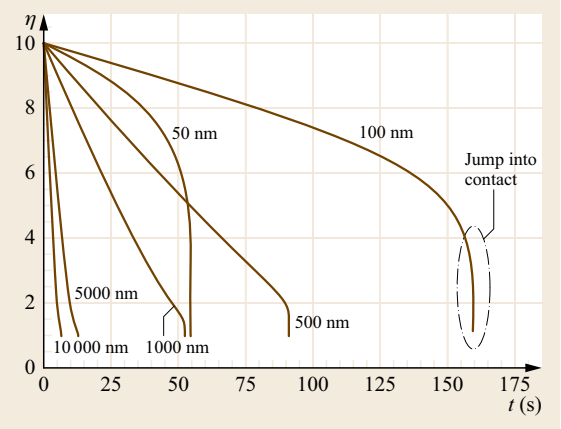

Fig. 38.62 The dimensionless particle position $\eta(= z/R)$ as a function of time t for different values of particle radius ($R = 10\,000$, 5000, 1000, 500, 100, and 50 nm). There exists a critical radius R_c at which the travel time is maximum (after [38.163])

the bloodstream and associated interaction forces. The model can be used to optimize the particle radii and material properties. Figure 38.61 shows a spherical particle freely circulating in the bloodstream with its center at a distance z from the endothelium wall. The particle has a radius R and its trajectory is governed by the forces exerted by the bloodstream, gravitation, and electromagnetic interactions. We assume that the particle is sufficiently far from the endothelium wall that specific interactions (such as ligand–receptor interactions) can be ignored. At short range (below 1−3 nm), solvation and other steric forces dominate. However, the most important long-range forces (5−10 nm) between particles and wall surfaces in the presence of a liquid are buoyancy and van der Waals, electrostatic and steric forces. Buoyancy is related to the radius of the particle R and the relative density of the particle relative to blood. The van der Waals interaction (generally attractive) is related to R, its relative position with respect to the endothelium wall z, and the Hamaker constant A, which depends upon the dielectric constants of the media involved. The electrostatic double layer (EDL) interaction (repulsive and attractive) is related to R, z, the ionic concentration, and the characteristic Debye length of the solution. Finally, steric repulsive interaction is related to the unperturbed radius of gyration of polymer chains grafted on the particle surface, R and z. The value of various forces as a function of the particle radius R for a fixed distance from the wall z is presented in Table 38.10. The dominating force is buoyancy when the particle radius is sufficiently large, and van der Waals when the particle is sufficiently small.

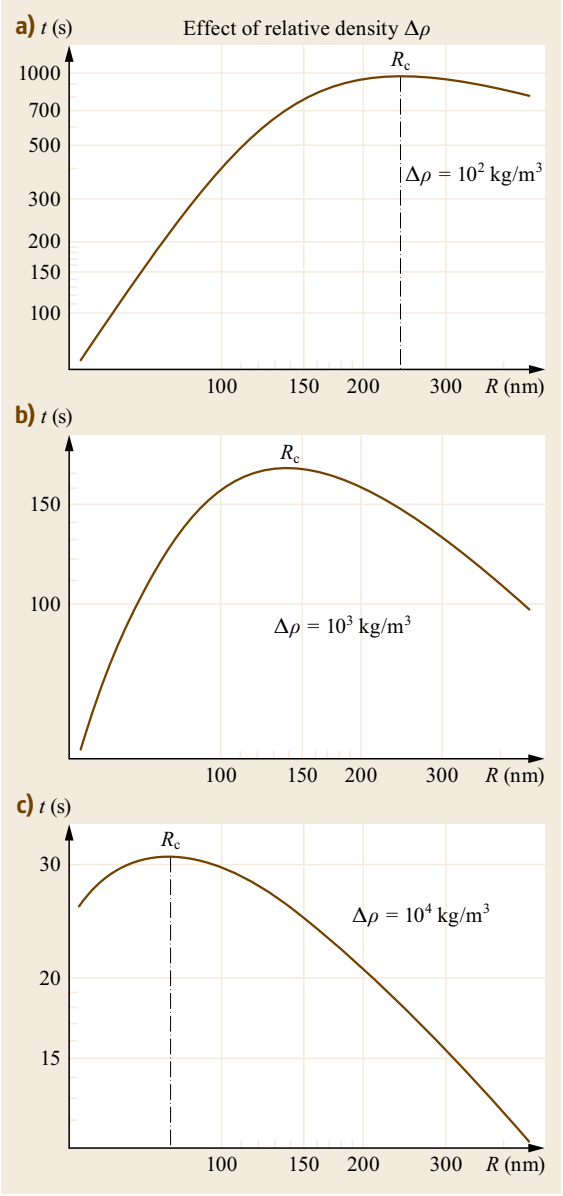

Fig. 38.63a–c The travel time as a function of particle radius R for different values of the relative density **(a)** $\Delta\rho = 10^2$, **(b)** $\Delta\rho = 10^3$, and **(c)** $\Delta\rho = 10^4$ kg/mm^3. The critical radius R_c depends upon $\Delta\rho$ (after [38.163])

Electrostatic and steric forces are negligible as long as the distance is larger than the 50 nm considered in this example.

The travel time needed to reach the wall depends upon the particle size, as shown in Fig. 38.62. In this figure, the dimensionless position of the particle center with respect to the endothelium wall η $(= z/R)$ is plot-

Table 38.10 The value of the buoyancy force F_b, van der Waals force F_{vdW}, electrostatic force F_{el} and steric force F_{sr} as a function of the particle radius for a fixed distance from the wall ($\eta = z/R = 2$ or $d = R$) (after [38.163])

R (nm)	F_b (pN)	F_{vdW} (pN)	F_{el} (pN)	F_{sr} (pN)
10 000	41.092	0.0005	≈ 0	≈ 0
1000	41.092×10^{-3}	0.005	≈ 0	10^{-33}
100	41.092×10^{-6}	0.05	10^{-52}	1.2×10^{-3}
50	51.3×10^{-7}	0.1	10^{-25}	3×10^{-2}

ted as a function of time t for different particle radii, ranging from $R = 10\,\mu m$ to 50 nm. It was assumed that particles were initially at a distance d_0 ($z_0 - R$) equal to $9R$ from the endothelium wall (i. e., the center of the particle is at $z_0 = 10R$, $\eta_0 = z_0/R = 10$). Thus, the distance traveled scales with the size of the particle. The data show that as the radius of the particle decreases, the time needed to reach the wall increases up to a maximum beyond which it decreases as the radius is further reduced. Larger particles are initially far from the endothelium wall; a 10 μm particle is initially 100 μm away from the endothelium ($z = 10R$) where electrostatic and van der Waals interactions are negligible and the particle motion is governed by buoyancy and hemodynamic resistance. As the particle approaches the endothelium wall, van der Waals attraction dominates, and a rapid increase in speed is observed with a *jump into contact* kind of behavior. Such a behavior is more clearly shown by particles with submicron radius closer to the endothelium wall, so the van der Waals force dominates from the beginning. We note that there is a critical radius at which the time taken for the particle to travel to the wall is maximum. The selected radius should be smaller or larger than the critical radius (possibly smaller so that they can circulate freely even in smaller capillaries).

The effect of the relative density of the particle $\Delta\rho$ on the critical radius R_c at which travel time is maximum is plotted in Fig. 38.63. We note that as $\Delta\rho$ reduces, the R_c increases. As $\Delta\rho$ decreases, the effect of buoyancy becomes less important, and van der Waals attractive forces exert a greater influence as particle radii decrease.

In summary, the interacting forces are weak, so the particle trajectory should be close to the endothelium lining. The trajectory and interaction forces depend upon the particle radii and material properties. These results suggest that particles for therapeutics and diagnostics should have a radius larger or smaller than the critical value (possibly smaller so that they can circulate freely even in smaller capillaries). The material properties of the particle and the polymer chains grafted on it, such as the relative density of the particle, can be tuned specifically to the type of malignant tissue and the state of disease, improving the particle affinity with the diseased cell.

38.8 Component-Level Studies

38.8.1 Surface Roughness Studies of Micromotor Components

Most of the friction forces resisting motion in a micromotor are concentrated near the rotor–hub interface where continuous physical contact occurs. Surface roughness usually has a strong influence on the friction characteristics on the micro/nanoscale. A catalog of roughness measurements on various components of a MEMS device does not exist in the literature. Using an AFM, measurements on various component surfaces were made for the first time by *Sundararajan* and *Bhushan* [38.267]. Table 38.11 shows various surface roughness parameters obtained from $5 \times 5\,\mu m$ scans of the various component surfaces of several unlubricated micromotors using the AFM in tapping mode. A surface with a Gaussian height distribution should have a skewness of zero and kurtosis of three. Although the rotor and stator top surfaces exhibit comparable roughness parameters, the underside of the rotors exhibits lower RMS roughness and P–V distance values. More importantly, the rotor underside shows negative skewness and lower kurtosis than the topsides, both of which are conducive to high real area of contact and hence high friction [38.91, 92]. The rotor underside also exhibits a higher coefficient of microscale friction than the rotor topside and stator, as shown in Table 38.11. Figure 38.64 shows representative surface height maps of the various surfaces of a micromotor measured using the AFM in tapping mode. The rotor underside exhibits varying topography from the outer edge to the middle and inner edge. At the outer edges, the topography shows smaller circular asperities, similar to the topside. The middle and inner regions show deep pits with

Table 38.11 Surface roughness parameters and microscale coefficient of friction for various micromotor component surfaces measured using an AFM. Mean and $\pm 1\sigma$ values are given

	RMS roughness[a] (nm)	Peak-to-valley distance[a] (nm)	Skewness[a], *Sk*	Kurtosis[a], *K*	Coefficient of microscale friction[b], μ
Rotor topside	21±0.6	225±23	1.4±0.30	6.1±1.7	0.07±0.02
Rotor underside	14±2.4	80±11	−1.0±0.22	3.5±0.50	0.11±0.03
Stator topside	19±1	246±21	1.4±0.50	6.6±1.5	0.08±0.01

[a] Measured from a tapping mode AFM scan of size 5 μm × 5 μm using a standard Si tip scanning at 5 μm/s in a direction orthogonal to the long axis of the cantilever.
[b] Measured using an AFM in contact mode at 5 μm × 5 μm scan size using a standard Si_3N_4 tip scanning at 10 μm/s in a direction parallel to the long axis of the cantilever

fine edges that may have been created by the etchants used for etching of the sacrificial layer. It is known that etching can affect the roughness of surfaces in surface micromachining. The residence time of the etchant near the inner region is high, responsible for larger pits. Figure 38.65 shows roughness of the surface directly beneath the rotors (the base polysilicon layer). There appears to be a difference in the roughness between the portion of this surface that was initially underneath the rotor (region B) during fabrication and the portion that was away from the rotor and hence always exposed (region A). The former region shows lower roughness than the latter region. This suggests that the surfaces at the rotor–hub interface that come into contact at the end of the fabrication process exhibit large real areas of contact that result in high friction.

38.8.2 Adhesion Measurements of Microstructures

Surface force apparatuses (SFA) and AFMs are used to measure adhesion on micro- to nanoscales between two surfaces. In the SFA, adhesion of liquid films sandwiched between two curved and smooth surfaces is measured. In an AFM, as discussed earlier, adhesion between a sharp tip and the surface of interest is measured. The propensity of adhesion between two surfaces can be evaluated by studying the tendency of microstructures with well-defined contact areas covering a wide spectrum of suspension compliances to stick to the underlying substrate. The test structures that have been used include the cantilever beam array (CBA) technique with different lengths [38.268–271] and stand-off multiple dimples mounted on microstructures with a range of compliances, standing above a substrate [38.272]. The more commonly used CBA technique uses an array of micromachined polysilicon beams (for Si MEMS applications) in the mesoscopic length scale that are anchored to the substrate at one

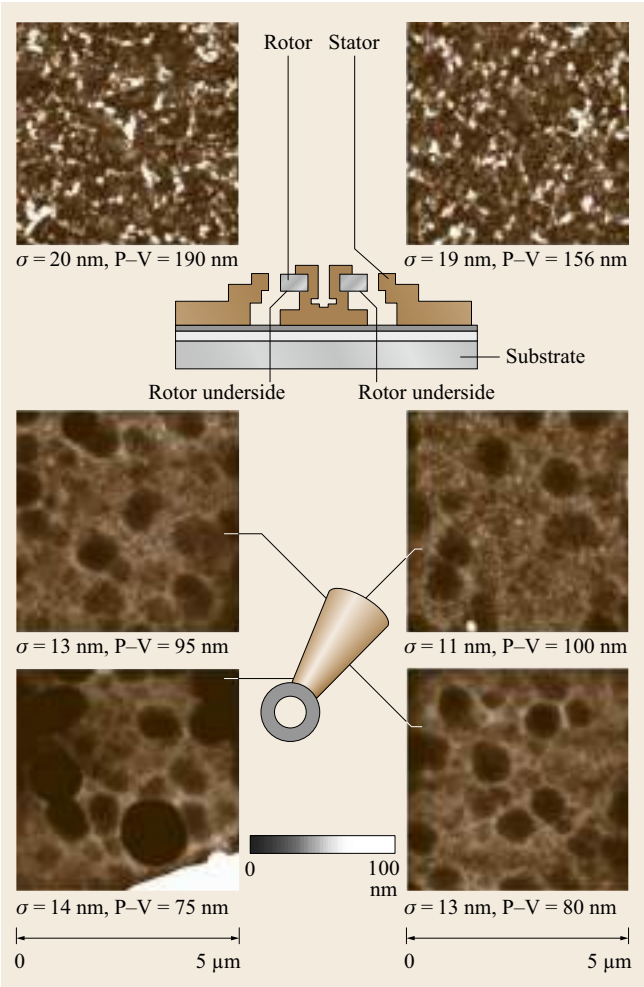

Fig. 38.64 Representative AFM surface height images obtained in tapping mode (5 μm × 5 μm scan size) of various component surfaces of a micromotor. RMS roughness and P–V values of the surfaces are given. The underside of the rotor exhibits drastically different topography from the topside (after [38.267])

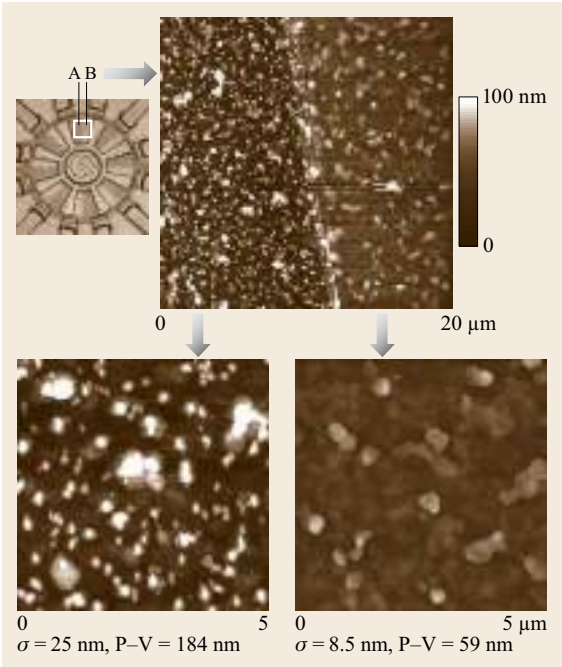

Fig. 38.65 Surface height images of polysilicon regions directly below the rotor. Region A is away from the rotor while region B was initially covered by the rotor prior to the release etch of the rotor. During this step, slight movement of the rotor caused region B to be exposed (after [38.267])

end and with different lengths parallel to the surface. CBA relies on peeling and detachment of cantilever beams. Change in free energy or reversible work done to separate unit areas of two surfaces from contact is called work of adhesion. To measure the work of adhesion, electrostatic actuation is used to bring all beams into contact with the substrate; Fig. 38.66 [38.268, 270]. Once the actuation force is removed, the beams begin to peel themselves off the substrate, which can be observed with an optical interference microscope (e.g., Wyko surface profiler). For beams shorter than a characteristic length, the so-called detachment length, their stiffness is sufficient to free them completely from the substrate underneath. Beams larger than the detachment length remain adhered. The beams at the transition region start to detach and remain attached to the substrate just at the tips. For this case, by equating the elastic energy stored within the beam and the beam–substrate interfacial energy, the work of adhesion, W_{ad}, can be calculated by the following equation [38.268]

$$W_{ad} = \frac{3Ed^2t^3}{8\ell_d^4}\,, \tag{38.1}$$

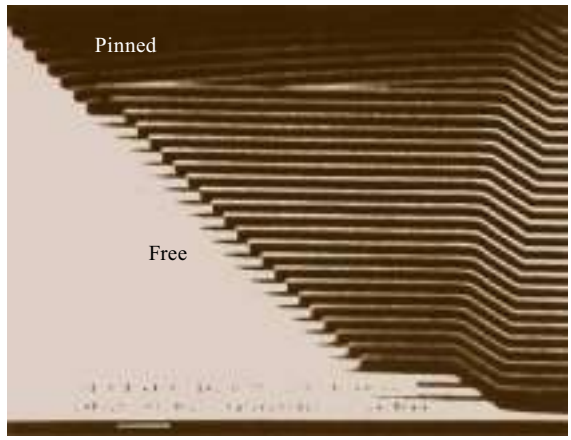

Fig. 38.66 SEM micrograph of micromachined array of polysilicon cantilever beams of increasing length. The micrograph shows the onset of pinning for beams longer than 34 μm (after [38.268])

where E is the Young's modulus of the beam, d is the spacing between the undeflected beam and the substrate, t is the beam thickness, and ℓ_d is the detachment length. The technique has been used to screen methods for adhesion reduction in polysilicon microstructures.

38.8.3 Microtriboapparatus for Adhesion, Friction, and Wear of Microcomponents

To measure adhesion, friction, and wear between two microcomponents, a microtriboapparatus has been used. Figure 38.67 shows a schematic of a microtriboapparatus capable of using MEMS components for tests [38.273]. In this apparatus, an upper specimen, mounted on a soft cantilever beam, comes in contact with a lower specimen mounted on a lower specimen holder. The apparatus consists of two piezoelectric bodies (x- and z-piezoelectric bodies) and four fiber-optic sensors (x- and z-displacement sensors, and x- and z-force sensors). For adhesion and friction studies, the z-piezoelectric body is used to bring the upper specimen and lower specimen into contact, and the x-piezoelectric body is used to apply a relative motion in the lateral direction. The x- and z-displacement sensors are used to measure the lateral position of the lower specimen and vertical position of the upper specimen respectively. By monitoring the deflection of the cantilever, the x- and z-force sensors are used to measure friction force and normal load/adhesive force between the two specimens respectively.

As most MEMS/NEMS devices are fabricated from silicon, study of silicon-on-silicon contacts is important. This contact was simulated by a flat single-crystal

Si(100) wafer (phosphorus-doped) specimen sliding against a single-crystal Si(100) ball (1 mm in diameter, 5×10^{17} atoms/cm^3 boron doped) mounted on a stainless steel cantilever [38.273, 274]. Both of them have a native oxide layer on their surfaces. With an objective to reduce adhesion and friction and humidity effects, the other materials studied were 10 nm-thick DLC deposited by filtered cathodic arc deposition on Si(100), 2.3 nm-thick chemically bonded PFPE (Z-DOL, BW) on Si(100), and hexadecane thiol (HDT) monolayer on evaporated Au(111) film to investigate their anti-adhesion performance. For completeness, other approaches to reduce liquid-mediated adhesion include the formation of dimples on the contact surfaces to reduce contact area [38.13, 87, 88, 91, 92, 173, 270] and bioinspired superhydrophobic surfaces [38.275].

It is well known that in computer rigid disk drives, the adhesive force increases rapidly with an increase in rest time between a magnetic head and a magnetic disk [38.32]. Considering that adhesion and friction are the major issues that lead to the failure of MEMS/NEMS devices, the rest time effect on the microscale for Si(100), DLC, PFPE, and HDT was studied, and the results are summarized in Fig. 38.68a. It was found that the adhesive force of Si(100) logarithmically increases with the rest time to a certain equilibrium time ($t = 1000$ s), after which it remains constant. Figure 38.68a also shows that the adhesive force of DLC, PFPE, and HDT does not change with rest time. Single-asperity contact modeling of the dependence of meniscus force on the rest time has been carried out by *Chilamakuri* and *Bhushan* [38.276], and the modeling results (Fig. 38.68b) verify experimental observations. Due to the presence of a thin film of water adsorbed on Si(100), a meniscus forms around the contacting asperities and grows with time until equilibrium occurs, which causes the rest time effect on its adhesive force. The adhesive forces of DLC, PFPE, and HDT do not change with rest time, which suggests that the water meniscus is not present on their surfaces.

The measured adhesive forces of Si(100), DLC, PFPE, and HDT at rest time of 1 s are summarized in Fig. 38.69. It shows that the presence of solid films of DLC, PFPE, and HDT greatly reduced the adhesive force of Si(100), whereas HDT film had the lowest adhesive force. It is well known that the native oxide layer (SiO_2) on the top of a Si(100) wafer exhibits hydrophilic properties, and water molecules, produced by capillary condensation of water vapor from the environment, can easily be adsorbed on this surface. The condensed water will form a meniscus as the upper specimen approaches the lower specimen surface. The meniscus force is a major contributor to the adhesive force. In the case of DLC, PFPE, and HDT, the films

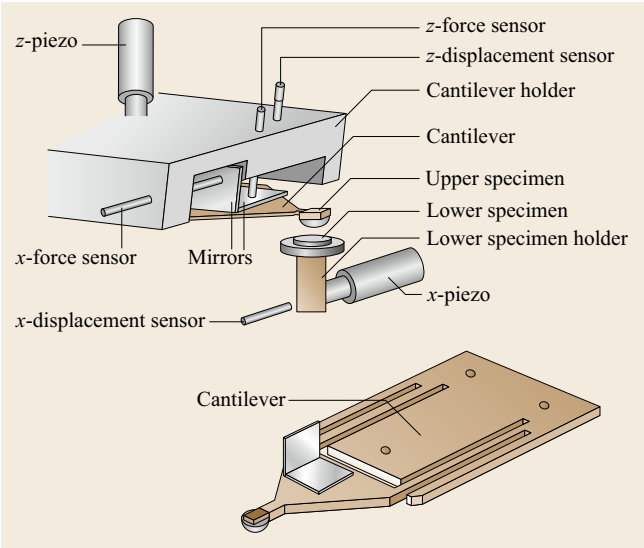

Fig. 38.67 Schematic of the microtriboapparatus including specially designed cantilever (with two perpendicular mirrors attached on the end), lower specimen holder, two piezoelectric bodies (x- and z-piezoelectric bodies), and four fiber-optic sensors (x- and z-displacement sensors and x- and z-force sensors) (after [38.273])

were found to be hydrophobic based on contact angle measurements, and the amount of condensed water vapor was low as compared to that on Si(100). It should be noted that the measured adhesive force is generally higher than that measured in AFM, because the larger radius of a Si(100) ball as compared to that of an AFM tip induces larger meniscus and van der Waals forces.

To investigate the velocity effect on friction, the friction force as a function of velocity was measured and is summarized in Fig. 38.70a. For Si(100), the friction force initially decreases with increasing velocity until equilibrium occurred. Figure 38.70a also shows that the velocity had almost no effect on the friction properties of DLC, PFPE, and HDT. This implies that the friction mechanisms of DLC, PFPE, and HDT do not change with the variation of velocity. For Si(100), at high velocity, the meniscus is broken and does not have enough time to rebuild. In addition, it is also believed that tribochemical reaction plays an important role. The high velocity leads to tribochemical reactions of Si(100) (which has native oxide SiO_2) with water molecules to form a $Si(OH)_4$ film. This film is removed and continuously replenished during sliding. The $Si(OH)_4$ layer at the sliding surface is known to be of low shear strength. The breaking of the water meniscus and the formation of a $Si(OH)_4$ layer results in a decrease in friction force of Si(100). For DLC, PFPE, and HDT, their surfaces exhibit hydrophobic properties, and only can adsorb a few water molecules

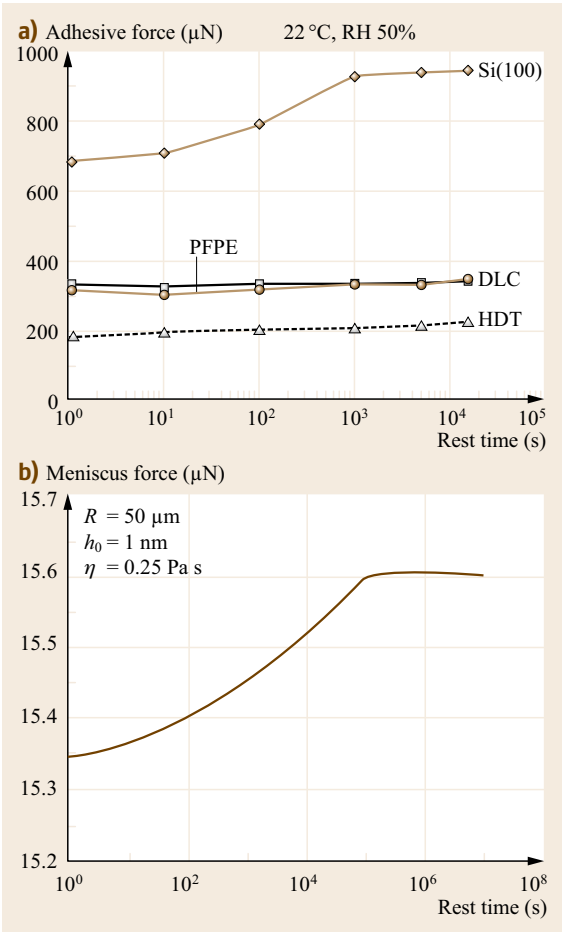

Fig. 38.68 **(a)** The influence of rest time on the adhesive force of Si(100), DLC, chemically bonded PFPE, and HDT, and **(b)** single-asperity contact modeling results of the rest time effect on the meniscus force for an asperity of radius R in contact with a flat surface with a water film of thickness of h_0 and absolute viscosity of η_0 (after [38.276])

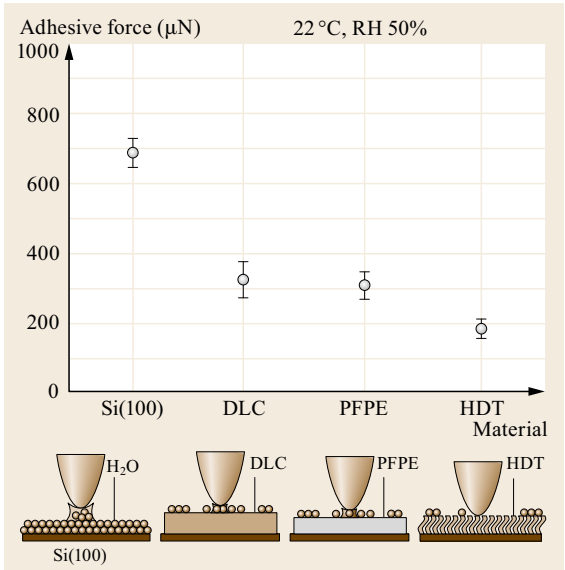

Fig. 38.69 Adhesive forces of Si(100), DLC, chemically bonded PFPE, and HDT at ambient conditions, and a schematic showing the relative size of water meniscus on different specimens

in ambient conditions. The above-mentioned meniscus breaking and tribochemical reaction mechanisms do not exist for these films. Therefore, their friction force does not change with velocity.

The influence of relative humidity was studied in an environmentally controlled chamber. The adhesive force and friction force were measured by making measurements at increasing relative humidity, and the results are summarized in Fig. 38.70b. It shows that for Si(100), the adhesive force increased with relative humidity, but the adhesive force of DLC and PFPE only showed a slight increase when humidity was higher than 45%, while the adhesive force of HDT did not change with humidity. Figure 38.70b also shows that for Si(100), the friction force increased with an increase in relative humidity up to 45%, and then it shows a slight decrease with a further increase in the relative humidity. For PFPE, there was an increase in the friction force when humidity was higher than 45%. In the whole testing range, relative humidity did not have any apparent influence on the friction properties of DLC and HDT. In the case of Si(100), the initial increase of relative humidity up to 45% caused more adsorbed water molecules, and formed a bigger water meniscus, which led to an increase of friction force. But at very high humidity of 65%, large quantities of adsorbed water can form a continuous water layer that separates the tip and sample surfaces, and acts as a kind of lubricant, which causes a decrease in the friction force. For PFPE, dewetting of the lubricant film at humidities higher than 45% resulted in an increase in adhesive and friction forces. For DLC and HDT, their surfaces show hydrophobic properties, and increasing relative humidity did not play much of a role in their friction force.

The influence of temperature was studied using a heated stage. The adhesive force and friction force were measured by making measurements at increasing temperatures from 22 to 125 °C. The results are presented in Fig. 38.70c. It shows that once the temperature was higher than 50 °C, increasing temperature caused a significant decrease of adhesive and friction forces of Si(100) and a slight decrease in the case of DLC and PFPE. But the adhesion and friction forces of HDT did not show any apparent change with test

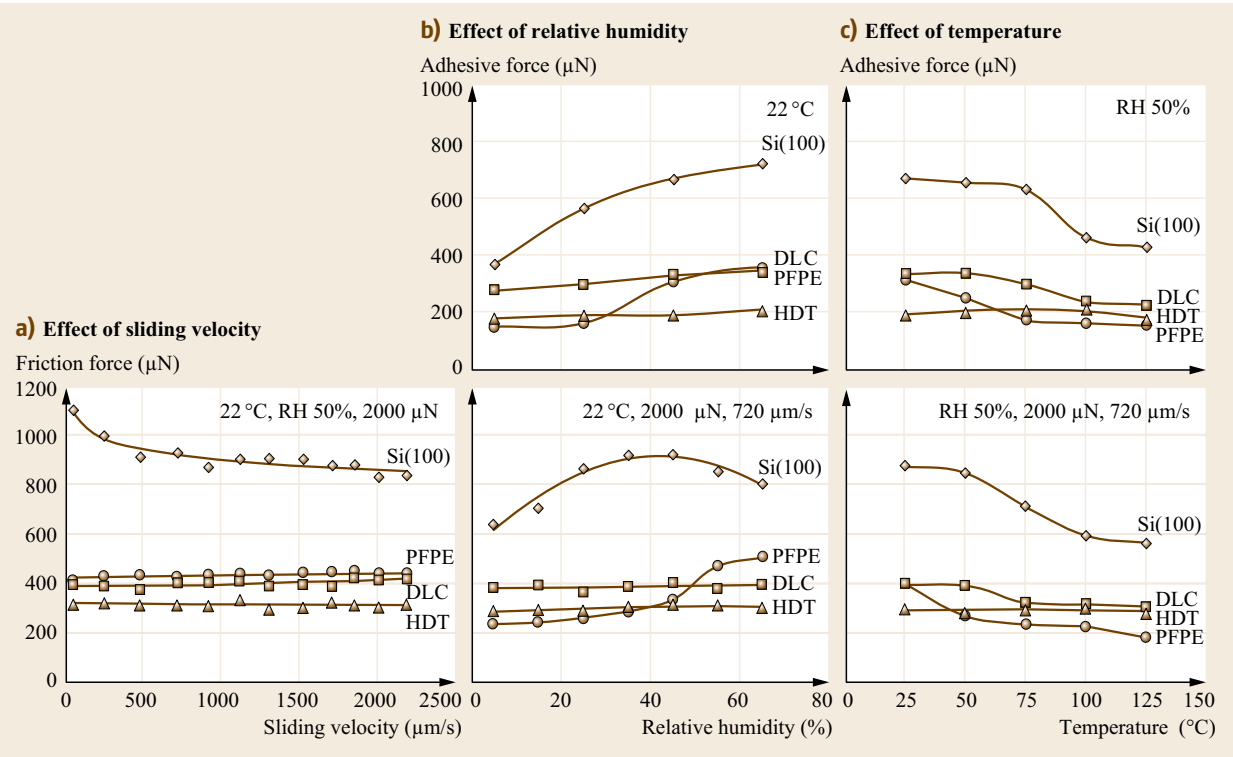

Fig. 38.70a–c The influence of (a) sliding velocity on the friction forces, (b) relative humidity on the adhesive and friction forces, and (c) temperature on the adhesive and friction forces of Si(100), DLC, chemically bonded PFPE, and HDT

temperature. At high temperature, desorption of water and reduction of the surface tension of water led to the decrease of adhesive and friction forces of Si(100), DLC, and PFPE. However, in the case of HDT film, as only a few water molecules were adsorbed on the surface, the above-mentioned mechanisms did not play a big role. Therefore, the adhesive and friction forces of HDT did not show any apparent change with temperature. Figure 38.70 shows that in the whole velocity, relative humidity, and temperature test range, the adhesive force and friction force of DLC, PFPE, and HDT were always smaller than that of Si(100), whereas HDT had the smallest value.

To summarize, several methods can be used to reduce adhesion in microstructures. MEMS/NEMS surfaces can be coated with hydrophobic coatings such as PFPEs, SAMs, and passivated DLC coatings.

38.8.4 Static Friction Force (Stiction) Measurements in MEMS

In MEMS devices involving parts in relative motion to each other, such as micromotors, large friction forces become the limiting factor to the successful operation and reliability of the device. It is generally known that most micromotors cannot be rotated as manufactured and require some form of lubrication. Therefore, it is critical to determine the friction forces present in such MEMS devices. To measure in situ the static friction of a rotor-bearing interface in a micromotor, *Tai* and *Muller* [38.277] measured the starting torque (voltage) and pausing position for different starting positions under a constant-bias voltage. A friction-torque model was used to obtain the coefficient of static friction. To measure the in-situ kinetic friction of the turbine and gear structures, *Gabriel* et al. [38.278] used a laser-based measurement system to monitor the steady-state spins and decelerations. *Lim* et al. [38.279] designed and fabricated a polysilicon microstructure to measure in situ the static friction of various films. The microstructure consisted of a shuttle suspended above the underlying electrode by a folded beam suspension. A known normal force was applied, and lateral force was measured to obtain the coefficient of static friction. *Beerschwinger* et al. [38.280] developed a cantilever-deflection rig to measure friction of LIGA-processed micromotors (see also [38.281]) These techniques employ indirect methods to determine the friction forces or involve fabrication of complex structures.

A novel technique to measure the static friction force (stiction) encountered in surface micromachined polysilicon micromotors using an AFM was developed by *Sundararajan* and *Bhushan* [38.267]. Continuous physical contact occurs during rotor movement (rotation) in the micromotors between the rotor and lower hub flange. In addition, contact occurs at other locations between the rotor and the hub surfaces and between the rotor and the stator. Friction forces will be present at these contact regions during motor operation. Although the actual distribution of these forces is not known, they can be expected to be concentrated near the hub where there is continuous contact. If we therefore represent the static friction force of the micromotor as a single force F_s acting at point P_1 (as shown in Fig. 38.71a), then the magnitude of the frictional torque about the center of the motor (O) that must be overcome before rotor movement can be initiated is

$$T_s = F_s \ell_1 \,, \tag{38.2}$$

where ℓ_1 is the distance OP_1, which is assumed to be the average distance from the center at which the friction force F_s occurs. Now, consider an AFM tip moving against a rotor arm in a direction perpendicular to the long axis of the cantilever beam (the rotor arm edge closest to the tip is parallel to the long axis of the cantilever beam), as shown in Fig. 38.71a. When the tip encounters the rotor at point P_2, the tip will twist, generating a lateral force between the tip and the rotor (event A in Fig. 38.71b). This reaction force will generate a torque about the center of the motor. Since the tip is trying to move further in the direction shown, the tip will continue to twist to a maximum value at which the lateral force between the tip and the rotor becomes high enough such that the resultant torque T_f about the center of the motor equals the static friction torque T_s. At this point, the rotor will begin to rotate, and the twist of the cantilever decreases sharply (event B in Fig. 38.71b). The twist of the cantilever is measured in the AFM as a change in the lateral deflection signal (in volts), which is the underlying concept of friction force microscopy (FFM). The change in the lateral deflection signal corresponding to the above-mentioned events as the tip approaches the rotor is shown schematically in Fig. 38.71c. The value of the peak V_f is a measure of the force exerted on the rotor by the tip just before the static friction torque is matched and the rotor begins to rotate.

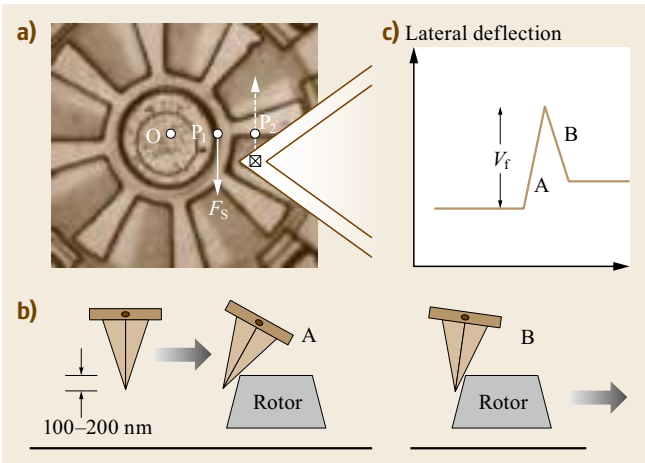

Fig. 38.71 (a) Schematic of the technique used to measure the force, F_s, required to initiate rotor movement using an AFM/FFM. **(b)** As the tip is pushed against the rotor, the lateral deflection experienced by the rotor due to the twisting of the tip prior to rotor movement is a measure of static friction force, F_s, of the rotors. **(c)** Schematic of lateral deflection expected from the above-mentioned experiment. The peak V_f is related to the state of the rotor (after [38.267])

Using this technique, the viability of PFPE lubricants for micromotors has been investigated, and the effect of humidity on the friction forces of unlubricated and lubricated devices was studied as well. Figure 38.72 shows static friction forces, normalized over the weight of the rotor, of unlubricated and lubricated micromotors as a function of rest time and relative humidity. Rest time here is defined as the time elapsed between the first experiment conducted on a given motor (solid symbol at time zero) and subsequent experiments (open symbols). Each open symbol data point is an average of six measurements. It can be seen that for the unlubricated motor and the motor lubricated with a bonded layer of Z-DOL(BW), the static friction force was highest for the first experiment, and then dropped to an almost constant level. In the case of the motor with an as-is mobile layer of Z-DOL, the values remained very high up to 10 days after lubrication. In all cases, there was negligible difference in the static friction force at 0 and 45% RH. At 70% RH, the unlubricated motor exhibited a substantial increase in the static friction force, while the motor with bonded Z-DOL showed no increase due to the hydrophobicity of the lubricant layer. The motor with an as-is mobile layer of the lubricant showed consistently high values of static friction force that varied little with humidity.

Figure 38.73 summarizes static friction force data for two motors, M1 and M2, along with schematics of the meniscus effects for the unlubricated and lubricated surfaces. Capillary condensation of water vapor from the environment resulted in the formation of meniscus bridges between the contacting and near-contacting asperities of two surfaces in close proximity to each other, as shown in Fig. 38.73. For unlubricated surfaces, more menisci were formed at higher humidity resulting in

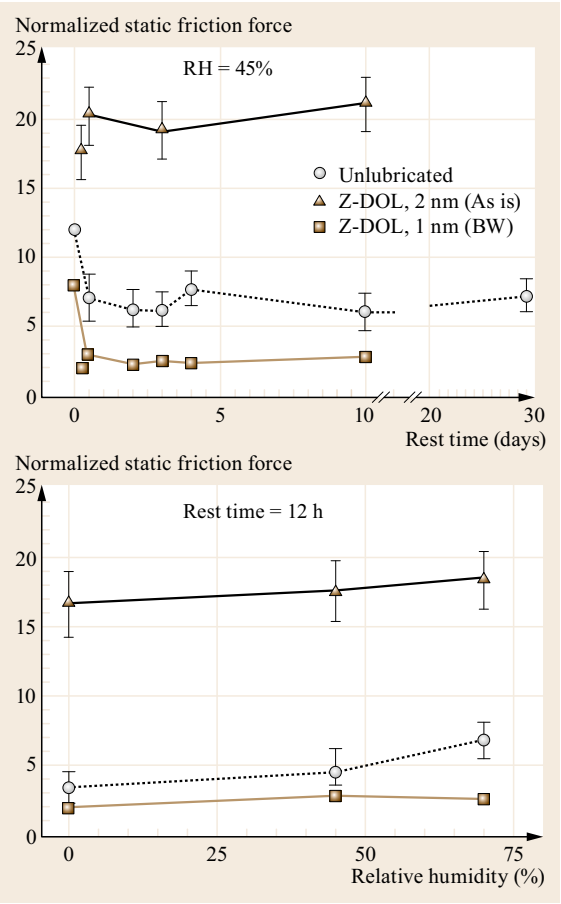

Fig. 38.72 Static friction force values of unlubricated motors and motors lubricated using PFPE lubricants, normalized over the rotor weight, as a function of rest time and relative humidity. Rest time is defined as the time elapsed between a given experiment and the first experiment in which motor movement was recorded (time 0). The motors were allowed to sit at a particular humidity for 12 hours prior to measurements (after [38.267])

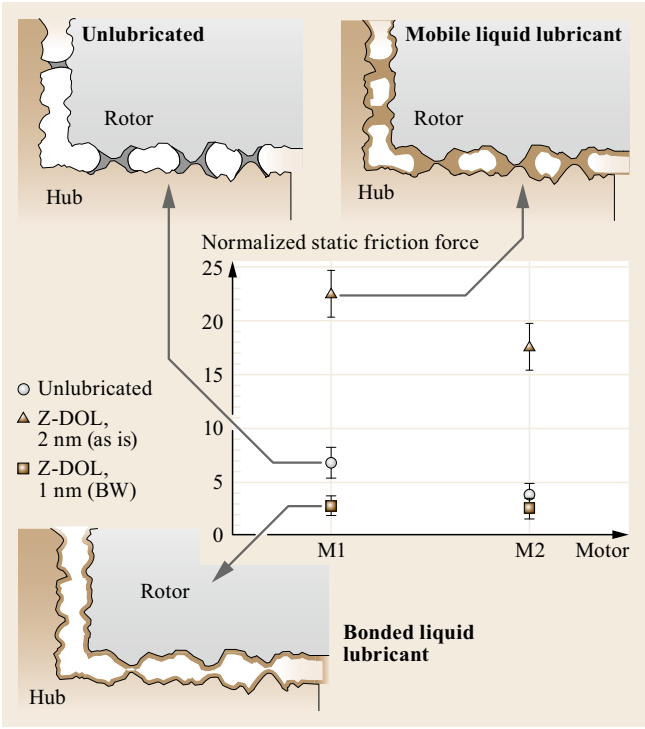

Fig. 38.73 Summary of effect of liquid and solid lubricants on static friction force of micromotors. Despite the hydrophobicity of the lubricant used (Z-DOL), a mobile liquid lubricant (Z-DOL as-is) leads to very high static friction force due to increased meniscus forces whereas a solid-like lubricant (bonded Z-DOL, BW) appears to provide some amount of reduction in static friction force

higher friction force between the surfaces. The formation of meniscus bridges is supported by the fact that the static friction force for unlubricated motors increases at high humidity (Fig. 38.73). Solid bridging may occur near the rotor–hub interface due to silica residues after the first etching process. In addition, the drying process after the final etch can result in liquid bridging formed by the drying liquid due to meniscus force at these areas [38.91, 92, 268, 269]. Therefore, the initial static friction force will be quite high, as evidenced by the solid data points in Fig. 38.73. Once the first movement of the rotor permanently breaks these solid and liquid bridges, the static friction force of the motors will drop (as seen in Fig. 38.73) to a value dictated predominantly by the adhesive energies of rotor and hub surfaces, the real area of contact between these surfaces and meniscus forces due to water vapor in the air. At that point, the effect of lubricant films can be observed. Lubrication with a mobile layer, even a thin one, results in very high static friction forces due to meniscus effects of the lubricant liquid itself at and near the contact regions. It should be noted that a motor submerged in a liquid lubricant would result in a fully flooded lubrication regime. In this case, there is no meniscus contribution, and only the viscous contribution to the friction forces would be relevant. However, submerging the device in a lubricant may not be a practical method. A solid-like hydrophobic lubricant layer (such as bonded Z-DOL) results in favorable friction characteristics for the motor. The hydrophobic nature of the lubricant inhibits meniscus formation between the contact surfaces and maintains low friction even at high humidity (Fig. 38.73). This suggests that solid-like hydrophobic lubricants are ideal for lubrication of MEMS, while mobile lubricants result in increased values of static friction force.

38.8.5 Mechanisms Associated with Observed Stiction Phenomena in Digital Micromirror Devices (DMDs) and Nanomechanical Characterization

DMDs are used in digital projection displays, as described earlier. The DMD has a layered structure, consisting of an aluminum alloy micromirror layer, yoke and hinge layer, and metal layer on a CMOS memory array [38.5, 26, 27]. A blown-up view of the DMD and the corresponding AFM surface height images are presented in Fig. 38.74 [38.117]. Single-layered aluminum alloy films are used for the construction of micromirrors. Sometimes these also are used for the construction of hinges, spring tips, and landing sites. The aluminum alloy films are overwhelmingly comprised of aluminum; trace elements (including Ti and Si) are present to suppress contact spiking and electromigration, which may occur if current densities become high during electrostatic operation. Multilayered sputtered SiO_2/TiN/Al alloy films are now generally used for the landing-site structure to minimize refraction throughout the visible region of the electromagnetic spectrum in order to increase the contrast ratio in projection display systems [38.282, 283]. These multilayered films generally also are used for hinges and spring tips. A low surface energy SAM is maintained on the surfaces of the DMD, which is packaged in a hermetic environment to minimize stiction during contact between the spring tip and the landing site. A SAM of perfluorinated n-alkanoic acid ($C_nF_{2n-1}O_2H$) (e.g., perfluorodecanoic acid or PFDA, $CF_3(CF_2)_8COOH$) applied by the vapor phase deposition process is used. A getter strip of PFDA is included inside the hermetically sealed enclosure containing the chip, which acts as a reservoir in order to maintain a PFDA vapor within the package.

In order to identify a stuck mirror and characterize its nanotribological properties, the chip was scanned using an AFM [38.117]. It was found that it is hard to tilt the stuck micromirror back to its normal position by adding a normal load at the rotatable corner of the micromirror; thus it is called a *hard* stuck micromirror. An example of a stuck micromirror is shown in Fig. 38.75a. Once the stuck micromirror was found, the region was repeatedly scanned at a large normal load, up to 300 nN. After several scans, the stuck micromirror was removed. Once the stuck micromirror was removed, the surrounding micromirrors also could be removed by continuous scanning under a large normal load (Fig. 38.75a bottom row). The adhesive force of the landing site underneath the stuck micromirror and the normal micromirror are presented in Fig. 38.75b. It clearly indicates that the landing site underneath the stuck micromirror had much larger adhesion. 1 μm × 1 μm view of landing sites under stuck and normal micromirrors are also shown in Fig. 38.75b. The landing site under the stuck micromirror had an apparent U-shaped wear mark, which was surrounded by a smeared area.

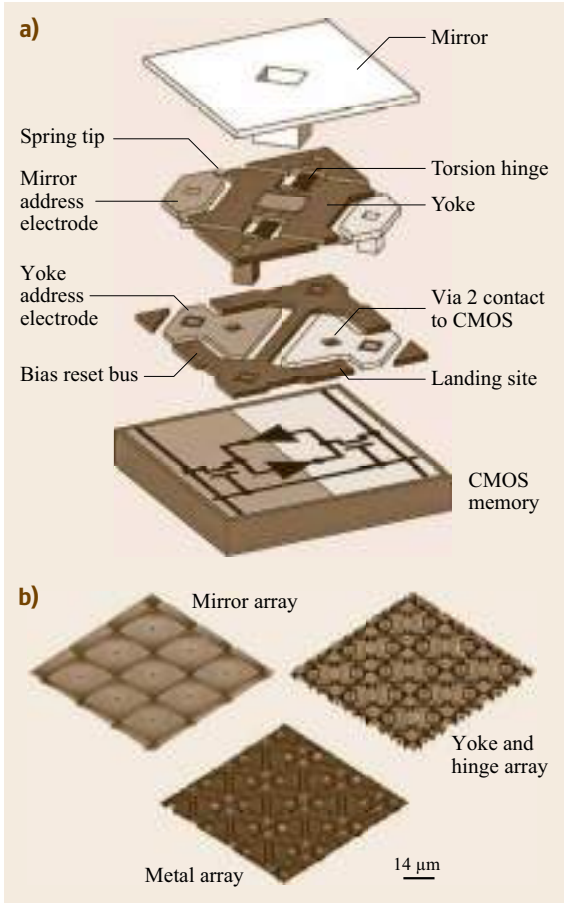

Fig. 38.74 (a) Exploded view of a DMD pixel and **(b)** AFM surface height images of various arrays. The DMD layers were removed by an ultrasonic method (after [38.117])

Liu and *Bhushan* [38.117] calculated contact stresses to examine whether the stresses were high enough to cause wear at the spring tip landing site interface. The calculated contact stress value was about 33 MPa, which is substantially lower than the hardness. Therefore, not much plastic deformation and consequent wear was expected. A wear mark was only found on a very few landing sites on the DMD, which means that the SAM coating generally can endure such high contact stresses. Based on data reported in the literature, coverage for vapor-deposited SAMs is expected to be about 97%. The bond strength of the molecules

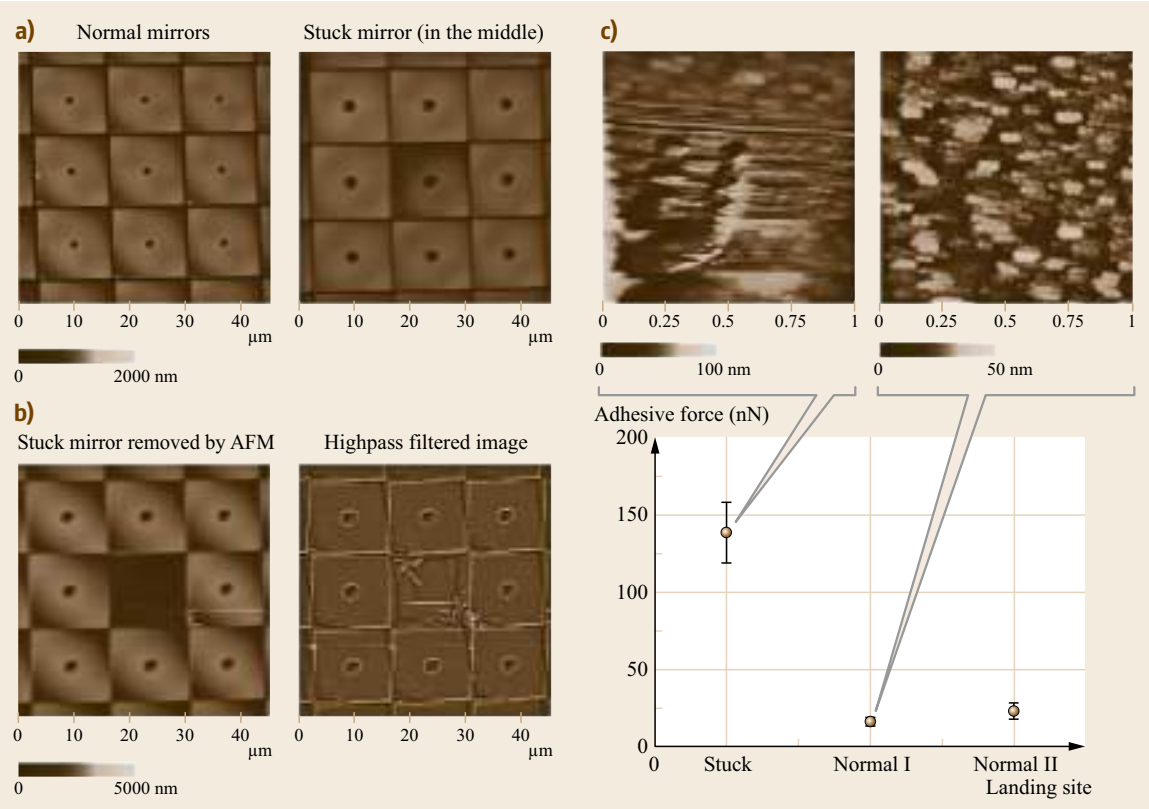

Fig. 38.75 **(a)** shows AFM surface height images of a stuck micromirror surrounded by eight normal micromirrors. **(b)** *Left image* shows the stuck micromirror that was removed by an AFM tip after repeated scanning at high normal load. The *right image* row presents the high-pass filtered image showing that the residual hinge that sits underneath the removed micromirror is clearly observed. **(c)** AFM surface height images and adhesive forces of the landing sites underneath the two normal micromirrors and the stuck micromirror (after [38.117])

close to the boundary of the uncovered sites is expected to be weak. Thus, the uncovered sites and the adjacent molecules are referred to as defects in the SAM coating. Occasionally, if contact occurs at the defect sites, the large cyclic stress may be close to the critical load, and lead to the initial delamination of the SAM coating at the interface. Continuous contact leads to the formation of a high surface-energy surface by exposure of the fresh substrate and formation of SAM fragments. This eventually leads to an increase in stiction by the formation of large menisci. Once this happens, the stress at the contact area is increased, which would accelerate the wear. Based on this hypothesis, suggested mechanisms for the wear and stiction of the landing site are summarized in Fig. 38.76. Wear initiates at the defect sites and consequently high stiction can result in high wear. Improving the coverage and wear resistance of SAM coatings could enhance the yield of DMD.

In some cases, the micromirrors are not fully stuck, and can be moved by applying a load at the rotatable corner of the micromirror with a discontinuous motion, thus called *soft* stiction. Soft stuck micromirrors studied by *Liu* and *Bhushan* [38.118] were identified in quality inspection. These micromirrors encountered slow transition from one end to the other end $(+1/-1)$. Figure 38.77 shows the AFM surface height images of a location showing a stuck mirror (S) and surrounding normal micromirrors N_i ($i = 1, 2$, and 3). Surprisingly, the images of the stuck and normal micromirror array are almost the same. On the micromirrors of interest, a tilting test was performed at the corner of the micromirrors; the rotatable direction of the microarray is indicated by an arrow bar in Fig. 38.77. The load displacement curve for the stuck micromirror is presented in Fig. 38.78. The curve is not smooth and appears serrated. It clearly indicated that, although the S micromirror can be rotated, it rotates with hesitation. In regimes 1 and 2, as marked in Fig. 38.78, the slopes are much higher. In order to understand the occurrence mechanisms of stiction, stiction of the landing sites

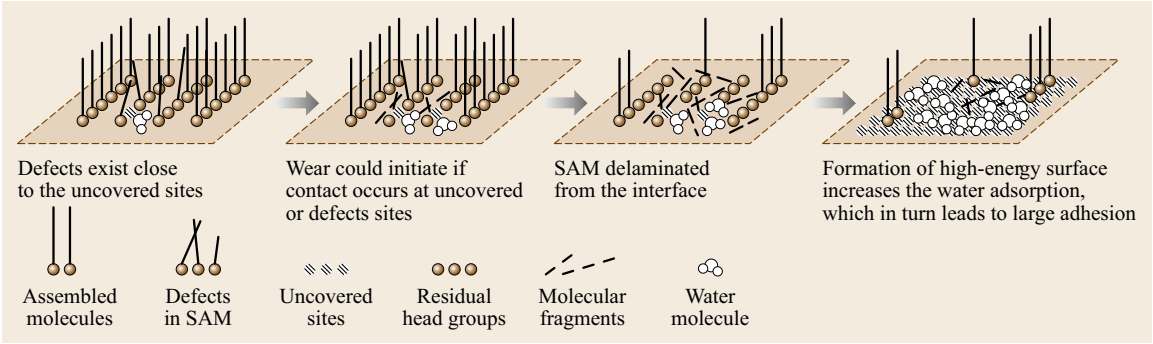

Fig. 38.76 Suggested mechanisms for wear and stiction (after [38.117])

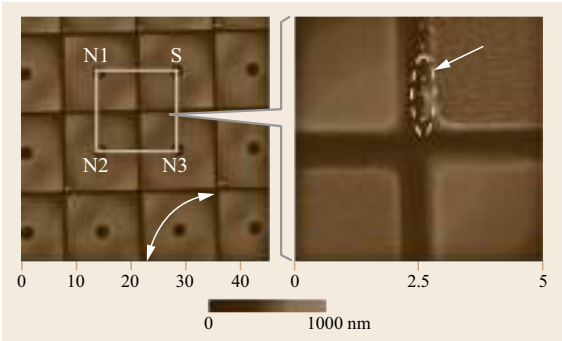

Fig. 38.77 AFM surface height images of normal micromirrors and a soft-stuck micromirror. The soft-stuck micromirror was labeled as S, and the normal micromirrors studied are labeled as N1, N2, and N3 (after [38.118])

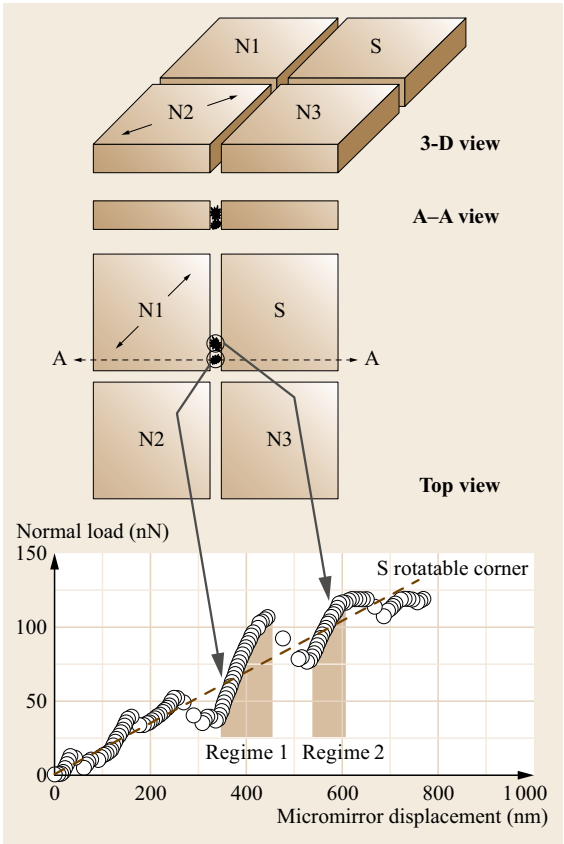

Fig. 38.78 Load–displacement curve obtained on the rotatable corner of S micromirror and schematic to illustrate the suggested mechanism for soft stiction occurrence

of normal and stuck mirrors were measured. Unlike a hard-stuck mirror, adhesive forces of soft stuck and normal mirrors were comparable, which suggests that the SAM coating is intact with the soft-stuck mirror. It was found that a high normal load (about 900 nN) and on the order of couple of hundred scans were required to remove the soft-stuck micromirrors by an AFM. For comparison, only about 300 nN and about ten scans were required to remove the hard-stuck mirror. After careful examination of the AFM images of the micromirror sidewalls in Fig. 38.77 (bottom left), it is noted that there are contaminant particles attached to the sidewalls of the S mirror. Therefore, it is believed that during the tilting test for the S micromirror (see schematic in Fig. 38.78), a sharper slope regime will occur in the displacement curve. Extra force is required to overcome the resistance that is induced by the sidewall contamination particles. This is believed to be the reason for the slow transition of the micromirror during quality inspection.

Finally, nanomechanical characterization of various layers used in the construction of landing sites, hinge, and micromirror materials have been measured by *Wei* et al. [38.282, 283]. Bending and fatigue studies of the hinge have been carried out by *Liu* and *Bhushan* [38.284] and *Bhushan* and *Liu* [38.285] to measure stiffness and fatigue properties. For these studies, the micromirror was removed. During removal,

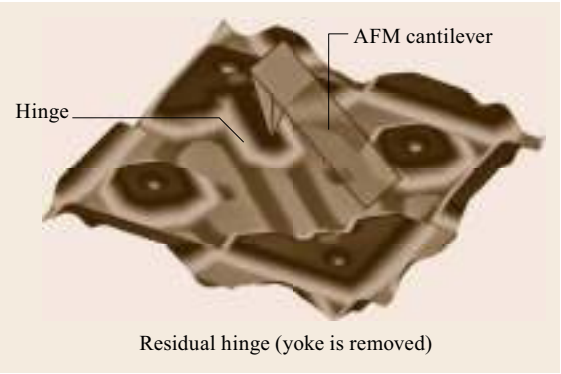

Fig. 38.79 AFM surface height image of the residual hinge and schematic diagram of relative position of the hinge and AFM tip during the nanoscale bending and fatigue tests. The tip is located at the free end of the hinge (after [38.284]) ◄

the micromirror/yoke structure was removed simultaneously, leaving the hinge mounted on one end of the array; see Fig. 38.79. The stiffness of the Al hinge was reported to be comparable to the stiffness of bulk Al. The Al hinge exhibited higher modulus than the SiO_2 hinge. The fatigue properties depended upon the preparation of the hinge for testing.

38.9 Conclusion

The field of MEMS/NEMS and bioMEMS/bioNEMS has expanded considerably since its inception in the late 1980s. Large surface-to-volume ratios of the devices results in very high surface forces, such as adhesion and friction/stiction, which seriously undermine the performance and reliability of the devices. There is a need for a fundamental understanding of adhesion, friction, stiction, wear, and lubrication, and the role of contamination and environment, all on the nanoscale. Most mechanical properties are known to be scale dependent. Therefore, the properties of nanostructures need to be measured. Using AFM-based techniques, researchers have conducted nanotribological and nanomechanical studies of materials and devices. In addition, component-level testing has also been carried out to aid in better understanding of the observed nanotribological phenomena in MEMS/NEMS.

Macroscale and microscale tribological studies of silicon and polysilicon films have been performed. The effect of doping and oxide films and environment on the tribological properties of these popular MEMS/NEMS materials have also been studied. SiC film is found to be a good candidate material for use in high-temperature MEMS/NEMS devices. Perfluoroalkyl SAMs and bonded perfluoropolyether lubricants are well suited for lubrication of micro/nanodevices under a range of environmental conditions. DLC coatings can also be used for low friction and wear.

Nano-objects exhibit enhanced mechanical, electrical, magnetic, and chemical properties. Many nano-objects also exhibit low friction and wear properties due to their size, shape, and unique properties. Nano-objects of interest include Au nanoparticles, MoS_2 and WS_2 MWNTs, and CNHs. Nanoscale friction and wear properties have been investigated in single nano-object contact and multiple nano-object contact modes using an AFM. All nano-objects exhibit low friction and wear. Lower friction forces occur in submerged-in-liquid environments, as compared to dry environments.

For bioMEMS/bioNEMS, nanoscale adhesion, friction, and wear of a number of protein layers on polystyrene surfaces have been investigated. Adhesion between biological molecular layers and the substrate, and friction and wear of biological layers can be important. Adhesion of biomolecules on Si substrate surfaces for various bioMEMS applications can be improved by nanopatterning and the chemical linker method. Friction and wear mechanisms of protein layers have been studied. Trajectory of submicron particles in the bloodstream used for therapeutic and diagnostics purposes needs to be optimized in order for them to bond to the target sites on endothelium walls. An analytical model has been developed for this purpose.

Surface roughness measurements of micromachined polysilicon surfaces have been made using an AFM. The roughness distribution on surfaces is strongly dependent upon the fabrication process. Adhesion and friction of microstructures can be measured using a novel microtriboapparatus. Adhesion and friction measurements on silicon-on-silicon confirm AFM measurements that show hexadecane thiol and bonded perfluoropolyether films exhibit superior adhesion and friction properties. Static friction force measurements of micromotors have been performed using an AFM. The forces are found to vary considerably with humidity. A bonded layer of perfluoropolyether lubricant is found to satisfactorily reduce the friction forces in the micromotor. Tribological failure modes of digital

micromirror devices are either *hard* stiction or *soft* stiction. In hard stiction, the tip on the yoke remains stuck with the landing site underneath. The mechanism responsible for the hard stiction is the localized damage to the SAM on the landing site. In soft stiction, the mirror-yoke assembly rotates with hesitation. The mechanism responsible for the soft stiction is contaminant particles present at the mirror sidewalls.

AFM/FFM-based techniques show the capability to study and evaluate nanotribology and nanomechanics related to MEMS/NEMS and bioMEMS/bioNEMS devices.

38.A Appendix: Micro/Nanofabrication Techniques

Micro/nanofabrication techniques include top-down methods, in which one builds down from the large to the small, and bottom-up methods, in which one builds up from the small to the large.

38.A.1 Top-Down

The top-down fabrication methods used in the construction of MEMS/NEMS include lithographic and nonlithographic techniques to produce micro- and nanostructures. The lithographic techniques fall into three basic categories: bulk micromachining, surface micromachining, and LIGA (a German acronym for Lithographie Galvanoformung Abformung), which translates to lithography, electroplating, and molding. The first two approaches, bulk and surface micromachining, mostly use planar photolithographic fabrication processes developed for semiconductor devices to produce two-dimensional (2-D) structures [38.7, 13, 286–289]. The various steps involved in these two fabrication processes are shown schematically in Fig. 38.80. Bulk micromachining employs anisotropic etching to remove sections through the thickness of a single-crystal silicon wafer, typically 250–500 μm thick. Bulk micromachining is a proven high-volume production process and is routinely used to fabricate microstructures such as accelerometers, pressure sensors, and flow sensors. In surface micromachining, structural and sacrificial films are alternatively deposited, patterned, and etched to produce a freestanding structure. These films are typically made of low-pressure chemical vapor deposition (LPCVD) polysilicon film with 2–20 μm thickness. Surface micromachining is used to produce sensors, actuators, micromirror arrays, motors, gears, and grippers. The resolution in photolithography is dependent upon the wavelength of light. A commonly used light source is an argon fluoride excimer laser with 193 nm wavelength (ultraviolet or UV) used in patterning 90 nm lines and spaces. Deep-UV wavelengths, x-ray lithography, electron beam (e-beam) lithography, focused ion beam lithography, maskless lithography, liquid-immersion lithography, and STM writing by removing material atom by atom are some of the recent developments for sub-100 nm patterning.

The fabrication of nanostructures such as nanochannels with sub-10 nm resolution can be accomplished through several routes: e-beam lithography and sacrificial layer lithography (SLL). The process for e-beam

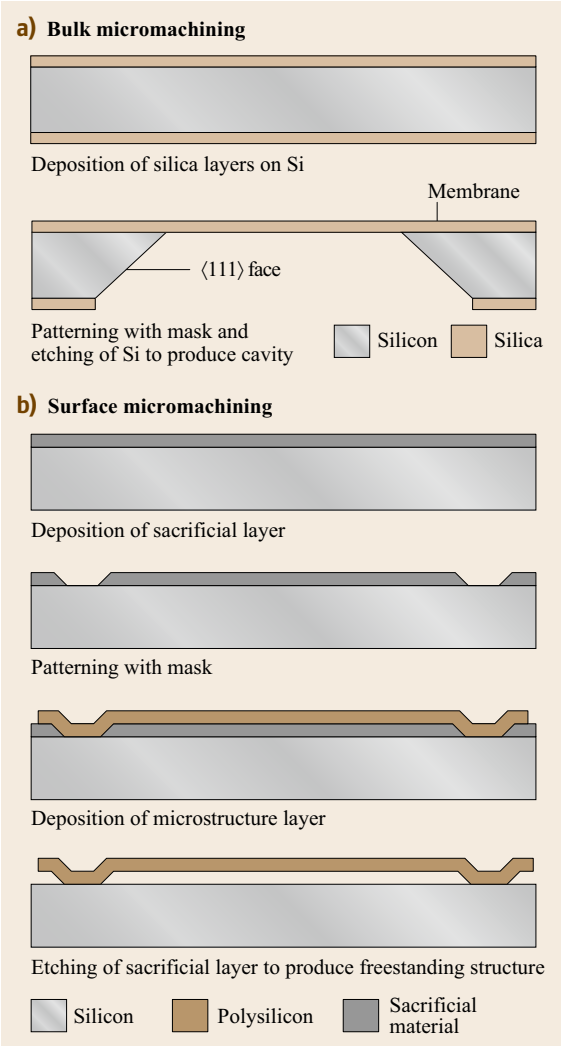

Fig. 38.80a,b Schematic of process steps involved in (a) bulk micromachining and (b) surface micromachining fabrication of MEMS

lithography is a finely focused electron beam that is exposed over a resist surface, and the exposure duration and location is controlled with the use of a computer [38.290, 291]. When the resist is exposed to the electron beam, the electrons either break or join the molecules in the resist, so the local characteristics are changed in such a way that further processes can either remove the exposed part (positive resist) or remove the unexposed part (negative resist). The resist material determines if the molecules will either break or join together; thus, determining if a positive or negative image is produced. E-beam lithography can be used either to create photolithographic masks for replication or to create the devices directly. The masks that are created can be used for either optical or x-ray lithography. One limitation of e-beam lithography is that throughput is drastically reduced since a single electron beam is used to create the entire exposure pattern on the resist. While this technique is slower than conventional lithographic techniques, it is ideal for prototype fabrication because no masks are required.

In SLL process, the use of a sacrificial layer allows the direct control of nanochannel dimensions so long as there exists a method for removing the sacrificial layer with absolute selectivity to the structural layers. A materials system with such selectivity is the silicon/silicon oxide system used widely in the microfabrication of MEMS devices. The use of sidewall deposition of the sacrificial layer and subsequent etching allows for the fabrication of high-density nanochannels for biomedical applications. It is based on surface micromachining [38.83]. Figure 38.81 shows a schematic of the process steps in SLL based on *Hansford* et al.'s [38.83] work on fabrication of polysilicon membranes with nanochannels. As with all the membrane protocols, the first step in the fabrication is the etching of the support ridge structure into the bulk silicon substrate. A low-stress silicon nitride (LSN or simply nitride), which functions as an etch stop layer, is then deposited using LPCVD. The base structural polysilicon layer (base layer) is deposited on top of the etch stop layer. The plasma etching of holes in the base layer is what defines the shape of the pores. The buried nitride etch stop acts as an etch stop for the plasma etching of a polysilicon base layer. After the pore holes are etched through the base layer, the pore sacrificial thermal oxide layer is grown on the base layer. The basic requirement of the sacrificial layer is the ability to control the thickness with high precision across the entire wafer. Anchor points are defined in the sacrificial oxide layer to mechanically connect the base layer with the plug layer (necessary to maintain the pore spacing between layers). This is accomplished by using the same mask shifted from the pore holes. This produces anchors in one or two corners of each pore hole, which provides the desired connection between the structural layers while opening as much pore area as possible. After the anchor points are etched through the sacrificial oxide, the plug polysilicon layer is deposited (using LPCVD) to fill in the holes. To open the pores at the surface, the plug layer is planarized using chemical mechanical polishing (CMP) down to the base layer, leaving the final structure with the plug layer only in the pore hole openings. As the silicon wafer is ready for release, a protective nitride layer is deposited on the wafer (completely covering both sides of the wafer). The backside etch windows are etched in the protective layer, exposing the silicon wafer in the desired areas,

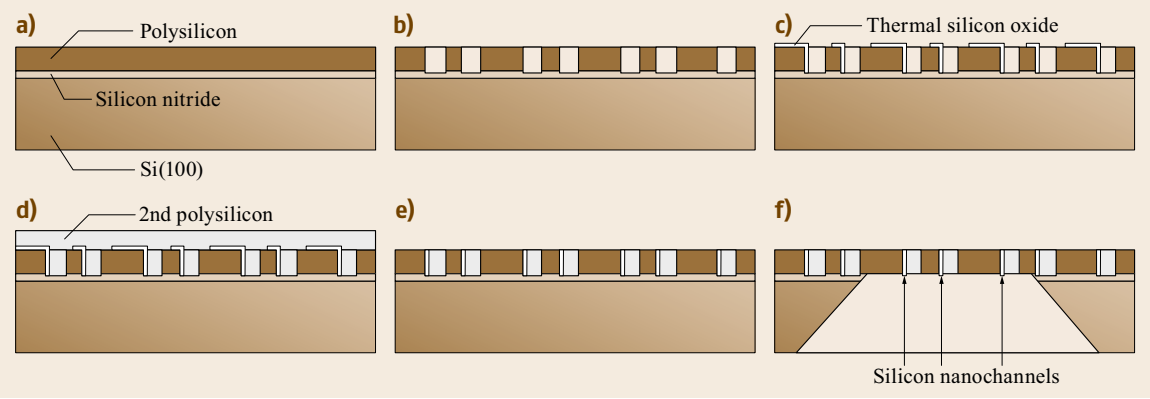

Fig. 38.81a–f Schematic of process steps involved in sacrificial layer lithography: **(a)** growth of silicon nitride layer (etch stop) and base polysilicon deposition, **(b)** hole definition in base, **(c)** growth of thin sacrificial oxide and patterning of anchor points, **(d)** deposition of plug polysilicon, **(e)** planarization of plug layer, and **(f)** deposition and patterning of protective nitride layer through etch, followed by etching of protective, sacrificial and etch layers and final release of the structure in HF (after [38.83])

and the wafer is placed in a KOH bath to etch. After the silicon wafer is completely removed up to the membrane (as evidenced by the smooth buried etch stop layer), the protective, sacrificial, and etch stop layers are removed by etching in concentrated HF. Etching of the sacrificial layer in polysilicon film defines nanochannels.

The LIGA process is based on the combined use of x-ray lithography, electroplating, and molding processes. X-rays produced by synchrotron radiation are used to prepare the mold. The steps involved in the LIGA process are shown schematically in Fig. 38.82. LIGA is used to produce high-aspect-ratio MEMS (HARMEMS) devices that are up to 1 mm in height and only a few microns in width or length [38.292]. The LIGA process yields very sturdy 3-D structures due to their increased thickness. One of the limitations of silicon microfabrication processes originally used for fabrication of MEMS devices is the lack of suitable materials that can be processed. With LIGA, a variety of nonsilicon materials such as metals, ceramics and polymers can be processed.

Nonlithographic micromachining processes, primarily in Europe and Japan, are also being used for fabrication of millimeter-scale devices using direct material microcutting or micromechanical machining (such as microturning, micromilling, and microdrilling) or removal by energy beams (such as microspark erosion, focused ion beam, laser ablation, and laser polymerization) [38.7, 293]. Hybrid technologies including LIGA and high-precision micromachining techniques have been used to produce miniaturized motors, gears, actuators, and connectors [38.98, 100, 101, 294]. These millimeter-scale devices may find more immediate applications.

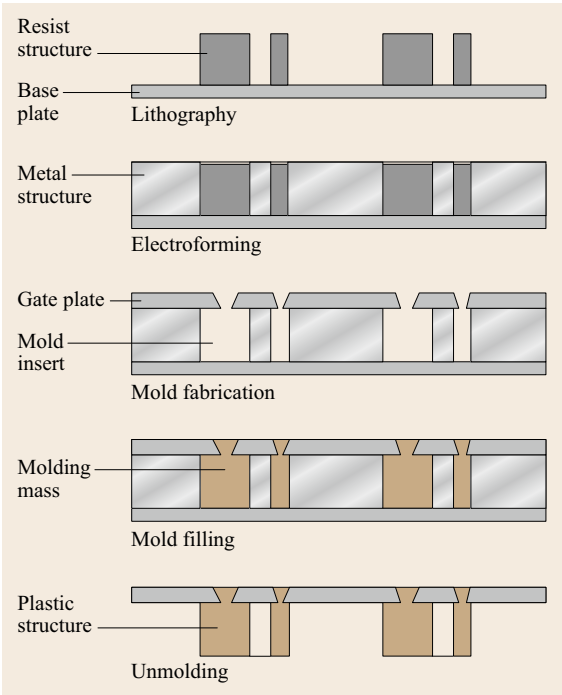

Fig. 38.82 Schematic of process steps involved in LIGA fabrication of MEMS

A micro/nanofabrication technique, so-called *soft lithography*, is a nonlithographic technique [38.63, 69, 295, 296] in which a master or mold is used to generate patterns, defined by the relief on its surface, on polymers by replica molding [38.297], hot embossing (nanoimprint lithography) [38.298], or by contact printing (known as microcontact printing or μCP) [38.299]. Soft lithography is faster, less expensive, and more suitable for most biological applications than glass or silicon micromachining. Polymers have established an important role in bioMEMS/bioNEMS because of their reduced cost. The use of polymers also offers a wide range of material properties to allow tailoring of biological interactions for improved biocompatibility. Polymer fabrication is believed to be about an order of magnitude cheaper than silicon fabrication.

Replica molding is the transfer of a topographic pattern by curing or solidifying a liquid precursor against the original patterned mold. The mold or stamp is generally made of a two-part polymer (elastomer and curing agent), such as poly(dimethylsiloxane) (PDMS) from a photolithographically generated photoresist master. Solvent-based embossing or imprinting uses a solvent to restructure a polymer film. Hot embossing, also called nanoimprint lithography, usually refers to the transfer of pattern from a micromachined quartz or metal master to a pliable plastic sheet. Heat and high pressure allow the plastic sheet to become imprinted. These sheets can then be bonded to various plastics such as polymethyl methacrylate (PMMA). Nanoimprint lithography can produce patterns on a surface having 10 nm resolution. Contact printing uses a patterned stamp to transfer ink (mostly self-assembled monolayer) onto a surface in a pattern defined by the raised regions of a stamp. These techniques can be used to pattern line widths as small as 60 nm.

Replica molding is commonly used for mass-produced, disposable plastic micro/nanocomponents, for example micro/nanofluidic chips, generally made of PDMS and PMMA [38.296, 300] and more flexible in choice of materials for construction than conventional photolithography.

To assemble microsystems, microrobots are used. Microrobotics include building blocks, such as steering links, microgrippers, conveyor systems, and locomotive robots [38.17].

38.A.2 Bottom-Up Fabrication (Nanochemistry)

Bottom-up approaches (from small to large) largely rely on nanochemistry [38.37, 38, 40–45]. The bottom-up approach includes chemical synthesis, the spontaneous *self-assembly* of molecular clusters (molecular self-assembly) from simple reagents in solution or biological molecules as building blocks to produce three-dimensional nanostructures as done by nature, quantum dots (nanocrystals) of arbitrary diameter (about $10–10^5$ atoms), molecular beam epitaxy (MBE) and organometallic vapor phase epitaxy (OMVPE) to create specialized crystals one atomic or molecular layer at a time, and manipulation of individual atoms by a scanning tunneling microscope or an AFM or atom optics. The self-assembly must be encoded, that is, one must be able to precisely assemble one object next to another to form a designed pattern. A variety of nonequilibrium plasma chemistry techniques are also used to produce layered nanocomposites, nanotubes, and nanoparticles. Nanostructures can also be fabricated using mechanosynthesis with proximal probes.

39. Friction and Wear in Micro- and Nanomachines

Maarten P. de Boer, Sameer S. Shroff, Frank W. DelRio, W. Robert Ashurst

The prediction and characterization of multi-length-scale tribological phenomena is challenging, yet essential for the advancement of micro- and nanomachine technology. Here, we consider theoretical underpinnings of multiasperity friction, review various approaches to measure micro- and nanoscale friction and discuss the effect of monolayer coatings to reduce friction and wear. We then overview a theoretical framework known as rate-and-state friction (RSF), in which friction is considered to be a continuous function of velocity and interface state. A microscale test platform that is used to measure friction over multiple decades of velocity and normal load is presented and results are reported. Using the RSF framework, we quantitatively predict and validate the transition from stick-slip to steady sliding, enabling the creation of a microscale kinetic phase diagram. Next, we take a brief look at continued progress in spinning micromachine motor technology. Finally, we discuss wear- and tribopolymer-related phenomena in micro- and nanoswitches, which are promising devices to complement transistors due to their low on resistance and steep subthreshold swing. We anticipate great progress towards reliable, contacting micro- and nanomachines by linking theory and experiment to nano- and microscale tribological phenomena and by improving the testing, materials and processing methods used to characterize these phenomena.

Friction and wear phenomena present both challenges and opportunities for micro- and nanosystems. In many possible applications, counterfaces rub against each other. Examples of how this can occur are illustrated in Fig. 39.1, where a close-up of features in a complex locking mechanism [39.1] are shown. Here, a large gear ratio is employed to amplify torque. The gear teeth mesh and rotate about hubs that are made by a five structural level polycrystalline silicon (polysilicon) surface micromachining technology at Sandia National Laboratories, known as the SUMMiT V^{TM} process [39.2]. Features known as dimples are attached under the gears to minimize contact and hence adhesion with the substrate. The dimples also prevent the gears from tilting excessively, as does a guide that is shown at the top right of Fig. 39.1. The output gear meshes with a linear rack that is guided via long rails; rubbing contact is also made there. To move from right to left, a pin must correctly traverse a maze inside the linear rack. If an incorrect decision is made, a ratchet and pawl mechanism (not shown), which also requires rubbing contact, prevents resetting.

In the example from Fig. 39.1, friction is generally a parasitic effect and efforts are directed towards minimizing it. Eliminating friction in micromachines has proven difficult, yet therein lies opportunity. A number of researchers have chosen to take advantage of friction, achieving impressive micro- and nanoscale actuation performance. Microscale stepper motors are linear actuators with step sizes on the order of 10–100 nm. Their actuation forces can reach the mN scale and travel ranges up to hundreds of μm have been demonstrated. These characteristics compare favorably with the more commonly used comb drives, which typically move 10–20 μm and deliver forces in the low μN range. Stepper motors are attractive for applications such as positioning for optics [39.3], data storage [39.4, 5] and medicine [39.6]. We also envision that they may be very useful for testing properties of micro- and nanoscale specimens [39.9], and as nanoscale manipulation instruments.

Representative implementations of stepper motors, in which actuation is based on frictional effects, are illustrated in Fig. 39.2. Each of these devices has unique design features, performance tradeoffs and processing requirements. An asymmetric bushing geometry enables the motion of the scratch drive actuator (SDA) in Fig. 39.2a [39.7]. The layout and the drive signal for the SDA are simple, the device area is small ($\approx 30\,\mu m \times 100\,\mu m$), the applied voltage is moderate (30–100 V depending on layer thicknesses), the unidirectional travel distance is 500 μm or more [39.10] and the force output is reasonably large (tens of μN) [39.7]. A model that predicts operating voltages has been developed, but it does not treat frictional forces [39.11]. The shuffle motor [39.12] and nanotractor [39.13] designs place voltage-controlled clamps at the ends of an actuator plate, enabling bidirectional motion. These actuators can be modeled well and the nanotractor, pictured in Fig. 39.2b, achieves a theoretical maximum force value of $F_{max} = 0.5\,mN$ [39.13]. A subsequent design known as the μWalker with two degrees of freedom has been demonstrated [39.8, 14] as shown in Fig. 39.2c. Both the nanotractor and the (2-D) μWalker achieve other theoretical expectations including step size on the order of tens of nm and average velocity proportional to step frequency up to the mm/s range. The 2-D μWalker is produced in a four mask process with two layers of structural polysilicon. It takes advantage of a Si_3N_4 coating for in-plane isolation of voltage applied to the clamps, and also as a mechanical layer to enhance wear characteristics. The nanotractor is fabricated in the SUMMiT V™ process and is also a model friction test structure.

In the following sections, we shall describe the theoretical underpinnings of multiasperity friction, micromachined test structures to measure friction and monolayer coatings that have been used to reduce friction on microelectromechanical systems (MEMS). The major focus of this chapter will then be on testing, metrology, friction and wear.

39.1 From Single- to Multiple-Asperity Friction

According to Amontons' empirically deduced law [39.15], the friction force, F_f, is directly proportional to the applied normal load, F_n, and independent of the apparent contact area, as described by

$$F_f = \mu F_n \,, \tag{39.1}$$

where μ is the coefficient of friction. For surfaces at rest, the coefficient of static friction is denoted as μ_s, while for surfaces in relative motion, the coefficient of dynamic friction is denoted as μ_d.

Upon considering two surfaces in mechanical contact, it becomes clear that real surfaces are rough on the microscale, consisting of many peaks and valleys. Thus, the *real* contact area A_r between two surfaces is actually defined by the highest peaks, also known as asperities, and is much less than the *apparent* contact area A_a. *Bowden* and *Tabor* [39.16] presented the idea that friction is related to the real (as opposed to apparent) area of contact via two basic mechanisms: shearing and plowing. Shearing refers to the force required to break the junctions at contacting asperities, while plowing represents the force needed for a hard asperity to displace softer material. In the absence of plowing (i. e., for two materials with roughly the same hardness as is usually the case in micromachined materials), friction is directly proportional to the real contact area via

$$F_f = \tau A_r \,, \tag{39.2}$$

where τ is the shear strength of the contact. Hence Amontons' law is recovered if A_r is proportional to normal load.

The proportionality between real contact area and applied load, however, seems to disappear for two asperities in *elastic* contact. *Hertz* [39.17] provided the first analysis of the stress distribution and displacement at the interface of two elastic spheres, which can be simplified to a sphere in contact with a flat surface. The total load F_n compressing a sphere of radius R into a flat surface can be related to the contact area A_r by

$$A_r = \pi \left(\frac{3F_n R}{4E^*} \right)^{\frac{2}{3}} , \tag{39.3}$$

where the combined elastic modulus of the two contacting surfaces

$$E^* = \left(\frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2} \right)^{-1} .$$

Johnson, *Kendall*, and *Roberts* (JKR) later observed that the contact area between two rubber spheres was larger than that predicted by the Hertz theory and developed a model to account for the surface forces at the interface [39.18]. The model was based on a balance between the stored elastic energy, the mechanical energy in the applied load, and the surface energy. *Derjaguin*, *Muller*, and *Toporov* (DMT) used a thermodynamic approach to consider the molecular forces in and around the contact zone [39.19]. Unlike the JKR approach, the profile of the sphere outside of the contact area was assumed to be Hertzian (i. e., the surface forces are small enough that their effect on the deformation of the sphere can be neglected). Initially, the models seemed to contradict each other. *Tabor* [39.20] determined that the models represent the extreme ends of a spectrum, and developed a parameter μ_T to span the spectrum. Accordingly, the JKR theory is suitable for elastically compliant materials with a large radius and surface energy w, while the DMT theory is appropriate for elastically stiff materials with a small radius and surface energy. *Maugis* [39.21] later developed a semi-analytical solution using a Dugdale approximation; the transition from DMT to JKR was described in terms of the parameter λ, which is related to μ_T via $\lambda = 1.16\mu_T$. Figure 39.3 illustrates the relationship between A_r and F_n for all of these models. In the presence of attractive forces, the contact area increases at a given load, which increases the friction force, as depicted by (39.2). More importantly, all of the models exhibit a nonlinear relationship between real contact area and applied load, contradicting expectations from Amontons' law.

A number of researchers [39.22–24] have successfully used the aforementioned single-asperity relationships to model friction measurements taken via friction-force microscopy (FFM). However, micro- and nanodevices fabricated using surface micromachining techniques often have contacting surfaces with nanometer-scale surface roughness. As a result, it be-

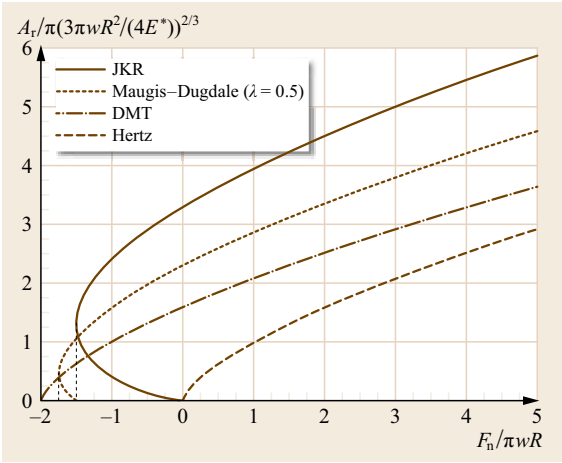

Fig. 39.3 Normalized A_r–F_n curves for the Hertz, DMT, Maugis–Dugdale, and JKR contact models. As the transition parameters μ_T and λ increase from zero to infinity, there is a continuous transition from the DMT to the JKR regime. In the absence of adhesion, all of the models approach the Hertzian case

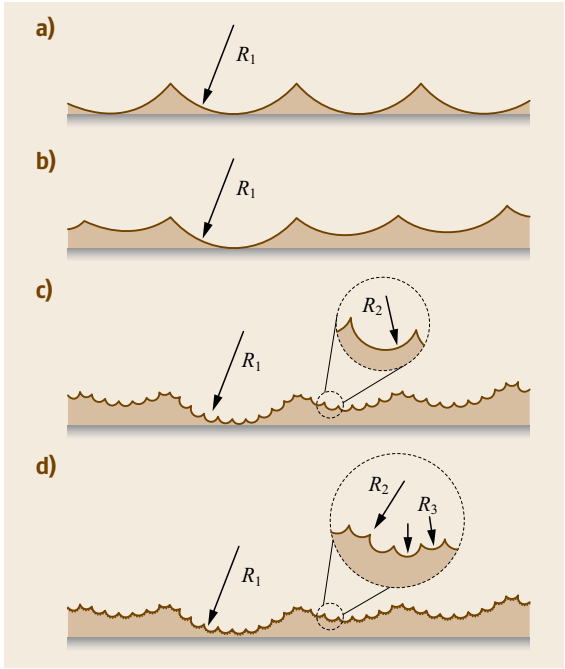

Fig. 39.4a–d Multiple-asperity models (after [39.26]). Assuming elastic deformation, the relationship between the contact area A_r and the applied load F_n are **(a)** $A_r \propto F_n^{2/3}$, **(b)** $A_r \propto F_n^{4/5}$, **(c)** $A_r \propto F_n^{14/15}$, and **(d)** $A_r \propto F_n^{44/45}$. In general, the index n in the relationship $A_r \propto F_n^n$ ranges from $2/3$ for a series of asperities at the same height to ≈ 1 for a multiple-asperity surface with several sets of protuberances

comes important to develop *multiple*-asperity contact models to elucidate the impact of surface topography on the relationship between contact area and applied load. In the simplest case, the rough surface consists of a series of identical asperities all at the same height, as shown in Fig. 39.4a. Here, the applied load is divided evenly among all of the contacting asperities, which results in $A_r \propto F_n^{2/3}$. *Archard* [39.25, 26] improved on this idea by considering a *uniform* distribution of spherical asperities (radii of curvature R_1) in contact with a rigid flat surface as shown in Fig. 39.4b. For elastic deformation, $A_r \propto F_n^{4/5}$. To examine multiscale roughness, a second set of protuberances (radii of curvature R_2) can be evenly distributed over the surface of the existing spheres, such that $R_2 \ll R_1$, as shown in Fig. 39.4c. In this case, $A_r \propto F_n^{14/15}$. With even smaller protuberances of radius R_3, as shown in Fig. 39.4d, the relationship becomes $A_r \propto F_n^{44/45}$. This indicates that proportionality between area and load is not necessarily the result of plastic flow in the contact zones, as originally proposed, but can be due to elastic contact between rough surfaces.

Greenwood and *Williamson* (GW) considered a *statistical* distribution of N asperities with constant radius of curvature R in contact with a flat surface [39.27]. For a Gaussian distribution of asperity heights, A_r is almost exactly proportional to F_n. *Fuller* and *Tabor* [39.28] extended the GW model for JKR contacts to study rough surface adhesion and defined the adhesion parameter θ, which represents the competition between the compressive forces exerted by the higher asperities and the adhesive forces acting between the lower asperities (analogous to the Tabor parameter). In a similar manner, *Maugis* [39.29] extended the GW model for DMT contacts. For infinite θ (work of adhesion $w = 0$), the Maugis theory is equivalent to the GW model and $A_r \propto F_n$. On the other hand, as θ decreases (w increases), the relationship between the contact area and applied load becomes more nonlinear. More advanced theories that extend these ideas are under development [39.30–32].

39.1.1 Micromachined Test Structures

From this survey of multiple-asperity contact models, we see that adhesive forces and asperity distribution can significantly impact the relationships between friction force, contact area and applied load. Therefore, although widely observed, Amontons' law is not necessarily expected. While there are techniques in place to convert topographic data from real surfaces into Gaussian asperity distribution data [39.33], it is unclear as to whether these statistical models accurately represent the surface topography [39.32]. Therefore, it becomes nec-

essary to fabricate micromachined test structures that can be used to measure friction directly. Moreover, micromachined structures are appropriate test vehicles for studying friction and wear because their performance will reflect any effects that are due to details of the fabrication process. These include technologically relevant issues such as the effect of sidewall slope on vertical surfaces, surface roughness and the ability to coat micromachined structures with friction-reducing coatings in spite of sometimes tortuous access paths.

One of the earliest systematic studies of microscale friction was carried out by *Howe* et al. at the University of California, Berkeley [39.34]. Since then, a number of researchers have investigated this critical issue using a variety of techniques and devices. A common approach is to design a moveable beam that can be brought into contact and slid against a counter surface [39.35–41]. An example from [39.39] is shown in Fig. 39.5a,b. The measurements from this study showed that statistical contact models as described above may not apply to lightly loaded, small apparent contact areas in MEMS. This is because such models would predict less than one contact within the contact area! The researchers also found that adhesion between the surfaces must be recognized as an important contribution to the applied normal load. Most microdevice friction work has involved so-called *sidewall* devices such as this one, where the contacting surfaces are the result of an etching procedure and may have vertical striations and significant directional anisotropies. The topography of sidewalls is influenced by lithography, etching *and* grain boundaries, as seen in Fig. 39.5c [39.42], and often exhibits significantly higher roughness than in-plane surfaces where topography is primarily determined by grain growth phenomena.

Timpe and *Komvopoulos* [39.40] developed a sidewall microscale friction device that involved a push drive and a shear drive. Testing of the device consisted of first loading the contact and then shearing the newly formed interface while monitoring the position of the shear drive with a charge-coupled device (CCD) camera, with a spatial resolution of about 0.3 μm. It was shown that the engineering coefficient of friction exhibited a nonlinear dependence on contact pressure that was unique to the testing environment; higher friction was observed at higher humidity levels. Further, the adhesion forces, significant at the microscale, added substantially to the friction when the external load was comparable to the adhesion force [39.40].

Frenken and co-workers recently developed a similar sidewall device, but included an on-device, real-time, electrical capacitance readout mechanism for high-resolution displacement measurement (about 4 nm peak-to-peak noise sensitivity). Their device, called the

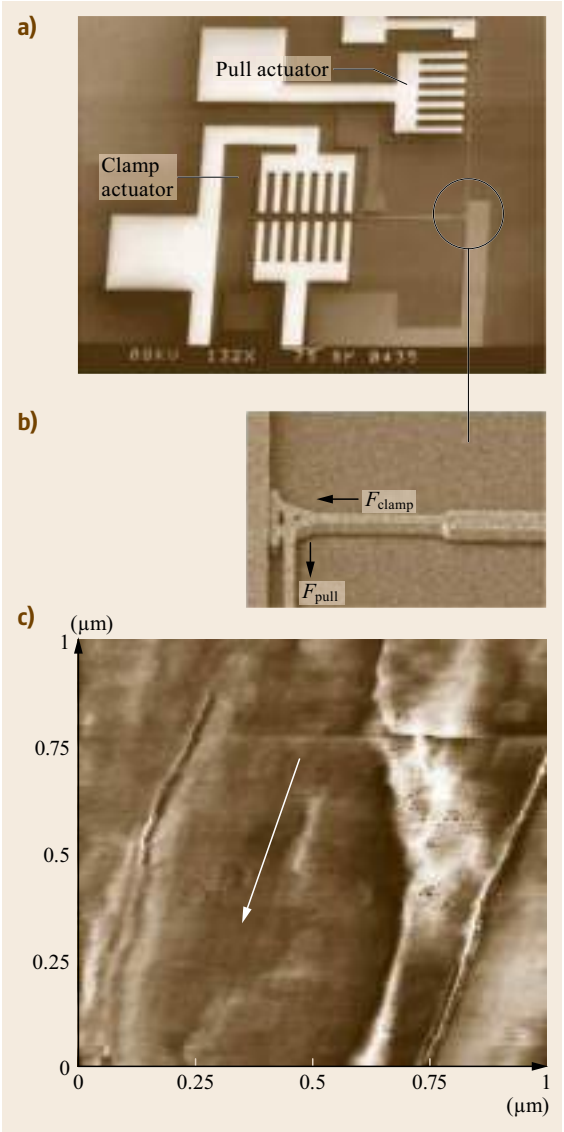

Fig. 39.5 **(a)** A MEMS test structure **(b)** designed to measure sidewall friction (after [39.39], © VSP). **(c)** Topographical image of a sidewall surface, where the RMS roughness is 40 nm (after [39.42], © Xavier by permission)

Leiden MEMS Tribometer, consists of two orthogonally oriented comb drives that are used to position a test slider against a fixed surface. The comb drives are used to generate loading and shearing forces on the contact surface. They indicated two regimes in the friction behavior depending on the load. For the low-loading regime, a wearless stick-slip phenomenon is observed that is repeatable over many cycles but stochastic in position and presumably related to the details of the topography. In the high-loading regime, wear was ob-

served, and although the stick-slip behavior exhibited in the low-load regime disappeared, the motion was not smooth, as ongoing wear processes altered the surface topography and changed the contact mechanics [39.38].

39.1.2 Monolayer Lubrication in Nano- and MEMS Tribology

While the results in the previous section are of interest, the effects of monolayer coatings, which significantly reduce friction, were not studied. It has been well established that monolayer lubricants are effective at reducing friction at the nanoscale. Much of this knowledge has been achieved through nanotribology experiments involving atomic-force microscopy (AFM) [39.43, 44] or a surface-forces apparatus (SFA) [39.45], where ideal systems (i. e., pristine environments, single-crystal substrates, perfect monolayers, etc.) are employed to probe fundamental aspects of friction phenomena using single-asperity contacts.

Nanotribology studies have shown significant (and sometimes conflicting) impact of monolayer thickness (i. e., precursor chain length) and terminal group on friction [39.46–49]. Similar to rough surfaces, there are two basic phenomena involved in single-asperity friction: plowing and shearing [39.44]. With regard to monolayer coatings, plowing refers to the action of the asperity tip deforming the monolayer thereby dissipating energy by introducing chain defects that may elastically relax after the tip has passed, while shearing refers to the localized disruption of intermolecular forces as a result of the shear interaction of the film surface with the tip. Some researchers report an increase in friction as chain length increases [39.50], while others report a decrease in friction [39.48]. These conflicting findings suggest that additional experimental factors contribute to the frictional behavior of monolayer films, and the operating conditions must be considered in the friction study.

As discussed above, the friction force may be proportional to the true contact area, leading to a nonlinear dependence of friction with load. This has been supported by experimental data for inorganic materials. However, in many studies of organic monolayers, a linear relationship is found [39.46, 48, 51–53]. This could be attributed to plastic deformation, to multiple contacting nanoasperities on the single-AFM tip or to viscoelastic deformation during the sliding. It is important to note that many of the fundamental mechanistic studies of nanoscale friction have involved high-modulus inorganic materials with similar bulk and surface properties. Since monolayers are comparatively compliant materials, usually deposited on a stiff material, the validity of applying findings from such fundamental studies to monolayer systems can be questioned. Another aspect to consider is that deviation from linearity as in the JKR model [39.18] may be small and experimentally obscured for low loadings, typical of AFM studies [39.44]. Recently, a continuum thin-coating theory was developed to address these issues [39.54, 55].

Some researchers have successfully applied monolayer films to micromachines for the purpose of studying their effects on friction [39.13, 56–59]. The most convenient monolayers to apply to polysilicon microdevices involve silane-based linking reactions with the oxide layer present on the surface. From the silane class of materials, one of the most commonly studied monolayer film is that produced by octadecyltrichlorosilane (OTS). This particular film has received much attention in the literature due to its self-assembly characteristics [39.60]. Work using AFM has shown that the friction behavior of the film is dependent on the local 2-D phase (liquid expanded or liquid condensed) at the asperity contact [39.61] and that liquid-condensed phases are likely to be associated with grain boundary areas for polysilicon devices [39.62]. It is generally accepted by the MEMS community that OTS and other low-friction monolayer boundary lubricant films reduce the friction on microdevices when properly integrated and applied to the device. For example, a factor of ≈ 4 reduction in friction was reported at 100 nN normal load for self-mated OTS versus self-mated silicon surfaces [39.63].

The findings assembled from uncoated and coated sidewall devices have significant value to the MEMS community and provide guidance on how to more reliably design and operate microdevices. However, statistical contact mechanics models, which rely on numerous contacts, do not apply because of the small contact areas and nonvertical nature of sidewall etching. Rather, an interface with uniform loading over a large area of in-plane (horizontal) surfaces during friction testing is needed.

39.2 Rate–State Friction

Clearly, it would be interesting to link single-asperity measurements made by nanotribologists to multiasperity measurements made by MEMS tribologists. This would involve a detailed understanding of the surface properties, loading characteristics and topography. Indeed, asperity radii of polycrystalline silicon are on

the order of 20–200 nm, in the same range as AFM tips. At the macroscale, friction measurements on kg-scale masses have revealed complex behavior including aging, velocity dependence, and stick-slip to steady-sliding bifurcations. From these, a phenomenological framework known as rate-state friction (RSF) has been advanced [39.64–68]. This development derives from detailed measurements with various combinations of springs, puller velocities and normal loads, and applies to a wide range of materials from rock [39.65] to cardboard [39.66] to plastic [39.69]. The phenomenology invokes the notion of contact rejuvenation and requires the solution of coupled differential equations in terms of rate (instantaneous velocity) and state (interface order or age) variables [39.70, 71]. Quite possibly, microscale friction will have similar dependencies. As an initial effort to explore some of these potential dependencies, we recently developed a platform to study whether RSF applies to this scale, where a typical mass is on the order of 10^{-10} kg.

Amontons' law states that friction is independent of load, while Coulomb's law states that dynamic friction is lower than static friction, but independent of velocity. Long ago, *Desaguliers* [39.72] observed that static friction tends to increase with time. RSF links these empirical observations and postulates that the coefficient of friction μ is a *continuous* function of state and time. Various functional forms have been proposed. The *Ruina–Dieterich* [39.68, 73, 74] *slip* law can be written as

$$\mu(\psi,\dot{x}) = \mu_0 + A\ln\left(1+\frac{|\dot{x}|}{v_c}\right) + B\ln\left(1+\frac{\psi}{\psi_c}\right), \tag{39.4}$$

where ψ represents the interface state, $\dot{x}$ the instantaneous block velocity (the overdot indicates the derivative with respect to time), μ_0 is a constant, A and B are respectively velocity strengthening and aging coefficients, and v_c and ψ_c are, respectively, velocity and time cutoffs. A coupled equation describes how ψ evolves with time. The *Dieterich–Ruina* [39.68, 73] *aging* law is

$$\dot{\psi} = 1 - \frac{|\dot{x}|\psi}{d_c}\,. \tag{39.5}$$

At rest, $\dot{x}=0$, and hence ψ is time. At constant velocity (steady sliding at steady state), $\dot{x}=v_p$, and $\psi = d_c/v_p$, where d_c is a memory length on the order of the diameters of contacting asperities in dry systems. Referring to the (1-D schematic in Fig. 39.6 with a puller at position x_p moving at velocity v_p, a spring with constant k and block of mass m_b subject to normal load N_b, we write

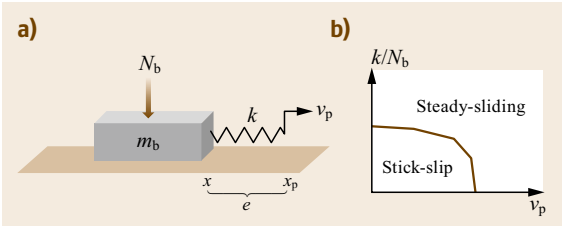

Fig. 39.6 **(a)** A puller moving at velocity v_p causes a block of mass m_b subject to normal load N_b to slide via a spring with constant k. **(b)** A schematic kinetic friction phase diagram indicating the block response as a function of v_p, k and N_b in the stick-slip or steady-sliding regimes

the block's equation of motion as

$$m_b\ddot{x} = k(x_p - x) - F_0\,, \tag{39.6}$$

where the friction $F_0 = \mu N_b + c\dot{x}$, and c is a viscous damping coefficient.

39.2.1 MEMS Rate-State Friction Test Platform with Decades of Range-in-Control Parameters

With a test platform as schematically illustrated in Fig. 39.6a, the coefficients in (39.4) can be found in principle. In order to do so, however, it is necessary that v_p, k and N_b be varied over a wide range as friction varies only slowly with velocity. While this is relatively straightforward to accomplish in macroscale experiments, its design and implementation at the microscale involves many considerations. The overarching objective in creating this apparatus is to determine quantitatively a full response of the system in [v_p, k, N_b] space using (39.4) and (39.5). One important outcome would be prediction of the stick-slip to steady sliding bifurcation line as seen in Fig. 39.6b. This would demonstrate that a microscale interface can have a predictable sliding response. Further, once the coefficients are known, in principle the response to any velocity or normal load stimulus can be known.

Figure 39.7 shows the microscale platform we have developed in pursuit of this objective [39.75]. A thermal actuator (TA) [39.76–78] is chosen as the puller. While its displacement versus voltage characteristic is nonlinear, it has the advantage that when voltage is applied, the time to achieve the final displacement value is governed by a thermal time constant, τ_H. When a voltage V_{TA} as in Fig. 39.7a is initially applied across the TA legs, a nonzero shuttle velocity is achieved almost instantaneously ($\approx 0.5\,\mu$s), but decays exponentially as the final displacement position is reached. In order to achieve a constant velocity, V_{TA} is continuously

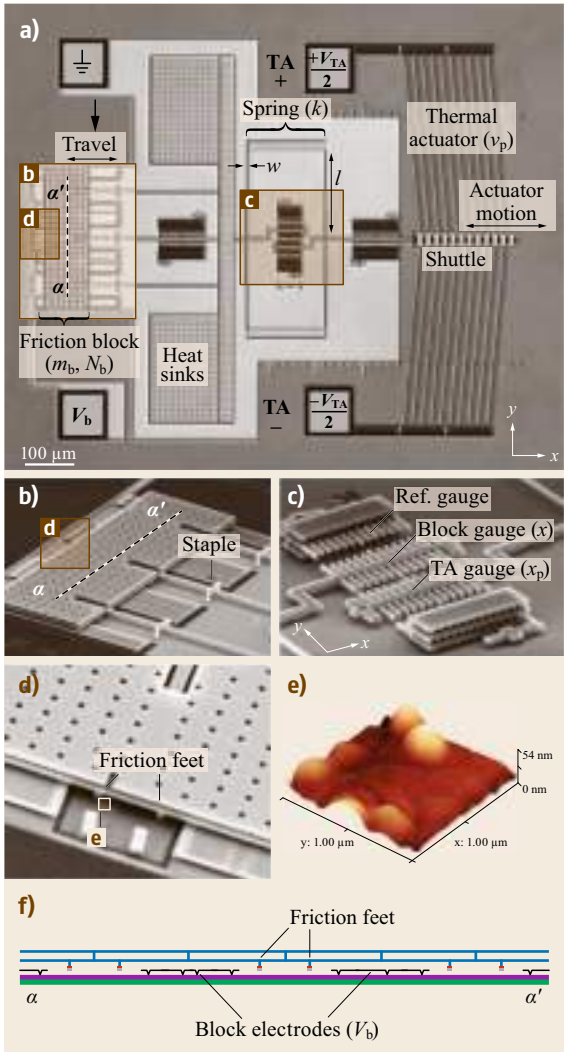

Fig. 39.7 **(a)** Optical image of a fabricated and released test platform with the basic components shown in Fig. 39.6 labeled. Here $k = 1\,\mu N/\mu m$. *Boxes* indicate details shown in the corresponding figure parts **(b–e)**. **(b)** SEM image of the friction block. Cross section α–α' is *labeled* and shown in **(f)**. The staple minimizes deflections during the release process and plays no role during testing. **(c)** SEM image of the displacement gauges used for position measurement. **(d)** SEM image showing two of the six friction feet below the friction block (shown from a different perspective than indicated in the *inset* of **(b)**). **(e)** AFM scan of the countersurface below the friction feet shown in **(d)**. The scan width is approximately half the width of the friction feet. **(f)** Schematic of cross section α–α' showing the electrically grounded friction feet and block actuation electrodes to apply electrostatic normal load

increased after a small fraction of τ_H. In detail, a training algorithm known as iterative learning control (ILC) [39.79] is applied to reach the desired velocity in a time on the order of $1/20$ of the time it takes to travel along the $\approx 10\,\mu m$ travel range. With ILC, we have trained the actuator to move at velocities from 0.1 to $3000\,\mu m/s$ with $\approx \pm 10\%$ control [39.75]. Using ILC, the actuator can also be trained to change velocity instantaneously [39.80].

Another important feature of this design is that the TA legs are much stiffer than k, so the shuttle's motion is independent of whether it is pulling a sliding block or not. The spring itself is labeled in Fig. 39.7. It consists of four fixed-guided beams and its constant k is determined by their width, w. By varying w, designs with $k = 0.1$, 1, 10 and $100\,\mu N/\mu m$ have been fabricated and tested. The TA is thermally isolated from the friction block. Its temperature is $\lesssim 2\,^\circ C$ above the substrate temperature [39.81].

The block's mass is $3.6 \times 10^{-10}\,kg$. Its gravitational normal force is negligible. The applied normal force is due to two main contributions: electrostatic loading F_{el} and adhesion, F_{adh}. Hence

$$N_b = F_{el} + F_{adh} \,. \tag{39.7}$$

The block is designed with nominally flat feet that contact the substrate over a nominal area of $A_{nom} = 1000\,\mu m^2$. Electrodes between the feet are used to apply the voltage to deliver F_{el}. The value for F_{adh} will be seen to be $\approx 1.6\,\mu N$. As measured by tapping mode AFM, the roughness of the combined top and bottom surfaces is about 8 nm RMS while the asperity radius of curvature is 35 nm. According to *Greenwood–Williamson* contact mechanics [39.27], the interface makes at most tens of contacts for the range of N_b values applied here.

The displacement gauge that is used for metrology is in the middle of the spring. Vernier scales are monitored optically through a 50× microscope objective with a high-speed camera at rates as high as 200 000 fps (frames per second). The images are analyzed using subpixel interpolation, with a resulting resolution of ± 2 nm. The spring force is simply $k\Delta e$, where Δe is the spring extension.

The experimental data that follows was measured using the Fig. 39.7 test platform coated by a 1.2 nm-thick monolayer coating (tridecafluoro-1,1,2,2-tetrahydrooctyl-*tris*(dimethylamino)silane, $CF_3C_5F_{10}C_2H_4Si(N(CH_3)_2)_3$, FOTAS) deposited from the vapor phase [39.82]. The 8-carbon chain molecule has a sufficiently high vapor pressure to allow vapor-phase deposition, which makes it highly reproducible in a manufacturing setting. However, it is too short to

form a self-assembled monolayer; rather the chains attached to the surface are believed to be somewhat disordered [39.83]. This lack of order may play an important role in the effects reported below.

A wear test was first conducted. In this test, with $F_e = 5$ or 250 μN, it was seen that $\mu \approx 0.3$ remained stable for 20 000 cycles for FOTAS-coated devices. For uncoated devices, $\mu \approx 0.65$ at $F_e = 5$ μN was also stable up to 10 000 cycles. In comparison, RSF tests require approximately 100 trials from a given device for complete characterization. Therefore, we can be optimistic that wear is not an issue with respect to assessing RSF with this test platform. We attribute the relatively low wear rate to the lightly loaded interface in which different asperities share the load over the sliding travel distance.

39.2.2 Rate-State Friction Measurements

Transition from Steady Sliding to Stick-Slip

We pull the block at puller speed $v_p = 1$ μm/s using a spring constant $k = 10$ μN/μm while applying electrostatic load F_e, and measure elongation e. The camera framerate is 300 fps, corresponding to a frame every 3.3 nm of puller position. The data in Fig. 39.8 begin at $F_e = 0$ μN. There, the extension is approximately constant. At $F_e = 0.3$ μN, the extension exhibits somewhat greater noise. At $F_e = 0.58$ μN, the data exhibit discontinuities in e, corresponding to slip events, and at $F_e = 0.90$ μN, the discontinuities are somewhat larger. Finally at $F_e = 2.01$ μN, the response is similar to a classic stick-slip curve. Dashed black lines indicate perfect stick of the block. Hence at $N_b = 2.01$ μN, there is frictional creep, but at a slower rate than at the lower F_e values of 0.58 and 0.90 μN. This creep is widely observed [39.66, 83, 84] and is indicative of an avalanche process leading to inertial slip.

A metric to deduce the transition between these regimes must be developed. For $N_b = 2.01$ μN in Fig. 39.8, a slip distance δ is indicated. If we consider the distribution of e data for a perfect stick-slip curve, it will be uniform. The standard deviation of the e data multiplied by $\sqrt{12}$ will equal the width of the (uniform) e distribution. We call this product the pseudo-slip distance.

In Fig. 39.9a, we plot the pseudo-slip distance against F_e for FOTAS-coated and oxide coated blocks. For the former, a small but clear abrupt drop in the pseudo slip distance is seen as F_e is reduced. We use this drop to estimate the transition from stick-slip to steady sliding. The uncoated block in Fig. 39.9a displays only stick behavior, and there is no abrupt drop in δ. Choosing the abrupt drop as a metric, the data in Fig. 39.8 for $F_e = 0$ and 0.3 μN correspond to steady sliding. We attribute the small deviations in e to local differences in the topography encountered, which can be important as there are likely only a few contacting asperities at these low F_e values.

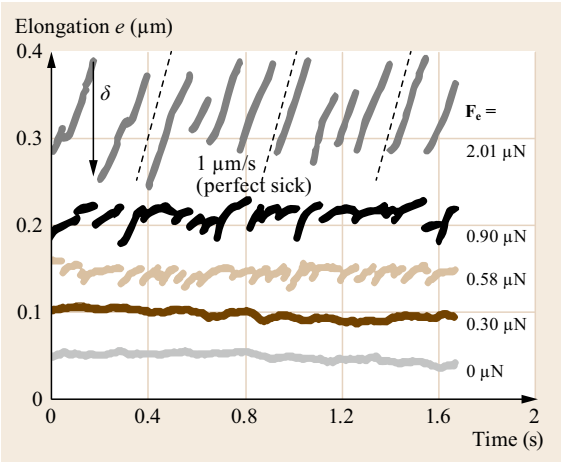

Fig. 39.8 Spring elongation versus time for increasing F_e. Here, $v_p = 1$ μm/s, $k = 10$ μN/μm and the camera framerate is 300 fps

The maximum extension e_{max} for the uncoated and coated blocks is plotted against F_e in Fig. 39.9b. We fit the data to (39.7), and find values $F_{adh} = 2.0$ and 1.6 μN for the two surfaces. With $A_{nom} = 1000$ μm^2, this corresponds to an adhesive pressure of 2.0 and 1.6 kPa, respectively. Such pressures are typical of rough micromachined interfaces, and are attributed not to the contacting asperities but to van der Waals forces across the relatively vast area of surface that are separated by just a few nm [39.85]. These F_{adh} values are not interpreted in the context of RSF, but provide a reasonable correction to N_b. F_{adh} sets a lower bound on N_b. All subsequent measurements discussed are only for FOTAS-coated blocks, and the N_b value including F_{adh} is reported.

We now present five tests: M1–M3, V1 and V2. Here M stands for measurement, while V stands for validation.

Test M1, Friction Versus Velocity. In the results shown in Fig. 39.10, v_p is varied from 0.1 to 3000 μm/s, while $k = 100$ μN/μm and $N_b = 14.1$ μN are held fixed. The stiff spring ensures steady sliding while the relatively high N_b value gives rise to an extension e that can be measured well. A frame was taken every 100 nm of travel, which corresponds to 30 000 fps at $v_p = 3000$ μm/s. The average and standard deviation of the block velocity are shown in the figure. There is a clear trend in which dynamic friction μ_d decreases from 0.1 to ≈ 300 μm/s, and increases thereafter.

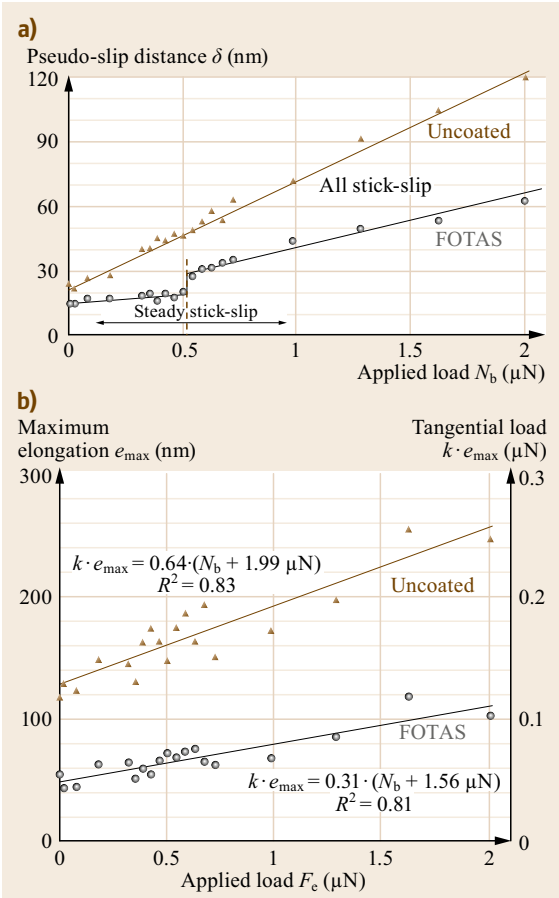

Fig. 39.9 **(a)** δ versus N_b for constant $v_p = 1\,\mu m/s$ and $k = 10\,\mu N/\mu m$ for uncoated (*triangles*) and FOTAS-coated (*circles*) devices. **(b)** e_{max} versus N_b for the same data set

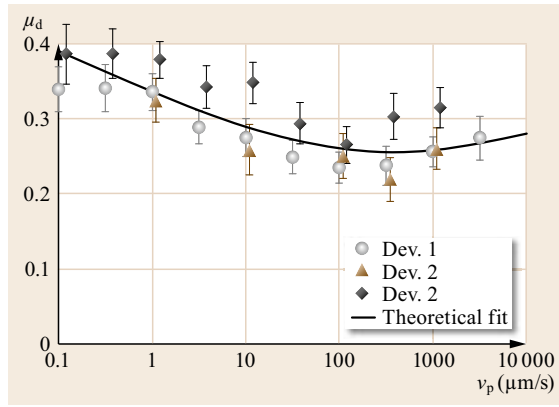

Fig. 39.10 Dynamic friction coefficient $\mu_d(v)$ versus actuator pulling velocity in the steady-sliding regime ($v = v_p$). Three devices are shown. Devices 2 and 3 are offset by $0.1\,v_p$ and $0.2\,v_p$, respectively. Here $k = 100\,\mu N/\mu m$ and $N_b = 14.12\,\mu N$. *Error bars* represent one standard deviation of μ_d by considering the time-weighted variation in spring elongation of one or more trials

Equations (39.4) and (39.5) are used to determine values of $\mu_0 = 0.19$, $A = 0.013$ and $B = 0.024$ from this data, as represented by the best fit solid black curve in Fig. 39.10. We also use values of $v_c = 10\,\mu m/s$, $\psi_c = 10\,\mu s$ and $d_c = 4.3\,nm$. The fit is only weakly dependent of the v_c and ψ_c values, and they are chosen such that v_p/v_c and $(\psi = d_c/v_p)/\psi_c$ are both $\gg 1$ in the relevant ranges. Meanwhile, d_c is determined as shown below. Note that in the fit to (39.4), μ initially decreases because $B > A$. That is, the asperity contact lifetime decreases as v_p increases, and hence less aging is responsible for the friction decrease. As v_p increases, this effect becomes small compared to μ_0 and the velocity strengthening effect due to A becomes significant.

Test M2, Velocity Step Response. Let us again consider (39.4) and (39.5). Upon an instantaneous change in v_p, state ψ remains the same. If $A > 0$, we expect a step increase in μ equal to $A \ln(v_{p2}/v_{p1})$, as shown in Fig. 39.11a. As represented in Fig. 39.11b, v_p was changed in $\approx 1\,\mu s$ from 50 to $1000\,\mu m/s$ with $k = 100\,\mu N/\mu m$ and $N_b = 15.4\,\mu N$. Here, imaging at 200 000 fps was necessary to capture the transient event, as its duration is $\approx 20\,\mu s$. The response data from three different trials is seen in Fig. 39.11c, where it is magnified in the offset on the right. An increase in e of approximately 5 nm occurs, corresponding to an increase in μ of $ke/N_b = 0.032$. Equating this with $A \ln(1000/50)$, we find $A = 0.011$. This is slightly lower than the value $A = 0.013$ reported above. The discrepancy is because in Fig. 39.11a it is assumed that the block velocity can change instantaneously. This is only possible if the spring is rigid, which would then mean that e could not be measured. In the actual situation, the state has had some time to change, so μ begins to decrease. A full numerical simulation incorporating (39.4)–(39.6) better estimates the value of A [39.86]. The final value of $A = 0.013$ from the data in Fig. 39.11c is in good agreement with the value obtained from Test M1.

As indicated by Fig. 39.11a, a fraction of the width of the response pulse can be used to estimate the memory length, d_c. That width gives $d_c \approx 0.5 \times (20\,\mu s) \times (1000\,\mu m/s) = 10\,nm$. The full numerical simulation, which is optimized to capture the response curve, gives $d_c = 4.3\,nm$. The value from GW contact mechanics is $d_c \approx 13\,nm$. However, it is difficult to get a good measure of asperity radius R from AFM because of tip convolution effects – the GW calculation may overestimate R. On the other hand, the monolayer chain length is $\approx 1.2\,nm$. The memory length is associated

with the notion that during sliding, asperities are new when they first make contact, and then age as they slide past each other. The contribution to μ is then due to the effective age d_c/v_p. The implicit assumption is that bonding is instantaneous when new asperities come into contact and subsequently make and break bonds. Poorly ordered monolayers such as FOTAS may reconfigure when brought into contact with a counterface. Hence, the value of $d_c = 4.3\,\text{nm}$ may reflect information on bonding dynamics as well as contact diameter. Work to understand the memory length in the context of microscopic processes is a topic of current interest [39.87].

Test M3, Static Aging. In this test, the block is held at $N_b = 300\,\mu\text{N}$ under zero spring force for a time ranging from 0.1 to 3120 s. After the hold time, the puller travels at $1\,\mu\text{m/s}$ and exerts a force ke (here $k = 100\,\mu\text{N}/\mu\text{m}$) until a slip event is observed at extension e_{crit}. The total time is taken to be the aging time t_{age}, and the static friction coefficient μ_s is then equal to ke_{crit}.

The resulting data is seen in Fig. 39.12, in the area annotated as *static aging trials*. Each data point is the average of about ten trials, except at the longest time of 3120 s where just three points were taken. The spread for each data point represents one standard deviation, and the dashed lines give the 95% confidence intervals for the average from a *t*-test. A logarithmic fit of the form $\mu_s = \mu_0 + B\ln(t_{age}/1\,\text{s})$, with $B = 0.0041 \pm 0.0016$ (95% confidence) and $R^2 = 0.80$. Hence, at long times, μ_s appears to be saturating. This could be indicative of the monolayer chains approaching their equilibrium configurations.

The data from Fig. 39.10 is replotted in Fig. 39.12, where time is taken to be d_c/v_p. The data from Tests M1 and M3 (dynamic and static friction measurements, respectively) extend towards each other, implying that the memory length concept applies during the sliding test. At short times, $B = 0.024$ is a better fit to the data, supporting the idea that the aging is saturating at long times.

Test V1, Crossing the Bifurcation Line with N_b. In Fig. 39.8, including the effect of F_a, the bifurcation line was crossed at $N_b \approx 2\,\mu\text{N}$ with $v_p = 1\,\mu\text{m/s}$. In Fig. 39.13, we see that at $v_p = 50\,\mu\text{m/s}$, the line is crossed at $N_b \approx 4\,\mu\text{N}$. This indicates a negative slope in the bifurcation line, as qualitatively indicated from Fig. 39.6b. The data now approaches the perfect stick lines, as the block has less time to creep.

Test V2, Crossing the Bifurcation Line with v_p. Using $N_b = 3.45\,\mu\text{N}$ and $k = 10\,\mu\text{N}/\mu\text{m}$, we see in Fig. 39.14 that the bifurcation line is also crossed

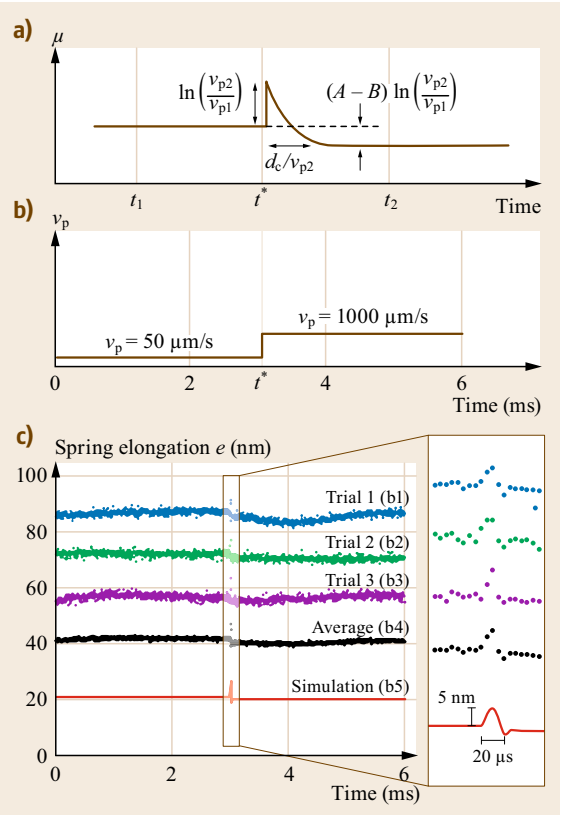

Fig. 39.11 **(a)** Expected friction versus time for a velocity step. **(b)** Pulling velocity versus time showing a velocity step at $t^* = 3\,\text{ms}$ ($k = 100\,\mu\text{N}/\mu\text{m}$, $N_b = 15.42\,\mu\text{N}$). **(c)** Spring elongation versus time for the pulling profile shown in **(b)**. Multiple trials (b1)–(b3) as well as the average (b4) are shown

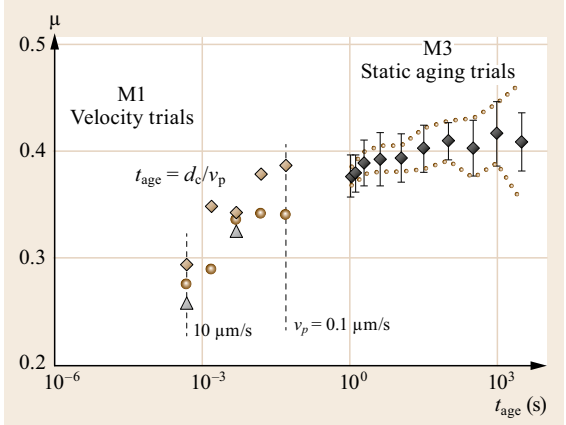

Fig. 39.12 Results of the static aging trials, plotted alongside the results of the velocity trials shown in Fig. 39.10 with $t_{age} = d_c/v_p$

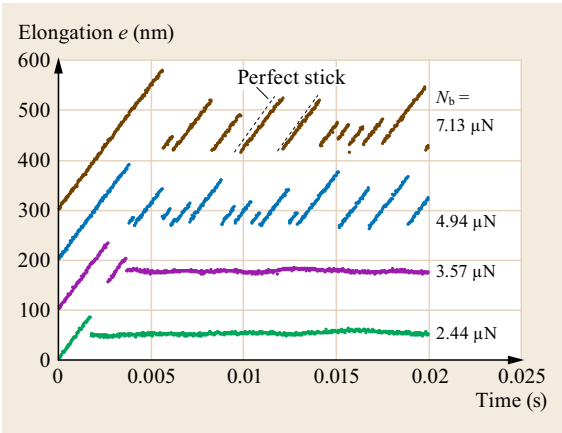

Fig. 39.13 Elongation versus time for a fixed $v_p = 50\,\mu m/s$ and $k = 10\,\mu N/\mu m$ for increasing N_b. The camera framerate was 30 000 fps. At this v_p, a transition between stick-slip and steady sliding is seen between $N_b = 3.57$ and $4.94\,\mu N$

between $v_p = 30$ and $40\,\mu m/s$. The black dashed horizontal lines indicate numerical modeling results of the maximum and minimum extensions taking the full RSF parameters and equations of motion into account. These lines indicate the average expected values. The data does show that the amplitude tends to decrease as v_p increases. The deviations from the average prediction observed in the data likely indicate that the actual topography sampled from point to point varies along the block trajectory.

Quantitative Bifurcation Line Prediction

The equation of motion incorporating the RSF coefficients can now be written. A perturbation on the extension e is applied to a condition where steady sliding exists. An exponential solution is assumed for the subsequent e time dependence. Negative roots mean that there will be an oscillatory decay back to steady sliding, while positive roots indicate a divergent response and that the system will take on a stick-slip response. The bifurcation line divides these two responses. The perturbation theory result is [39.88]

$$k_{crit} = N_b \left(1 + \frac{v_p m_b (v_p + v_c)}{N_b A d_c}\right) \times \left(\left(\frac{B}{d_c + v_p \psi_c}\right) - \left(\frac{A}{v_p + v_c}\right)\frac{v_p}{d_c}\right). \tag{39.8}$$

The values for the parameters A, B, d_c, v_c and ψ_c were determined from Tests M1 and M2 as described above. For a given value of k, $1/N_b$ can be plotted against v_p. This has been done in Fig. 39.15 using further data from Tests V1 and V2 above. Some 20 devices, different from the ones used to determine the parameters, were used to find the bifurcation experimentally. It is seen that the experimental results agree well with the predicted curve. While this is expected from theory, experimentally this means (1) that wear is sufficiently low over the ≈ 100 trials needed to characterize the experimental parameters, and (2) that the parameters apply to devices other than those measured, and therefore that the kinetic phase diagram has been well quantified.

RSF Summary

In this section, we have seen that RSF is a useful phenomenological framework for measuring the time and velocity dependence of friction not only at the scale

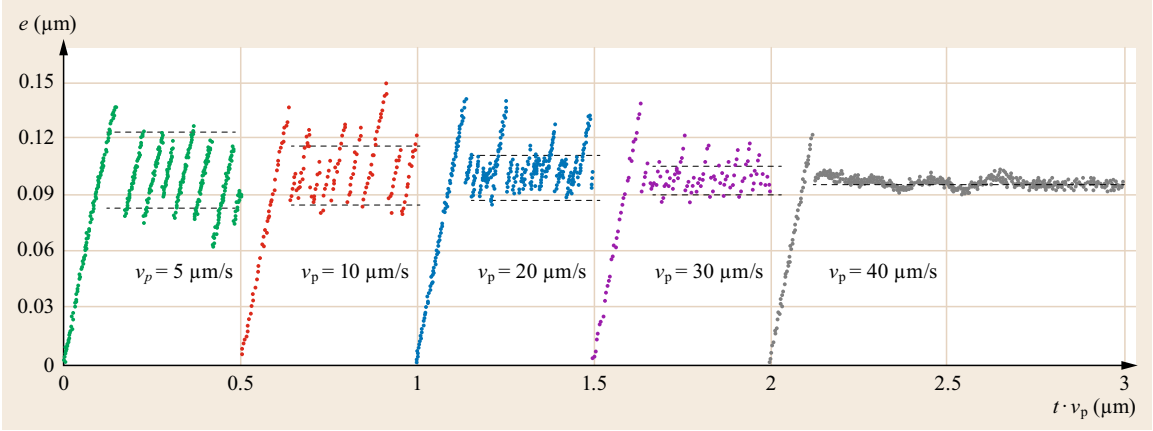

Fig. 39.14 Spring elongation versus actuator position $t\,v_p$ for a representative device at various velocities. Here $k = 10\,\mu N/\mu m$ and $N_b = 3.45\,\mu N$. RSF simulation maximum and minimum elongations are represented by *dashed lines*

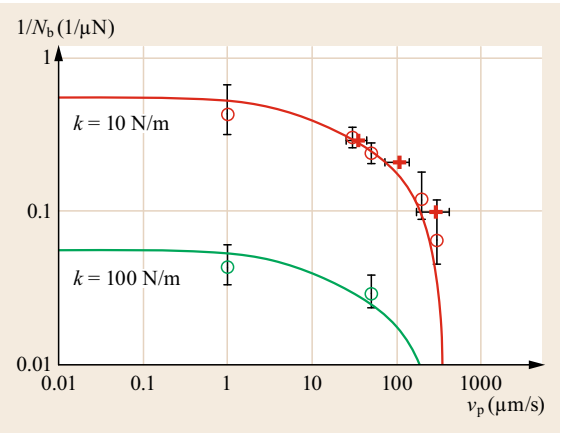

Fig. 39.15 Predicted bifurcation lines and average experimental transition between stick-slip and steady sliding via normal load variation (*circles*, *vertical error bars*) or velocity variation (*crosses*, *horizontal error bars*). *Error bars* represent one standard deviation of the critical velocity or inverse normal force at which the transition occurs ◀

of earthquakes [39.89] or macroscale objects (≈ 1 kg with μm-scale asperities) [39.66], but also at the scale of microscale objects ($\approx 10^{-10}$ kg with nm-scale asperities). Although RSF predicts average friction well at the microscale, very likely only a few asperities are in contact. This gives rise to noise in the friction behavior, which requires further study. Another area of interest is the dependence of the RSF parameters on the particular monolayer chain that is applied to the surface. Although bonding across the interface may lower the free energy, the chain's entropy is also lowered. The dynamical interplay between these factors will be interesting to study. It will also be of interest to see if and how nanotribology results can be linked to RSF.

39.3 Putting MEMS Friction to Use: Making Motors and Friction Instruments

39.3.1 Microengines, Pumps and Generators

A long-held dream is to fabricate reliable gas turbine engines from MEMS technology [39.90]. Such engines would theoretically deliver a thrust to weight ratio 100 times that of their macroscale counterparts. Most of the early work in this area involved high-speed dynamics control, with engines working above 1 million rpm on a cushion of air [39.91]. These engines were fabricated from multiple layers of silicon. The design allowed no taper during very deep etches and hence the manufacturing margin was low.

More recently, *Ghodssi* et al. put ball bearings to use in a six-phase electric micromotor that generated 300 μW at 500 rpm [39.92]. One advantage of the design is that the bearings allow precise control of rotation to within a few degrees, which is important for certain sensor designs [39.93]. Another is that fabrication tolerance need not be controlled as tightly. In principle, such machines could run up to 200 000 rpm [39.93]. Microscale pumps with ball bearings have also been investigated. They could feed hydrogen or alcohol to miniaturized fuel cells for electrical generation or microturbines for torque generation. Electric generators can also be built with this technology.

In the designs, a silicon raceway surrounds stainless steel microballs of 285 μm diameter. Friction is characterized using a *spin-down* test [39.94]. The friction platform is schematically represented in Fig. 39.16a. The rotor spins about the axis shown as driven by gas pressure that flow through stator vanes. The microballs enable the spinning and fill 85% of the racetrack. Normal force is provided by gas pressure through the thrust plenum flow, as shown in Fig. 39.16b. An optical probe measures radial displacement. Figure 39.16c shows spin-down data after the turbine flow is shut off. A simple friction torque model captures the data very well in this case.

Similar spin-down tests after increasing numbers of cycles (up to 200 million cycles) were used to characterize wear with raceways coated by SiC and TiN [39.95]. The SiC coating was quickly removed due to adhesive wear, and the balls adhered to the underlying silicon surface. The TiN coating wore gradually in select areas. Bare silicon raceways experienced high pressure, as evidence by a phase change to an amorphous phase as evidenced by Raman spectroscopy. The US Army is now supporting this research. Future work will address the ball strength and study the effect of molecular monolayers.

39.3.2 In-situ TEM for Friction Investigations

While driven by applications such as accelerometers, gyroscopes and displays, microtechnology evolution has also been heavily leveraged to develop ever more sophisticated scientific instruments. One example i the

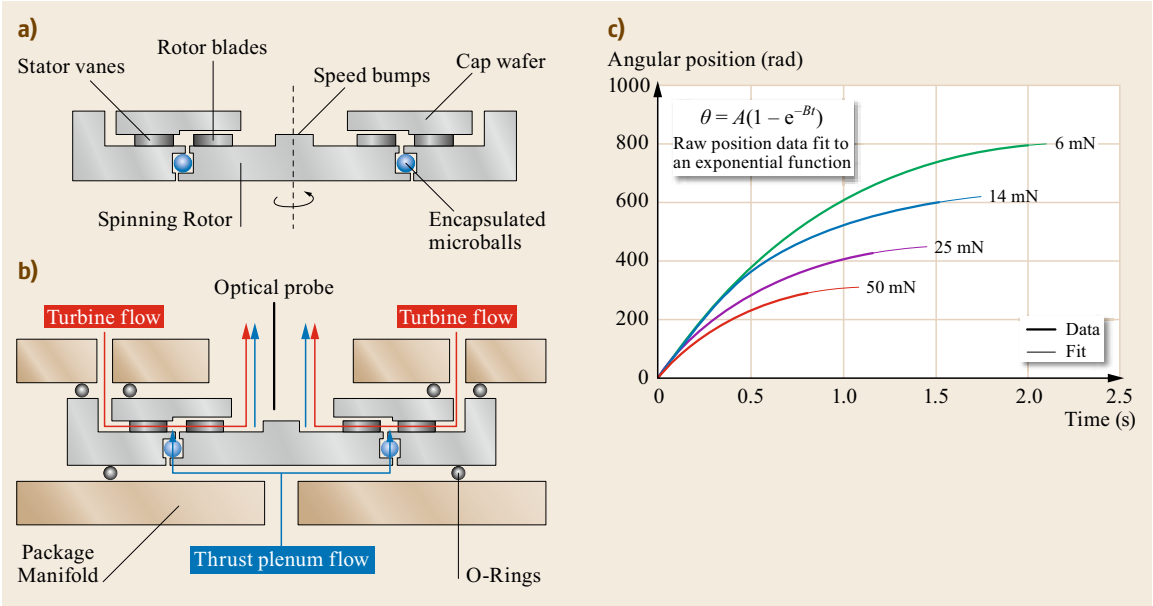

Fig. 39.16a–c Ball bearing friction test platform. **(a)** The rotor spins about the axis shown as driven by gas pressure that flow through stator vanes. The microballs enable the spinning. **(b)** Normal force is provided by gas pressure through the thrust plenum flow. An optical probe measures radial displacement. **(c)** Output data as a function of normal load from 6 to 50 mN (after [39.94])

push-to-pull indenter available from Hysitron [39.96, 97]. Transmission electron microscopy (TEM) has been applied to gain detailed images of the tips that are so widely used in FFM, both before and after use [39.98]. Wear has been analyzed by a transition state theoretical approach [39.99]. In-situ TEM friction force tools have also been recently been constructed [39.100–102]. The MEMS in-situ TEM platform of *Sato* et al. [39.102] has enabled real-time TEM imaging of shearing action on a Ag-Ag nanoasperity junction. This method may allow detailed observations of shear-induced dislocation motion at the interface versus in the bulk.

39.4 Wear and Tribopolymer Evolution in Micro- and Nanoswitches

We now present some closing thoughts on another nanotribology issue of great current interest. Micro- and nanoswitches afford many potential advantages including high switching speeds (ns to μs), low power operation (aJ to nJ per cycle), and high-temperature operation. Microswitch applications envisaged include radio-frequency phased array radars [39.103] and downstream circuit breakers [39.104]. Nanoswitches are attracting attention as candidate devices to complement metal oxide semiconductor field effect transistors (MOSFETs) in digital logic [39.105, 106]. MOSFETs are limited to ≈ 1 V operation, and begin to leak significantly as the voltage is reduced, creating static power losses [39.107]. Some nanoswitch designs employ electrostatic actuation and can switch in 10–20 ns [39.108] at gate voltages < 10 V while other designs use piezoelectric materials [39.109] and can be switched at voltages as low as 1 mV. These devices have shown negligible off-state leakage. Significant dynamic power savings can also be realized with nanoswitches. An important challenge in commercializing *microswitches* is that the electrical contact resistance (ECR) must often remain low (≈ 1 Ω) and stable over 10^8–10^9 cycles [39.103, 110]. This requirement may be relaxed for *nano*switch digital logic applications because even at several kΩ, mechanical delay time is large compared to electrical delay time [39.106]. However, to fulfill industry needs, they must also function reliably up to 10^{16} cycles. Their low-power consumption makes them exciting candidates for sensors in the developing internet of things (IoT) devices [39.111].

Given the daunting challenge of ultrahigh cycles, fundamental insight into the underlying reliability mechanisms must be gained. One important issue is ma-

terial wear [39.113]. We close here with some thoughts on the more poorly understood issue of tribopolymer (TP) development. It is well- known from *Hermance* and *Egan* [39.114] and subsequent work [39.115] that switch resistance is sensitive to trace levels of organic vapors, which can develop into TP when subject to shear. Such vapors are typically present in the atmosphere at the parts per billion (ppb) level. Because of the nN forces and mV levels in nanoswitches, a thin adsorbed layer must be considered as a potential cause of high resistance. TPs can deposit on nearly any material from both short- and long-chain molecules [39.114].

The ambient background may play an important role in their adsorption and evolution as well. *Brand* et al. have performed tests in both N_2 and $N_2 : O_2$ ambience [39.112, 116]. Figure 39.17 shows how the ECR of vacuum-baked switches increases when cycled in 0.25% by volume benzene. For Pt-coated switches, ECR rapidly rises with cycle count in an N_2 environment (Fig. 39.17a), but more slowly in $N_2 : O_2$ (Fig. 39.17b). RuO_2 is reported to be a catalytically *deactivated* surface [39.117] that has been used to enhance reliability in reed relays, but in an N_2 environment, ECR rises quickly (Fig. 39.17c). However, in an $N_2 : O_2$ environment, ECR remains stable at just 30 Ω in spite of the very high benzene concentration. Much less TP was generated in the case of Fig. 39.17d compared to Fig. 39.17a–c as indicated by SEM imaging [39.112]. Bridging oxygens may act to desorb the benzene and are subsequently replenished in the $N_2 : O_2$ atmosphere. Another important observation is that these switches were cycled under cold switching conditions, in which 5 V is applied to the contacts only after they were closed. It appears that the TP breaks down electrically and forms a graphitic layer that conducts [39.118]. In the absence of current, a thick insulating layer builds up even under repetitive normal load cycling.

Materials, environment and cycling conditions each play a significant role in micro- and nanoswitch reliability. This short overview indicates that fundamental understanding of the mechanisms leading to contact degradation may enable a tribological interface to be engineered that will meet device reliability requirements.

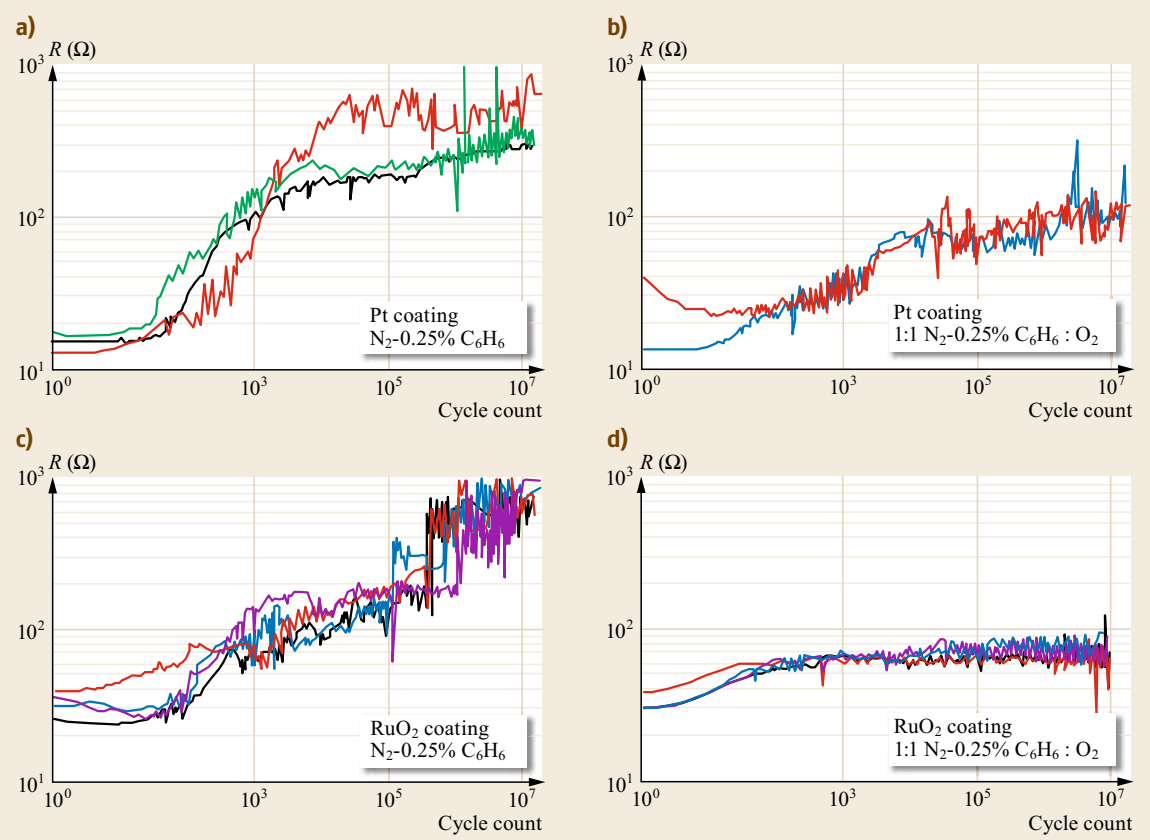

Fig. 39.17 ECR versus cycle count for Pt and RuO_2 coating in N_2-0.25% C_6H_6 and 1 : 1 N_2-0.25% $C_6H_6 : O_2$ atmospheres (after [39.112])

39.5 Concluding Remarks

We have reviewed the background and taken a whirlwind tour of the status and recent progress in micro- and nanotribology. Understanding and solving the challenging issues in this area could enable components such as forceful linear actuators and micropowered pumps, motors and generators to come into use. Low-power switches may become integral to IoT sensors. In order to attain these goals, further progress towards a fundamental understanding of the links between interfacial shear and normal stress and the effect of intended (and unintended) lubricants is needed. Rate-state phenomenology is a promising framework for understanding friction at many length scales.

Acknowledgments. This work was partially supported by NSF CMMI Grants 1030322, 1030278 and 1334572. SSS was supported by the NSF Graduate Research Fellowship Program. Many of the MEMS devices discussed were fabricated by Sandia National Laboratories, Albuquerque, NM, USA. Certain commercial equipment, instruments, or materials are identified in this chapter in order to specify the experimental procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology, nor is it intended to imply that the materials or equipment identified are necessarily the best available for the purpose.

40. Failure Mechanisms in MEMS/NEMS Devices

W. Merlijn van Spengen, Robert Modliński, Robert Puers, Anne Jourdain

The commercialization of MEMS/NEMS devices is proceeding slower than expected, because the reliability problems of microscopic components differ from macroscopically known behavior. In this chapter, we provide an overview of the state of the art in MEMS/NEMS reliability. We discuss the specific, MEMS-related problems caused by stiction due to surface forces and electric charge. Materials issues such as creep and fatigue are treated as well. Nanoscale wear is covered briefly. MEMS packaging is also discussed, because the reliability of MEMS/NEMS components critically depends on the available protection from the environment.

References 1454

With the rapid spread of micro-electromechanical systems (MEMSs) technology in the 1990s, it has become clear that the reliability of microscopic mechanical devices is a large concern [40.1]. It is one of the main reasons that much of the micromechanical technology available all over the world in laboratories has not been commercialized yet. The route from a working prototype to a commercial MEMS component should not be underestimated: the pioneering effort of Texas Instruments to bring the digital micromirror device (DMD) MEMS chip to the market took more than 10 years after its invention [40.2]. The same holds for gyroscopes and accelerometers: many years of hard work were spent on the conversion of laboratory prototypes to commercial products [40.3].

The failure mechanisms of MEMS/NEMS (in the rest of this chapter we will use MEMS as a generic name that also includes devices with nanometer-scale features, which are increasingly being referred to as nanoelectromechanical systems (NEMSs)) components are widely differing from those of their macroscopic counterparts, and this is the main reason that this trajectory takes so long. Many MEMS designers still do not take into account the implications that the scale difference has on reliability when designing new devices, although the paradigmatic approach of *design for reliability*, i. e., taking into account reliability issues from the earliest design stage, is gaining more acceptance. A second point is that, even if people are willing to take into account all the available information on the failure modes and mechanisms of MEMS, they soon discover that not so much is known at all. Still, over the last few years, the information available on MEMS failure mechanisms has been steadily growing [40.4]. At present, we are not yet in a position to predict quantitatively when or where most of the different failure mechanisms will occur, but we can describe them in some detail and give rules of thumb to avoid many of them.

In this chapter we will introduce the basic MEMS failure mechanisms and point out when they are important and in which respects they differ from macroscopic failure mechanisms. We will study the most important of them in some detail and give recommendations for procedures that are known to counteract them.

40.1 Failure Modes and Failure Mechanisms

We have to start with a clear distinction between failure modes and failure mechanisms. The failure mode is the apparent failure. It might be that, e.g., a MEMS beam is stuck to the substrate. If this causes a device to malfunction, the failure mode of the device is a stuck beam. This failure mode may be caused by different failure mechanisms, such as stiction of the beam (stiction is a generic term for surfaces being stuck due to surface forces), it may be a fatigue fracture failure or caused by an overload condition, and so on. The failure mechanism is hence the physical cause of the failure mode. In Fig. 40.1 the failure mode is broken beams, but the failure mechanism is rough handling, causing a mechanical overload condition.

This distinction is important because often the failure mode is reported when something is wrong, while the problem can only be accurately addressed by investigating the failure mechanism. In Table 40.1, the most commonly encountered failure mechanisms are given (most of them taken from [40.5]).

Dedicated equipment to assess failure mechanisms is definitely needed, but only a few set ups have been reported to date. Sandia National Laboratories is famous for their Sandia high-volume measurement of micromachine reliability (SHiMMeR) system, where they can test a significant number of rotating micromachines simultaneously under various environmental conditions [40.6]. The operation of the micromotors is monitored with advanced software tools [40.7]. Inter-University Microelectronics Center (IMEC) has a dedicated system to assess radio-frequency (RF) MEMS switch reliability, where environmental conditions can be altered with in situ optical access and various stimuli can be applied [40.8]. Interferometry- and vibrometry-based optical systems of various kinds are in use to monitor the dynamic behavior of MEMS devices [40.9–12] (Fig. 40.2). Some commercial laboratories also have their dedicated systems but do not disclose their exact set ups.

Other equipment that is used for failure mechanism assessment has not been developed exclusively for MEMS, but the MEMS reliability community is relying heavily on them: scanning electron microscopy (SEM), focused ion beam (FIB) cross-sectioning, atomic force microscopy (AFM), optical microscopy, and various electronic actuation and detection systems are the most widespread among them.

Table 40.1 Common MEMS failure mechanisms

Fracture	Overload fracture Fatigue fracture
Creep	Applied stress Intrinsic stress Thermal stress
Stiction	Capillary forces Van der Waals molecular forces Electrostatic forces Solid bridging
Electromigration	
Wear	Adhesive Abrasive Corrosive
Degradation of dielectrics	Leakage Charging Breakdown
Delamination	
Contamination	
Pitting of contacting surfaces	
Electrostatic discharge (ESD)	

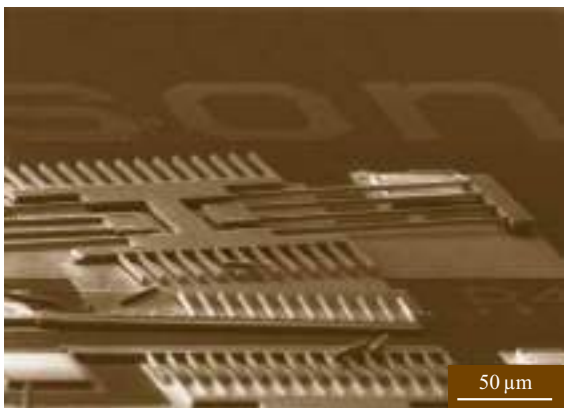

Fig. 40.1 The failure mode of this resonator is broken beams; the failure mechanism is rough handling, causing an overload stress in the beams and support

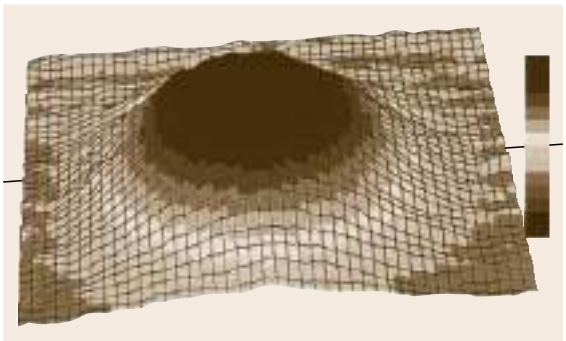

Fig. 40.2 Example of optical assessment of dynamic MEMS behavior: laser television (TV) holography measurement image of the first resonance mode of a MEMS pressure sensor membrane (after [40.8])

40.2 Stiction and Charge-Related Failure Mechanisms

40.2.1 Stiction Due to Surface Forces

One of the most important problems in MEMS/NEMS devices is stiction, i. e., the unintentional sticking of contacting surfaces (Fig. 40.3). Because forces intentionally generated in MEMS by, e.g., electrostatic actuation are generally very small, surface forces can dominate the device behavior. The fact that MEMS surfaces are so smooth that a large part of the surfaces is within the range of the atomic forces of the other surface aggravates the matter further. The most important surfaces forces commonly listed are: forces due to capillary condensation, van der Waals molecular forces, and chemical and hydrogen bonds between the surfaces. Surfaces tend to stick together when they are dried after the release etch, and a good overview of what happens is given by *Mastrangelo* and *Hsu* [40.13, 14]. From a reliability point of view, in-use stiction is more important.

The capillary condensation, van der Waals forces, and bonding force effects mentioned have in common that they are true interface forces. The force depends in this case on the situation at the interface, and not on effects far away from it. All these forces have in common that they are strong for surfaces very close together but fall off relatively fast when the distance is larger than a few nanometers.

As a result, surface roughness is an important parameter governing the stiction force, because the surface roughness of MEMS devices is commonly found to be of the same order of magnitude as the range of the surface forces (Fig. 40.4). This was demonstrated for the first time by *De Boer* et al. [40.15]. They monitored one-side-clamped free-standing cantilever MEMS structures that were stuck over a considerable part of their length, using an interferometer (Fig. 40.5). Fringes in the image indicated which part of the beams was free-standing and which part was stuck. Because the restoring spring force of the beams was known, the length over which the beams were not stuck gave a measure for the surface interaction energy (Fig. 40.6 and Table 40.2).

We have to distinguish for this calculation between beams that adhere only at the tip (*arc-shaped*) and beams that adhere over a considerable length (*S-shaped*). It was argued by De Boer and coworkers that the S-shaped beam gives a more precise measure for the surface interaction energy because the arc-shaped beam introduces a large statistical error; only the properties of the surface at the very small contacting tip produce the measured result. Arc-shaped beams can very easily be used to find the surface interaction energy to first order however, because we only have to look at which beams are stuck and which beams are free-standing.

De Boer et al. [40.15] found that the surface interaction energy varied considerably with the relative humidity and attributed this effect to capillary condensation. Small liquid bridges are supposed to form when two hydrophilic surfaces are in close contact (Fig. 40.7).

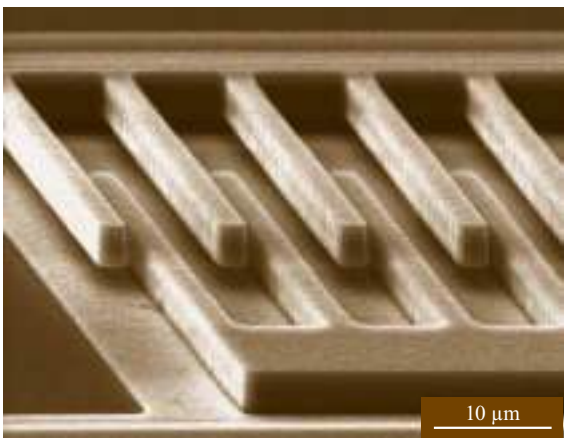

Fig. 40.3 Stiction failure of a comb drive

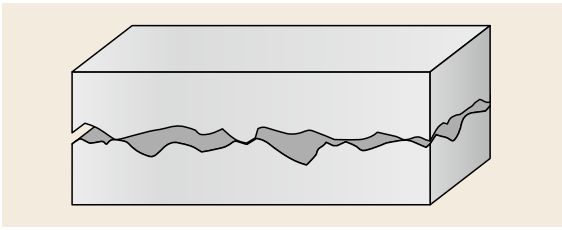

Fig. 40.4 Two rough surfaces in contact

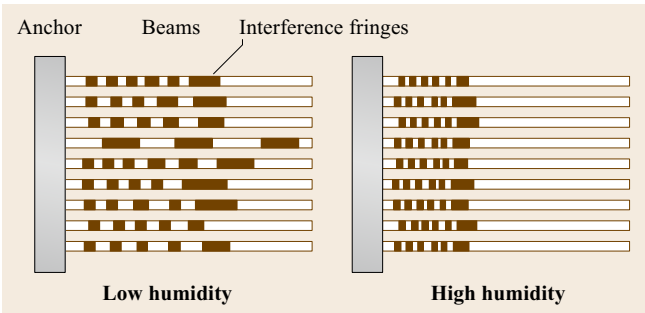

Fig. 40.5 Schematic top view of the measurement of adhesion as a function of relative humidity using interference imaging by *De Boer* et al. [40.15]. The *dark parts* are fringes created with an interferometric objective. The fringe pattern reveals where the beams are bending, and where they are flat, because fringes are only observed where the beams are not running perfectly in plane

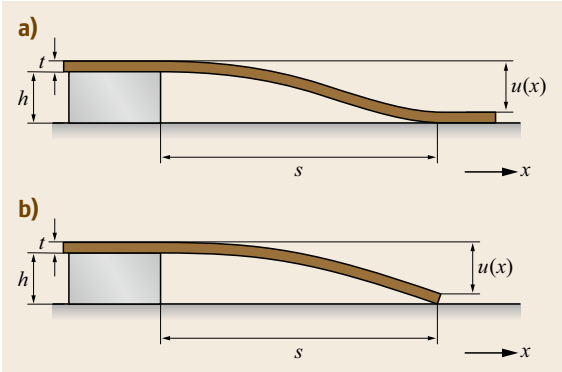

Fig. 40.6 (a) S-shaped beam; (b) arc-shaped beam

This effect had already been reported by *Bowden* and *Tabor* in 1950 [40.16] with a macroscopic measuring apparatus, but only with the development of MEMS technology has capillary condensation become a big technological issue. Because only the surface area that is closer to the other surface than a characteristic distance will be bridged by capillary condensed water, generally only part of the surface area is in contact in this sense.

Maboudian and *Howe* [40.17], *Legtenberg* et al. [40.18] and *Tas* et al. [40.19] provided the first quantitative models of stiction, making use the work of *Israelachvilli* [40.20] on more generic systems. They described the surface forces as a function of the distance between two flat surfaces. The relation between surface interaction energy and distance for capillary forces (a function of humidity) and of van der Waals molecular forces (a function of the Hamaker constant of the molecules at the surface) was presented with very general applicability.

The roughness of the surfaces (some parts are closer together and contribute more to the stiction force than others) was discussed briefly by *Komvopoulos* et al. [40.21] and more quantitatively by *van Spengen* et al. [40.22]. The procedure boils down to the determination of a distance distribution function $h(z)$, giving the amount of surface at every distance z from the other surface (Fig. 40.8). The total surface interaction energy Γ_i due to a certain i-th force $e_i(z)$, e.g., the van der Waals force, is then given by

$$\Gamma_i = \int_0^\infty e_i(z)h(z)\mathrm{d}z\,. \tag{40.1}$$

This principle is generally applicable. As long as the forces do not influence each other, they will be reasonably well described by (40.1) and can be added together.

It is not easy to predict the distance distribution function $h(z)$, as the two surfaces may deform each other at the contacting points, giving rise to both plastic and elastic deformation. If we know the height distribution of the contacting surfaces independently, a rough estimate can be obtained by assuming only plastic deformation. This gives rise to the *bearing area* representation [40.22], from which the distance distribution can be obtained. Unfortunately, the surface interaction energy value obtained in this way is expected to be too low, as elastic deformation is expected to bring larger parts of the surfaces closer together than in the fully plastic case. Purely elastic deformation can be treated by the Greenwood–Williamson model [40.23], but has been found to be useful from an experimental point of view only for very soft, elastic materials like rubber. The technologically more interesting cases (silicon on silicon, metals etc.) are best described with a mixed plastic/elastic model, but unfortunately only numerical simulations can be employed to describe this [40.24, 25].

A more experimental approach to characterize the rough contact between two MEMS surfaces is followed by *Kogut* et al. [40.26], who use electrical current mea-

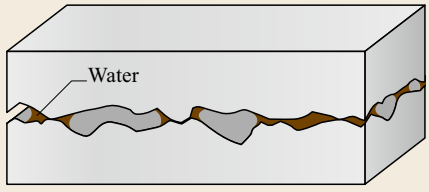

Fig. 40.7 Capillary condensation occurs on all places where the two contacting surfaces are closer together than a characteristic distance

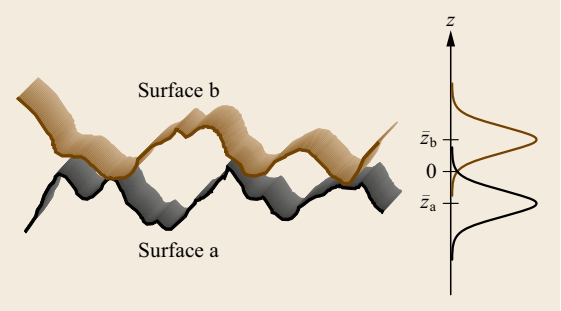

Fig. 40.8 The two surface-height distribution functions give rise to a distance distribution function $h(z)$ describing how large the part of the surface is that has an interaction with the other surface at a certain distance

surements through the contacting points to estimate the real contact area.

Whether the resulting surface interaction energies from the different force contributions result in a stiction failure or not depends on the restoring force. The peel number N_p (first coined by *Mastrangelo* and *Hsu* [40.14] and very well explained by *Zhao* [40.27]) can be used to find out whether a structure will suffer from stiction. For $N_p < 1$ the surfaces will adhere, while for $N_p > 1$ the surfaces will separate again if they are brought into contact.

The most cumbersome stiction force is that caused by capillary condensation. Water will only capillary condense onto hydrophilic surfaces, so a hydrophobic coating can be applied to prevent this. These layers are not unlike the boundary lubricants that have been used for decades to lower friction. Different ways of creating hydrophobic coatings have been applied but there is no industry standard yet. Antistiction coatings are generally made by either plasma deposition or self-assembled monolayer (SAM) deposition. The standard film quality test method is to bring a small water droplet to the surface and monitor the contact angle.

The gas used for the plasma deposition is usually a low-molecular-weight fluorinated organic compound, such as CHF_3 [40.28] or C_4F_{10} [40.29]. The MEMS device is bombarded with all kinds of free radicals and other reactive species generated from these molecules and forms a well-adhered water-repelling coating on the surfaces of the device. A big problem with plasma deposition is obtaining conformal coatings. Tricks such as having a Faraday cage inside the chamber are advantageous [40.29], but even then the conformity is usually not better than 2 : 1 for the top and bottom surfaces of a MEMS device.

The durability of plasma-deposited coatings is relatively good, although they tend to come off in boiling water. *Man* et al. [40.29] tested their films for water contact-angle changes at elevated temperatures. By determining the lifetime at different temperatures and using an Arrhenius relation for the mean time to failure (MTTF)

$$\mathrm{MTTF} \propto \exp\left(\frac{E_a}{k_B T}\right) , \tag{40.2}$$

they calculated a lifetime of more than 10 years at 150 °C. Knowing the Boltzmann constant k_B, one can obtain the activation energy E_a by performing experiments at different temperatures T. Impact wear was also tested.

To overcome the conformity problems associated with plasma deposition, and also because very thin layers are possible in this way, SAM coatings have been investigated since the middle of the 1990s. *Srinivasan* et al. [40.30] reported extensively on the subject. Silicon microstructures are released in HF, and while still in the liquid phase, the HF solution is replaced by a trichlorosilane solution. The most common are octadecyltrichlorosilane (OTS, $CH_3(CH_2)_{17}SiCl_3$) and 1*H*,1*H*,2*H*,2*H*-perfluorodecyltrichlorosilane (FDTS, $CF_3(CF_2)_7(CH_2)\ SiCl_3$). Figure 40.9 shows how such a film is formed on the surface of a MEMS device. A processing problem is that the reaction depends on trace amounts of water in the reaction environment. If the processing conditions are not extremely well controlled, micelles are formed as well as highly interconnected surface films that are easily peeled off [40.31].

Thermal stability tests show that, in air, the fluorocarbon films are able to stand 400 °C while the hydrocarbon films will degrade above 100 °C. In nitrogen no difference was observed [40.31]. *Kim* et al. [40.32] have suggested that the use of dimethyldichlorosilane (DDMS, $(CH_3)_2SiCl_2$) results in a process that is less sensitive to temperature, humidity and coating time. The films thus created withstood temperatures of above 450 °C without degradation.

De Boer et al. [40.15] found that FDTS films were susceptible to *water island formation* in a 90% rela-

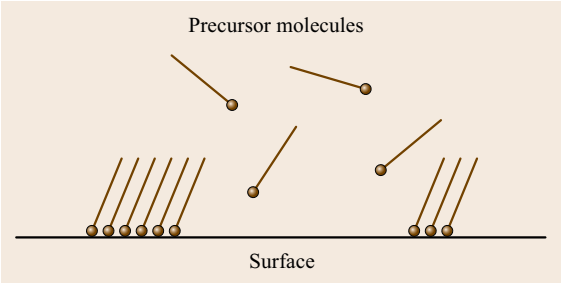

Fig. 40.9 SAM formation on a MEMS surface

tive humidity environment after only a few hours, while OTS films did not show such a dramatic effect. Whether this was a real difference or merely an effect of a difference in surface film quality has not been elucidated.

Another method besides antistiction coatings to reduce stiction problems is roughening the surfaces so that only small parts of the surfaces are in intimate contact. *Maboudian* et al. [40.17] show how this can be accomplished with different etchants (this also decreases van der Waals contributions). An absolutely water-free environment will also prevent capillary condensation problems altogether. The hermeticity of packages to accomplish this is discussed in the packaging section of this chapter (Sect. 40.3.4). The best solution to stiction due to surface interaction energies is the use of very stiff structures and high forces, which will separate the surfaces even under high adhesive contact forces. A typical higher limit for the surface interaction energy due to capillary forces is $0.1\,\mathrm{J/m^2}$ [40.17], which corresponds to water everywhere between the surfaces. Surface interaction energies in rough devices and with antistiction coatings are typically 10–1000 times lower. If these numbers are taken into account, finite element modeling of the structures before they are produced can be used to predict whether stiction due to surface forces will be a reliability threat or not.

40.2.2 Stiction Due to Electrostatic Attraction

Stiction due to dielectric charging is different from the previously discussed forces in the sense that it is not a true interface force. Charges may be present at the interface but may equally well reside in the bulk of a dielectric material. Electrostatic forces are very important on the microscale and hence an in-depth investigation of charge effects is important.

Charges may be generated in microsystems in different ways. It has been found that in devices with rubbing surfaces tribocharging may occur [40.33]. A rotating silicon micromotor was tested until it remained stuck due to the accumulated charge. Irradiation with a focused ion beam (FIB) neutralized the charges, after which the device resumed operation. Another situation where charge may be generated is where sparks in a small gap spray charge onto a surface [40.34]. Contact potentials of materials are usually $< 0.5\,\mathrm{V}$ and are not expected to give any trouble in normal applications.

Charges generated by irradiation with ionizing radiation constitute a considerable challenge in MEMS devices. Accelerometers subjected to nuclear radiation were found to drift with increased dose because the dielectric under the moving mass of such a device was charged [40.35, 36]. Accelerometers without a dielectric under the moving mass were found to be much less susceptible, because no charge can accumulate (Fig. 40.10). One can imagine that excessive radiation would cause the moving mass to snap in and constitute a stiction failure, but this has not yet been reported.

The largest problems with stiction due to electrostatic attraction are found in devices where a large voltage is applied across a thin dielectric, such as in RF MEMS switches [40.37]. The high field causes charge injection into the dielectric by Schottky- or Poole–Frenkel-type conduction and is experimentally found to depend exponentially on the actuation voltage [40.38]. The situation resembles that of the high-k-dielectric gate oxides of the newest generations of metal–oxide–semiconductor (MOS) transistors, where similar charging effects threaten the stability of the threshold voltage [40.39].

The exact charging properties of a dielectric thin film depend on the deposition conditions. A *leaky* dielectric with a low resistivity may have many trapping sites, but can still be good from a technological point of view if the charge can flow away easily [40.40]. The films have to be empirically optimized because no consistent theory to describe good films has been developed yet.

Much more is known about how parasitic charges, when they are present, influence device behavior. For a free-sanding structure with small-scale deflections, *Wibbeler* et al. [40.34] have presented a theory that describes the deflection as a function of the accumulated charge. *Reid* [40.41] has shown finite element model-

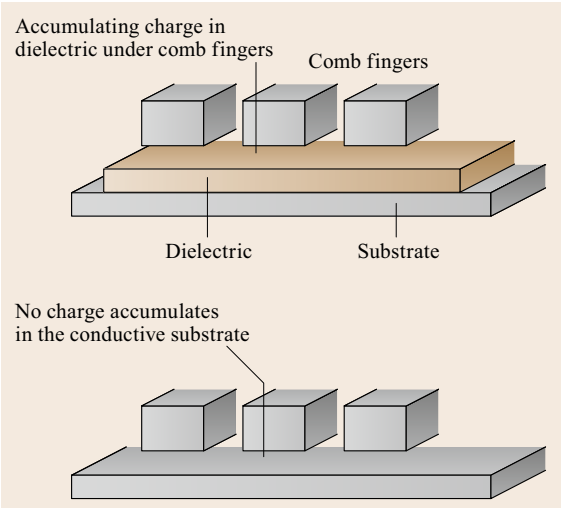

Fig. 40.10 Ionizing radiation can cause charging of the dielectric under the cantilevers (that are part of the moving mass) of an accelerometer and hence cause drift and in extreme cases stiction of the moving part

ing (FEM) simulations for large deflections, pull-in and pull-out effects and the effect of parasitic charge on them.

The most comprehensive efforts, which are very useful from the point of view of failure due to stiction, are the treatises of *van Spengen* et al. [40.42] for uniform charge densities in the dielectric and *Rottenberg* et al. [40.43] for inhomogeneous charge densities. These two papers consider RF MEMS switches, but the principles are generic.

In these models, elementary electrostatics is used to describe the peculiar dynamic effects in MEMS with a structure like that in Fig. 40.11. A free-standing structure (the *bridge*) is located above a dielectric with a lower conductor. The whole assembly behaves as a capacitor. When a voltage is applied between the bridge conductor and the lower conductor, the bridge is attracted. If the bridge is moved over more than one third of the gap, the system becomes unstable and the bridge lands on the dielectric (pull-in). At this point the capacitance of the system becomes much higher and this is the reason that it can be used to affect RF electronic signals. A much lower voltage is required to keep it there, so we have to lower the actuation voltage considerably to let it *pull out* again. This hysteresis is well known from RF MEMS *C–V* curves (Fig. 40.12).

Both positive and negative actuation voltages can cause the bridge to pull in (the *C–V* curve is symmetric for positive and negative voltages). For a uniform parasitic charge, the curve starts to shift. Negative charge causes the curve to shift to the right, while positive charge shifts the whole curve to the left on the voltage axis.

The effect of positive charge is easily understood: when the curve shifts so much to the left that the pull-out voltage crosses the 0 V line, the bridge will remain stuck even if the actuation voltage is removed. A negative charge results in a more tricky behavior. For small charge values, the pull-in and pull-out voltages will shift slightly upward so no stiction is expected. If too much charge accumulates, the pull out of the negative-going actuation will shift through 0 V (Fig. 40.13). For slow, positive-going voltages, this makes no difference. When we increase the voltage on an initially free-standing bridge, it will pull in at the shifted positive pull-in voltage, and return to its upward position when the voltage is again slowly decreased to below the pull-out voltage. Only when we go negative in actuation voltage will the bridge be pulled in again at the shifted negative pull-in voltage.

But when we change the actuation voltage quickly, as is often the case when devices are actuated, e.g., by a square wave, the behavior is completely different. We start in the same condition as before, with the bridge up, and increase the voltage quickly to above the pull-in voltage, the bridge will be pulled in after a characteristic time that is related to the mechanical resonance frequency of the device. When we quickly reduce the voltage to 0 V, the bridge stays behind again and is still down when the voltage is 0 V. However, now we are in a completely different situation. Because the pull-out voltage of the negative branch of the curve is positive,

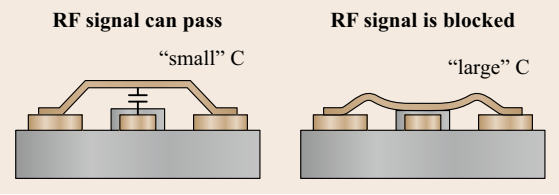

Fig. 40.11 RF MEMS switch cross section

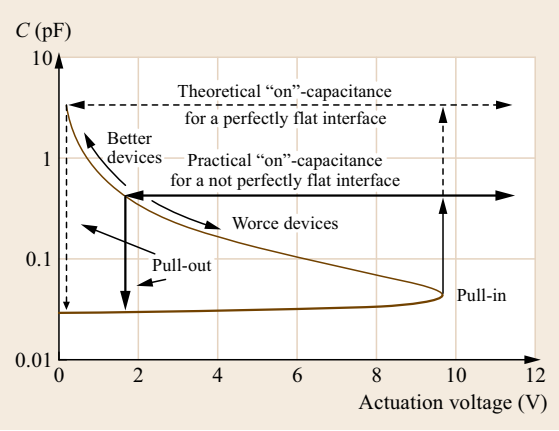

Fig. 40.12 *C–V* curve

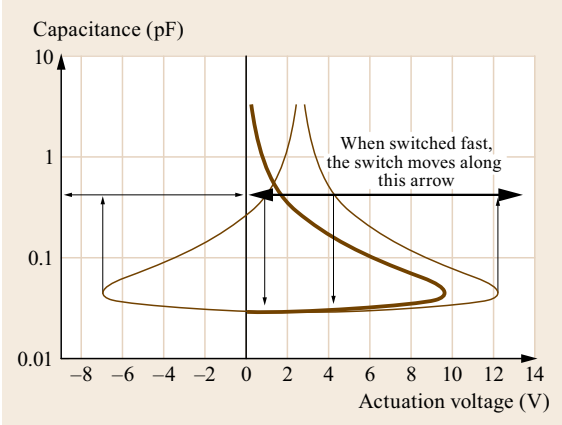

Fig. 40.13 With square-wave actuation, after the negative pull-out voltage has crossed 0 V due to a parasitic charge, the device moves only along the *bold arrow* and remains stuck

the bridge will remain stuck. The bridge does not know whether it came from a negative voltage or from a positive voltage. For a negative voltage it would only pull out above 0 V at the negative-branch pull-out voltage, so it will remain stuck. In this way both positive and negative charges can cause a MEMS device to remain stuck. It is even possible to calculate the approximate magnitude of the charge that is required to cause stiction in either case. The important case in which the negative pull-out voltage crosses zero and causes a device failure has also been verified experimentally [40.42].

Not only charge injection due to high voltages across the dielectric may cause this kind of reliability problems to emerge; ionizing radiation can also play a similar role. It has to be kept in mind however that, if the bridge or other moving structure does not intentionally or accidentally hit the surface below, stiction can only take place when the charge causes a shift that is so large that the much higher pull-in voltage crosses 0 V from either side.

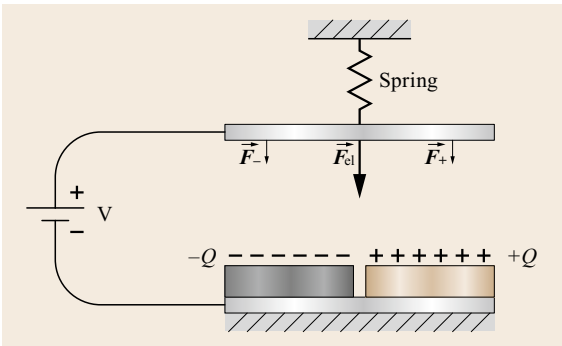

Fig. 40.14 A nonuniform charge can generate attraction of the upper conductor even when the net charge is zero (after [40.43])

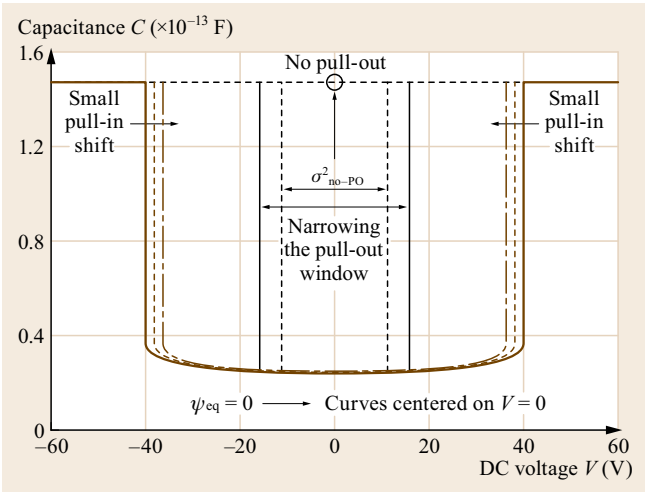

Fig. 40.15 The nonuniform charge causes the pull-out voltage to move to 0 V; in extreme cases the pull-out voltage disappears (after [40.43])

The previous explanation is valid only for uniform charge distributions (either bulk or surface charge). *Rottenberg* et al. [40.43] have extended the theory to deal with nonuniform charge distributions that give rise to effects that have also been experimentally observed. The nonuniform distribution can cause a nonzero force even when the net charge on the dielectric is zero (Fig. 40.14). This causes a narrowing of the C–V curve so that the positive and negative pull-out and pull-in are closer together (Fig. 40.15).

In conclusion, even relatively small charge values of both polarities that are present in or on a dielectric may affect the device reliability when the moving part intentionally or accidentally hits the lower surface. If this is not the case, stiction can only occur when the C–V curve is shifted so much that the pull-in voltage crosses 0 V.

Reduction of the sensitivity for charging phenomena in MEMS devices can be accomplished in different ways. The most obvious way is the reduction of charging by optimizing the dielectrics for low charging. This can be done either by making a very-high-quality dielectric with few trapping sites, or by increasing the trap density but making sure that the average time a charge remains in a trap is very short (the *leaky dielectric*). Another option is to design the dielectrics that are prone to charging out of the device concept. In RF MEMS this can be done with separate actuation pads where no dielectric is located so that no voltage acts across the high-k dielectric. In the accelerometer example of Fig. 40.10, this was done by removing the dielectric altogether. The third option, but probably the least satisfactory because of its added complexity and device cost, is to use advanced actuation schemes to reduce charging. *Goldsmith* et al. [40.38] use an advanced actuation waveform with a high initial voltage to pull the bridge down and a lower *holding* voltage to keep it down, so that charging is reduced. Polarity reversal is also used to sweep out the charges that are accumulating [40.44]. Both of these are useful with actuation signals that are known in advance and do not depend on the particular application in mind.

40.3 Creep, Fatigue, Wear, and Packaging-Related Failures

40.3.1 Creep

Creep is the permanent and irreversible deformation of a ductile material occurring below the yield strength. Its importance depends on temperature, mechanical stress, time, and material composition. It is easy to think of a solid metal as having a well-defined yield strength below which it does not flow and above which flow is rapid. This is unfortunately true only at absolute zero. Above this temperature, plastic flow is a dynamic process, where the strength of solids depends on strain and temperature. The irreversible time-dependent part of a strain ε is called creep.

The strain rate $\partial\varepsilon/\partial t$ (elongation speed) is extremely temperature-sensitive. It can often be approximated by a rate equation

$$\frac{\partial\varepsilon}{\partial t} = A\exp\left(-\frac{q}{k_\mathrm{B}T}\right), \tag{40.3}$$

where A and q are the fit parameters, k_B is Boltzmann's constant and T is the absolute temperature.

Thermal vibrations aid the applied stress in overcoming specific barriers (e.g., obstacles) to induce plastic flow in the metal. Slip, climb, shear on grain boundaries, and vacancy diffusion inside the grain (the so-called Nabarro–Herring effect) are the mechanisms responsible for deformation in metals [40.45]. The last of these is significant only at very high temperatures and under very small stresses. The normal operating temperatures in most practical engineering applications are too low and usually the operating stresses are too high for the Nabarro–Herring mechanism to occur, so we can conclude that creep deformation in metals depends primarily on dislocation movement (slip, climb and grain-boundary shearing).

Three creep stages can be distinguished: primary, secondary (so-called steady-state creep) and tertiary creep, which ends up with fracture (Fig. 40.16). Especially devices made out of low-melting-point metals are sensitive to creep. This is the case because the melting temperature of a material has a major influence on its creep behavior. There exists a threshold temperature, which divides the deformation of a material by creep into two parts: high-temperature and low-temperature creep (Fig. 40.17). In the regime of high temperature, creep is a rather fast deformation and depends strongly on temperature, whereas in the low-temperature regime, the creep rate decreases logarithmically with time. It is commonly accepted that this threshold temperature T_c is given by $T_\mathrm{c} = 0.5T_\mathrm{m}$, where T_m is the absolute melting temperature, although each material must be evaluated separately [40.46]. For instance, T_c is around 200 °C for aluminum and its alloys and 315 °C for titanium alloys.

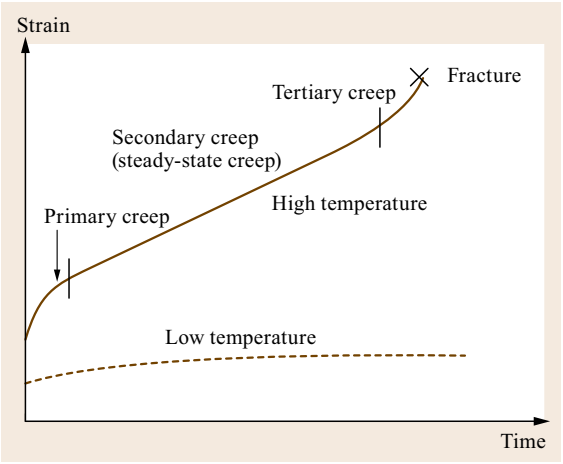

Fig. 40.16 Low-temperature and high-temperature creep under a constant stress (after [40.46])

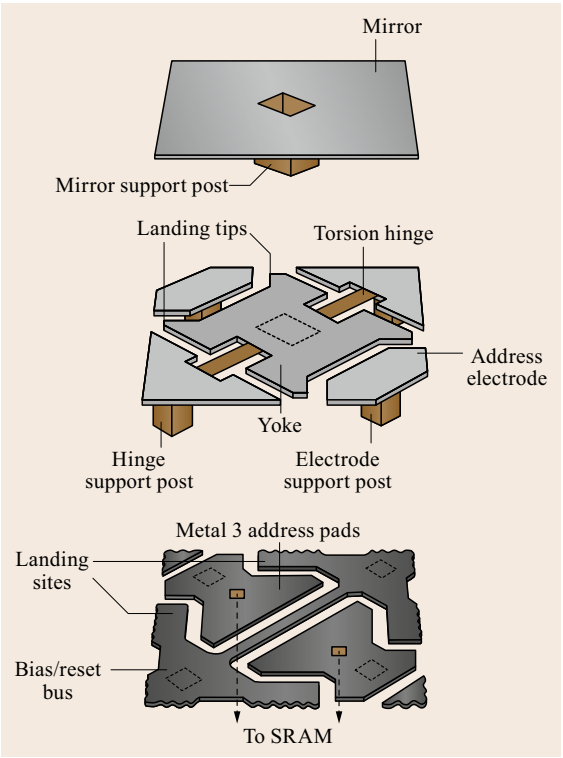

Fig. 40.17 Digital micromirror device for projection displays (© Texas Instruments)

Shape changes caused by creep can be undesirable and represent a limiting factor in the lifetime of a device. For instance, blades on the spinning rotors in turbine engines are endangered by creep. They slowly grow in length during operation and must be replaced before they touch the housing.

Some MEMS, like for instance RF MEMS switches can be affected by creep, and the creep properties of thin metal films are not necessarily the same as those of the bulk material.

Creep in MEMS

Creep is well characterized at the macroscopic level (usually under constant-stress/constant-temperature conditions), but has not been studied extensively in microsystems and therefore it can represent a reliability problem in MEMS. Many microdevices are fabricated by adopting low-melting-point metals (in particular aluminum). In most recent research work, long-term or accelerated reliability tests (i. e., creep tests) seldom attract much attention. In fact, feasibility studies are rarely conducted when starting research work (e.g., academic research). However, reliability became an issue in applications, where durability and reproducibility are a key element for commercial success. Creep can form a danger for commercial devices fabricated from low-melting-point metals, especially when operating at higher temperatures and stresses. Therefore, at an early stage of the design of metal MEMS, creep should be taken into account.

An important source of information on creep in MEMS is the work done by Texas Instruments on the digital micromirror device (DMD). *Van Kassel* et al. [40.47] have shown that creep was a problem in their micromirrors. This reliability problem was termed the hinge memory effect. Figure 40.18 depicts the sketch of a DMD. A single mirror is mounted on hinges and electrostatic attraction between the mirror structure and a semiconductor memory cell below is responsible for a $\pm 10^{\circ}$ tilt. Hinge memory occurs when a mirror is operated in the same direction for a long period of time (high duty cycle). A residual tilt when the voltage is removed appears over time. The lifetime of the mirror is reached when the residual tilt becomes excessive (dead pixels). *Van Kassel* et al. [40.47] related this effect to creep of the hinge material. The lifetime was increased by selecting more creep-resistant materials and by improving the fabrication process. The hinge memory effect was thermally activated. At 65 °C and high duty cycle, mirrors could operate for about 5000 h continuously, while at 45 °C they remained functional for more than 100 000 h even at high duty cycles.

Lee et al. [40.48] presented a test specimen for measuring fatigue and creep in microscale structures. They

Fig. 40.18 SEM image of a test specimen (after [40.48])

patterned wafers in the shape of common (macroscopic) tensile test specimens with 50 µm wide 500 µm long metal beams (Fig. 40.19). Al and Al-1.5 at.% Ti beams were tested in a piezoactuator-driven test apparatus. In stress relaxation tests (the samples were quickly loaded to a certain stress and then held at this strain while monitoring the change of stress), *Lee* et al. [40.48] observed a load drop of 56 and 15% for Al and AlTi beams, respectively. The measurements were carried out for 10 min at room temperature. Figure 40.20 shows these results. *Lee* et al. believe that the difference in the amount of relaxation was from Al_3Ti precipitates that are formed at the Al grain boundaries in the alloy samples. They showed that the microstructure accounted for the relaxation difference in the investigated films.

Cho et al. [40.49] presented creep data at elevated temperatures of electrodeposited lithography, electroforming and molding (LIGA is a German acronym for Lithographie, Galvanoformung, Abformung) nickel dog-bone-shaped microsamples. Figure 40.21 presents creep tests conducted at 265 and 290 °C at stresses significantly below the yield strength. The results clearly show the primary-creep regime, where the creep rate decreases with time, and a steady-state regime, where strain rate is constant in time. *Cho* et al. showed that the time needed to attain 0.5% creep strain (considered as being a significant deformation) was more that 6 h at 265 °C, 1 h at 290 °C and only about 4 min at 400 °C.

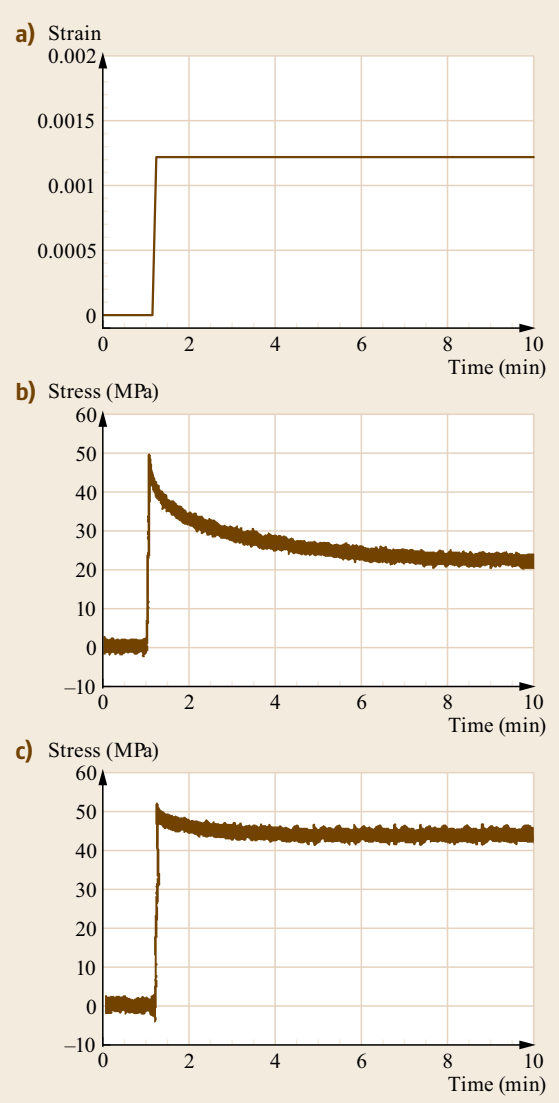

Fig. 40.19a–c Strain change with time **(a)** and corresponding stress change with time for Al beams **(b)** and AlTi beams **(c)** (after [40.48])

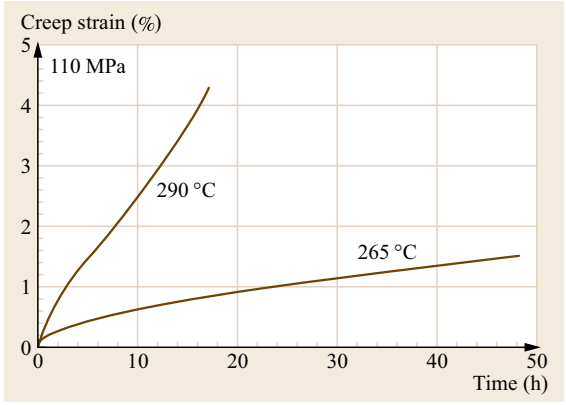

Fig. 40.20 Creep curves at 265 and 290 °C under the stress of 110 MPa (after [40.49])

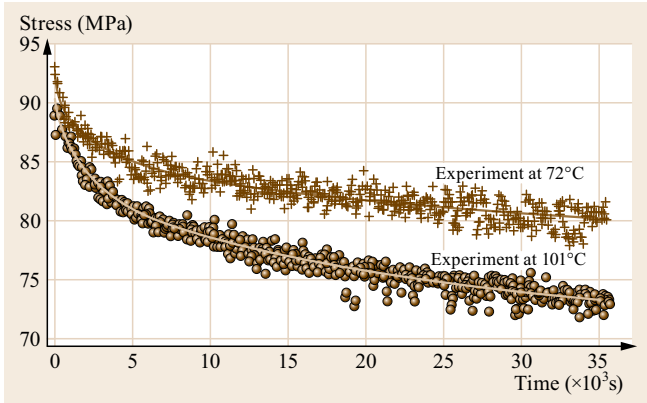

Fig. 40.21 Stress relaxations for Al-0.4 at.% Cu 5 µm thick film at 72 and 101 °C. *Solid lines* represent the fitted creep mechanism: dislocation glide limited by obstacles (after [40.50])

It is clear that the creep phenomenon is thermally activated and much more harmful to devices at elevated temperatures. However, *Larson* et al. [40.51] and *Yin* et al. [40.52] reported that some creep activity of nanocrystalline Ni was observed even at room and low temperatures. This means that for those materials care must be taken under almost any temperature conditions.

Hardened Pt alloys for MEMS have been presented by *Brazzle* et al. [40.53] to serve as creep-resistant materials. Solution-hardened Pt alloys for improved reliability of electromagnetically actuated micromirror devices exhibited precision angular displacement without observable fatigue and creep when used in flexures. *Brazzle* et al. [40.53] found that alloy 851 (79%Pt-15%Rh-6%Ru) and Pt(10%Ir) were very hard flexure materials. The alloying components (rhodium, ruthenium and iridium) impede dislocation movement, thereby increasing the yield strength and reducing fatigue and creep.

Modlinski et al. [40.50] have presented a simple way of selecting creep-resistant aluminum alloys for use in RF MEMS switches, but the technique is generically applicable. They propose substrate curvature measurements to study creep properties of Al alloy films using isothermal tensile stress relaxation (Fig. 40.22). The tensile stress relaxation data fitted well to a known deformation mechanism (dislocation glide limited by obstacles) in the temperature range 60–110 °C. The Al alloys studied were characterized by two creep parameters: the activation energy ΔF and the athermal flow stress τ. The higher these param-

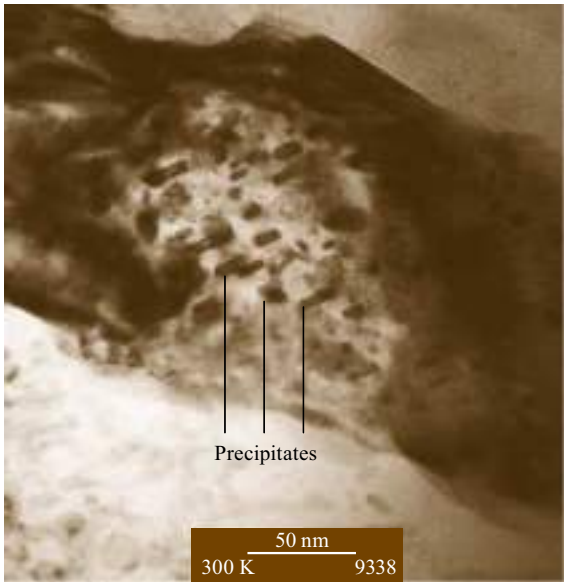

Fig. 40.22 TEM image of AlCuMgMn. Strong and highly dense precipitates hinder the dislocation movement in the grain interior

eters are, the more creep-resistant the alloy is. They selected a very promising Al alloy with the composition $Al_{93.5}Cu_{4.4}Mg_{1.5}Mn_{0.6}$ which has a very high ΔF (6.4 ± 2.5 eV) and τ (920 ± 420 MPa). It was also shown that there is a relation between the creep parameters and the microstructure of the Al alloys in more detail. The activation energy describes the strength of the precipitates, and also gives information about the coherency of the second-phase particles as well. The athermal flow stress, on the other hand, gives information on the density and arrangement of the obstacles. A transmission electron microscope (TEM) image of the AlCuMgMn alloy revealed very small, strong, coherent and/or semi-coherent (high-ΔF) and highly dense (high-τ) precipitates.

Creep is caused by the motion of dislocations inside grains in this temperature range. Impeding the dislocation motion inside the grains is a very effective way of increasing creep resistivity of an $Al_{99.6}Cu_{0.4}$ alloy thin film. It was done by a macroscopically well-known hardening mechanism: precipitation hardening. An increase of both ΔF (by 50%) and τ was observed.

RF MEMS switches are starting to be commercialized, but reliability is still a problem. Hot switching and the impact of RF power on the reliability of the MEMS switches has been extensively investigated, mainly by simulations. *Jensen* et al. [40.54], *Rottenberg* et al. [40.55] and many others reported that temperatures due to RF power present in some parts of a movable metal bridge are expected to be as high as 250 °C [40.54] and can easily exceed 100 °C. The high residual stresses (50–200 MPa) present in an RF MEMS bridge structure and the high temperatures caused by RF power may lead to creep deformation, deteriorating the functionality of a switch over time.

Creep Conclusion

At the macroscale level, creep tests are performed using tensile specimens subjected to constant stress and temperature. These tests are rather easy to prepare and perform. In microscale experiments, the situation is very different. There are no standardized specimens, and there is no standard way of investigating creep in microdevices. Some perform the tests on real MEMS devices (DMD); some try to mimic macroscopic tensile test specimens and use them in the microworld. A very good idea, although not often used, is to implement well-known macroscopic techniques to render a material more creep-resistant. For example, hardening mechanisms such as solution hardening or precipitation hardening are interesting in this respect. These treatments produce stronger obstacles and hence decrease dislocation motion.

The microstructure (grain sizes, precipitates in case of alloys) of deposited films is very process-dependent. There are no standard deposited films. For instance, Al alloy films will exhibit different creep behavior when sputtered under different conditions. Their properties depend on the deposition methods as well as conditions. This variation is a considerable challenge for microscopic creep research.

A human factor is certainly an issue in understanding the state of the art of creep in MEMS. Most engineers and scientists dealing with MEMS are silicon-or, in general semiconductor-oriented. Creep is not really an issue in monocrystalline silicon, polysilicon or silicon-germanium. There is probably a lack of know-how on plastic deformation in the MEMS society.

Research work in a field of metal plasticity in MEMS has been started. Increasing numbers of publications on understanding and investigating creep phenomenon on the microscale are being issued. MEMS engineers and scientists are facing new problems and challenges in metal MEMS, but fundamental research programs, discussions and exchange of views and knowledge of the plastic deformation of metals between specialists will speed up research in this field.

40.3.2 Fatigue

Fatigue of Metals

The only large source of information on fatigue of metal MEMS devices is again the research carried out by Texas Instruments of the digital micromirror device

(DMD). Macroscopically, the lifetime of many metal systems is limited by fatigue. A large, repetitive mechanical stress causes the accumulation of dislocation defects at the surface, resulting in fatigue cracks. In microscopic systems, the structural parts are only one, or a few grains thick, with very little dislocations. Therefore, not enough damage can accumulate at the surface to cause fatigue failures. It has been found indeed that MEMS devices suffer much less from fatigue than their macroscopic counterparts [40.56].

Fatigue behavior of materials is often shown in a so-called S-curve, in which the number of stress cycles to fracture is shown as a function of the applied maximum stress level. We usually find that at very high stresses only a small number of cycles is required to fracture the device, the low-cycle fatigue regime (Fig. 40.23). For lower stresses, the number of cycles increases. For very long low-stress cycling times, we find that different materials have different properties. Most steels, e.g., have a fatigue limit (Fig. 40.23a). Below this limit, the structure survives forever. Other materials, like aluminum, do not have such a threshold. The curve decreases slowly, even for very large numbers of cycles (Fig. 40.23b). Brittle materials such as ceramics do not have a cycling fatigue effect; below the fracture strength the lifetime is infinite, above it, they immediately break without any cyclic stress effect (Fig. 40.23c).

It has been found that high-cycle fatigue is thin films is very unlikely, as explained above. Aluminum RF MEMS switches have likewise never been reported to suffer from high-cycle fatigue [40.57]. An interesting feature of microscopic structures however is that low-cycle fatigue has been found in aluminum [40.58, 59]. This raises the question whether in thin films at very high cyclic stresses new defects are being formed, while at lower stresses only existing defects can move to the surface (and there are too few of them to do any harm). More research is definitely needed to figure out how the process really behaves, and where the turning point is between microscopic and macroscopic fatigue behavior. For the moment we can only say qualitatively that metals that macroscopically tend to have no threshold for fatigue do have such a threshold when used as thin films. Therefore the S-curve for thin-film aluminum resembles that of bulk steel (Fig. 40.23a) instead of bulk aluminum (Fig. 40.23b).

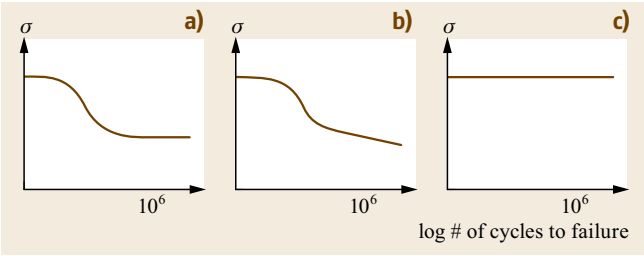

Fig. 40.23 (a) S-curve with threshold; (b) S-curve without threshold; (c) S-curve for ceramic

Fatigue of Silicon

From the early days of MEMS technology on, silicon in its mono- and polycrystalline form has been extensively used as a structural material. Silicon is a brittle material, and as such, should not intrinsically suffer degradation from fatigue (Fig. 40.23c). However, in air it is always covered with a native oxide, and concern was raised that this oxide might be susceptible to a stress corrosion cracking (SCC) phenomenon that is well known in glass technology [40.60]. SCC is the stress-assisted hydrolysis of the SiO_2 bonds at the crack tip under the influence of tensile stress and ambient humidity, causing crack propagation because atomic bonds are broken.

The phenomenon is thought to happen in the following way (Fig. 40.24). A small crack at the surface in the SiO_2 native oxide grows slightly due to SCC under the influence of a tensile stress, so that the silicon below the crack is slightly closer to the surface and oxidizes. Now the crack can propagate through the extended oxide layer, causing a new oxidation step in the silicon below. This continues until the whole structure fractures.

Connally and others [40.61–65] initiated research into SCC in silicon microstructures, and indeed found a large humidity influence on the crack propagation rate. *Muhlstein* et al. [40.66] measured a more realistic configuration in which they did not only monitor crack propagation but also took into account crack initiation. Another advantage over the earlier measurements was that the stress intensity factor at the tip was not a required parameter to have a meaningful description. Similar measurements were also reported by *Kapels* et al. [40.67] and *Kahn* et al. [40.68].

It is likely that there is a critical stress in the silicon device, above which SCC may occur. The native oxide of silicon is normally under a compressive stress [40.5] and the applied external stress should be so large that this stress has to become tensile for SCC to occur at all.

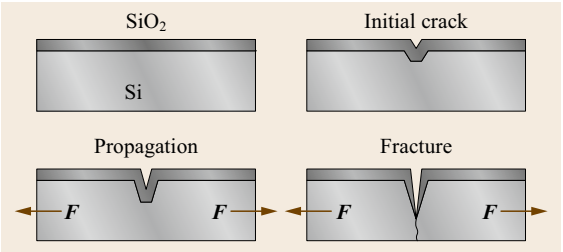

Fig. 40.24 SSC failure mechanism in silicon

If the stress in the silicon is kept below this transition point, where the oxide surface layer turns from its intrinsic compressive stress to tensile, no problems due to SCC are expected.

Bagdahn and *Sharpe* [40.69] put all the data available, including their own, in one table and showed that SCC cannot explain all the properties of the behavior that has been found. Being a chemical, stress-assisted process, SCC should not have a pronounced cycling-speed dependency; only the absolute time that the stress is applied counts towards the reaction rate. *Bagdahn* and *Sharpe* [40.69] showed that the data available provide a definite trend of the number of cycles to failure as a function of the applied stress, which contradicts the SCC assumption. We see in Fig. 40.25 that these effects only show up at very high stresses, near the fracture strength of silicon. Therefore in practical MEMS devices the fatigue of silicon may not be a big issue because it is good design practice to keep some margin to the fracture strength for brittle materials anyway. However, in harsh environments it may turn out to be a problem.

40.3.3 Wear

Wear is one of the major limiting factors in MEMS technology. After its occurrence had been shown by *Gabriel* et al. [40.70] and *Mehregany* et al. [40.71] in silicon micromotors in 1990, it was quickly recognized that wear is a severe limiting factor for almost all MEMS devices incorporating rubbing/sliding surfaces. At Sandia National Laboratories, a large effort was spent on understanding this effect, with experiments on a dedicated micromotor test vehicle (Fig. 40.26). This resulted in a quantitative empirical model to predict wear in certain types of micromotors [40.72]. Beautiful focused ion beam (FIB) cross sections in this work show that wear is indeed severe (Fig. 40.27). The wearing mechanism proposed is a kind of *adhesive wear*, where the surfaces adhere at their contacting points and shear off parts of the other surface (Fig. 40.28). Abrasive and corrosive wear take place at higher contact forces, or when a chemical reaction assists the wear process. A comprehensive overview of their work can be found in their MEMS reliability report [40.73].

A good overview from the middle of the 1990s is given by *Komvopoulos* [40.21]. Studying wear at a more fundamental level is difficult, because typical analytical measurement methods do not cover the whole range of speeds and contact forces in MEMS devices (Fig. 40.29) [40.74]. Atomic force microscopy/friction force microscopy (AFM/FFM) systems are very accurate in mimicking a single asperity, but only at, for MEMS devices, very low speeds [40.75]. A dedicated *tribo-apparatus* measurement system [40.76] fills part of the gap, but a large area remains outside the scope of the different (microscopic) measurement methods. Atomistic simulations can usually only be applied at much higher speeds, because otherwise computing time

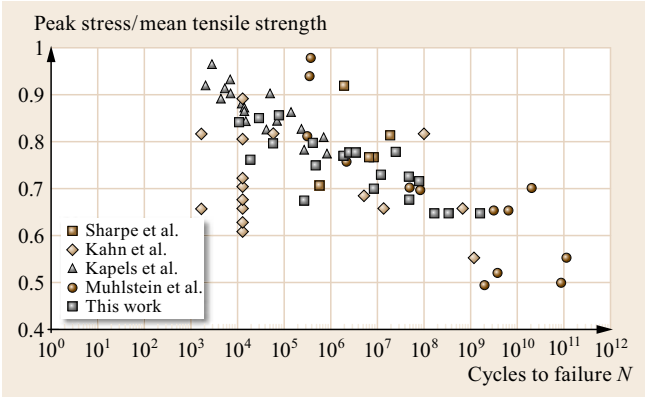

Fig. 40.25 *Bagdahn* and *Sharpe* [40.69] show that a definite trend appears if the applied stress is plotted as a function of the number of cycles to failure, contradicting the basic assumption of SCC

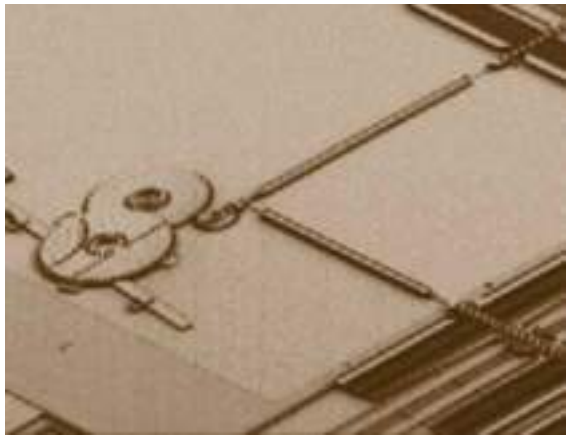

Fig. 40.26 Sandia's micromotor test vehicle to study wear

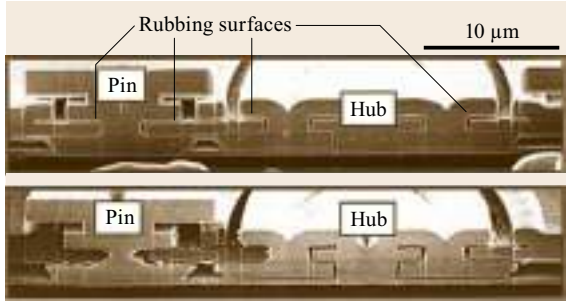

Fig. 40.27 FIB cross section of a new and a worn micromotor

becomes prohibitively long. As a result, wear is often studied using MEMS devices themselves as the measurement vehicle [40.77–80], but, of course, this is generally not as accurate as one would like.

Rymuza [40.81, 82] proposed the use of graphitelike materials embedded in the wear layer of a MEMS device. As the device loses its surface layer due to wear, small amounts of graphite are released to lubricate the device.

Recently, a lot of activity has been going on with respect to coating silicon MEMS devices with a friction-reducing and/or wear-resistant coating after the device has been released. This coating usually takes the form of a hard, chemically inert layer with a thickness of nanometers. Experiments have been performed using tungsten [40.83], SiN_x [40.84], diamondlike carbon (DLC) [40.85–88] ultrananocrystalline diamond (UNCD) [40.89], and SiC [40.90–92], among others. SAM coatings (Sect. 40.2.1) have also been investigated for this purpose but tend to wear off during rubbing [40.93].

The results of these studies show that especially DLC, UNCD and SiC are very promising coating materials, but also that their properties severely depend on the exact composition, roughness and surface termination (passivation) of the film. At this moment, there is no quantitative theory that is able to predict which coating compositions/properties are the best. Therefore optimization of these films is performed mainly using an experimental approach.

One finds that commercial applications of devices that have continuously rubbing/sliding surfaces, such as rotary micromotors, currently do not exist. This means that wear problems in MEMS devices are still so large that designers of commercial products avoid designs where rubbing surfaces have to survive more than a couple of million cycles.

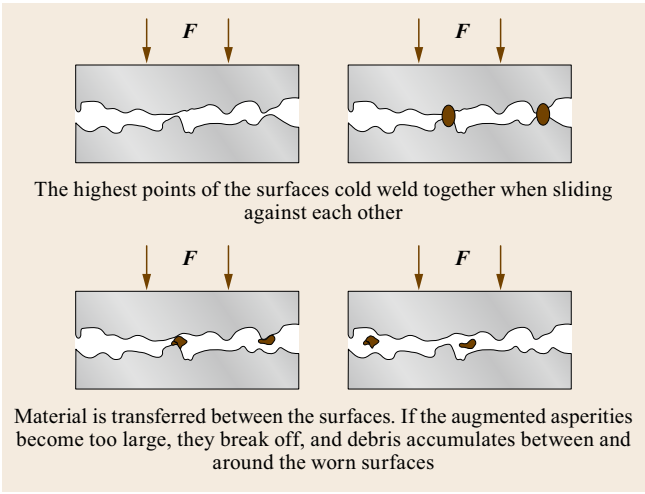

Fig. 40.28 Principle of adhesive wear

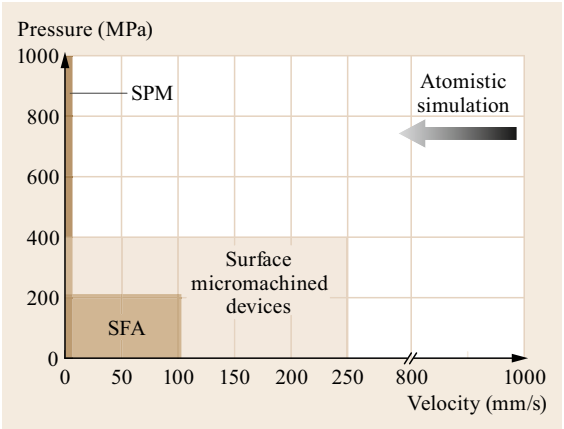

Fig. 40.29 MEMS surfaces have sliding speeds and contact forces not easily assessed by the available analysis methods: scanning probe microscopy (SPM) and surface force apparatus (SFA) (after [40.74])

40.3.4 Packaging

Introduction

Many MEMS contain movable and fragile parts. A specific packaging approach is required for protection during fabrication as well as during operation. For instance, standard wafer dicing will, if not destroy the MEMS device, at least introduce some contamination and particles that can lead to failure. Hence packaging must be carried out on the wafer during wafer processing, prior to die singulation. This packaging step is referred to as wafer-level or 0-level packaging. It defines the first protective interface for the MEMS device, achieved through on-wafer encapsulation of the movable parts in a sealed cavity. The cavity must be strong, for many applications hermetic, and equipped with electrical signal feedthroughs. An example of a 0-level packaging scheme for RF MEMS switches, which relies on wafer or chip stacking techniques using benzocyclobutene (BCB) as the bonding and sealing material, is shown in Fig. 40.30 [40.94].

Failure Modes and Failure Mode Investigation

Important requirements of MEMS packaging are resistance (against shear stress, pull stress, mechanical, thermal loads, etc.), and hermeticity against moisture, liquids, particles or gas contaminants, but also hermeticity to keep a controlled ambient (gas and pressure) inside the package. The most common failure modes that can occur are mainly related to the sealing material itself. For instance, a package can lose its shear

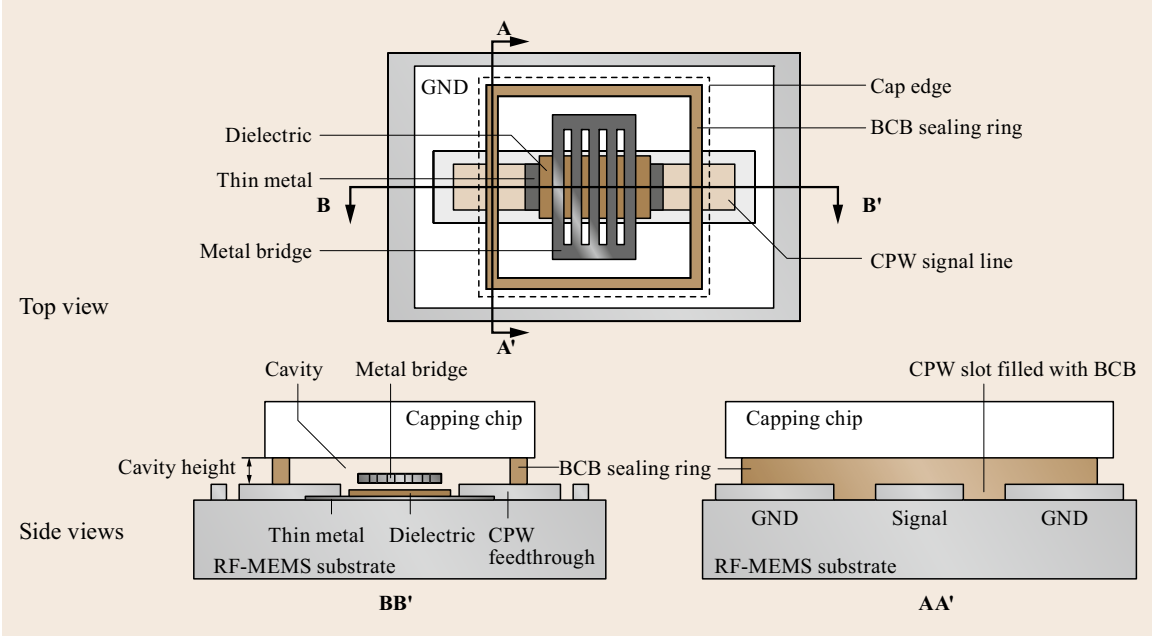

Fig. 40.30 Illustration of a wafer or 0-level packaged RF MEMS switch. The fragile MEMS part is housed in a cavity formed by a capping chip, bonded to the RF MEMS substrate using a layer of BCB

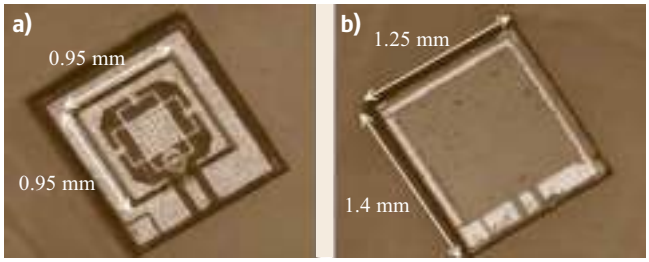

Fig. 40.31a,b Picture of a laser-diced *naked* **(a)** and packaged **(b)** RF tunable capacitor using solder (SnPb) flip-chip assembly

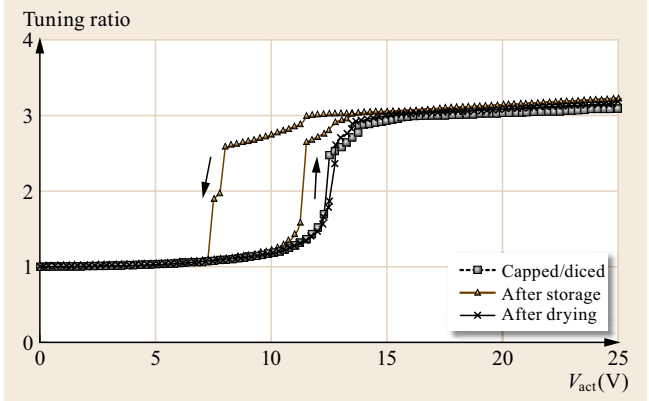

Fig. 40.32 Tuning ratio of the packaged tunable capacitor of Fig. 40.20 right after dicing (*squares*), after storage in ambient air (*triangles*) and after drying in dry N_2 at 75 °C (*crosses*)

or pull resistance in the case of bad adhesion between the sealing material and the MEMS die, although this is rarely the case and is process-related. More important is the loss of hermeticity in the case of an hermetic package. This can happen with the appearance of cracks in the sealing layer or at the bonding interfaces when the package device is subject to thermal shocks, for instance. The difference between the thermal coefficients of expansion of the different materials can induce a very high stress at the bonding interfaces and create some cracks, thus inducing gross leaks.

The importance of this can be seen in the following example. The package of Fig. 40.31b is made of a Si capping chip flip-chip bonded on top of an RF tunable capacitor using a solder seal (SnPb). Figure 40.32 shows the tuning ratio of the capacitor as a function of the actuation voltage, right after packaging and laser dicing, after storage in air, and after drying in dry N_2 at 75 °C, respectively. Compared to the curve obtained right after dicing, the tuning curve after storage in air is shifted towards lower actuation voltages and shows nonreversible tuning. This phenomenon could be explained by a moisture-related charging effect of the RF capacitor when the package is stored in ambient air. This is confirmed by the tuning curve obtained after drying the packaged device in dry N_2 at 75 °C: the initial reversible tuning curve is restored. This clearly shows that, in this example, the package is not hermetic to moisture and that this influences the electrical

performance of the MEMS device. Possible causes of packaging failure here could be microcracks in the solder sealing ring, bad adhesion between the solder and the MEMS die, particle contamination in the solder, or a local scarcity of solder.

For the same reasons, in the case of a (supposedly) hermetic package containing a controlled ambient (pressure and gas), the loss of hermeticity due to a leak in the sealing material will fill the package with air after a determined period of time, depending on the leak rate. For instance, a package of 100 nl (a few tens of nl are typically encountered in MEMS packaging) with an initial internal pressure of 1 mbar and displaying a leak rate as low as 10^{-10} mbar l/s will be filled with air after only 11 days.

Different testing methods exist or have been developed to first test the package (e.g., shear and pull strength, hermeticity, etc.) and second, to investigate the failure mechanisms. One can always refer to the MIL-STD-883 procedure to obtain the testing conditions and the rejection limits for the test [40.95]. This is the case for instance for the pull and shear testing (MIL-STD-883, method 2019.5). Hermeticity (fine leak) testing as specified by the MIL-STD-883 (method 1014.9) is still a problem because the fine-leak test conditions and specifications are clearly not applicable to MEMS packages due to the small cavity volumes they deal with [40.96]. Alternative methods are needed to investigate the leak rate of MEMS packages. However, gross-leak testing using fluorocarbon fluids is still applicable and is a good method to localize a leak path (e.g., a crack or a bad bonding) in the sealing material or the package itself. Similar to gross-leak testing is the dye penetrant method, as illustrated in Fig. 40.33. The package is immersed in a pressurized yellow dye (type Zyglo ZL-56 from Magnaflux). Next, the sample is rinsed with water, dried, and sprayed with a developer (type Zyglo ZP-9F). This developer has the property of sucking out the dye from the package if a leak exists, and some yellow fringes are then clearly visible under UV light.

Fig. 40.33 UV inspection of a leaky package using the dye-penetrant method

Another method to localize a gross leak in a package is scanning acoustic microscopy (SAM). A picture of a polymer-sealed leaky package is shown in Fig. 40.34 [40.97]. The black areas indicate that there is no adhesion between the sealing layer and the Si chip.

Other methods to look at the bonding interface are x-ray imaging and cross sectioning. Figure 40.35 is an x-ray image of a solder-sealed Si package. Irregularities

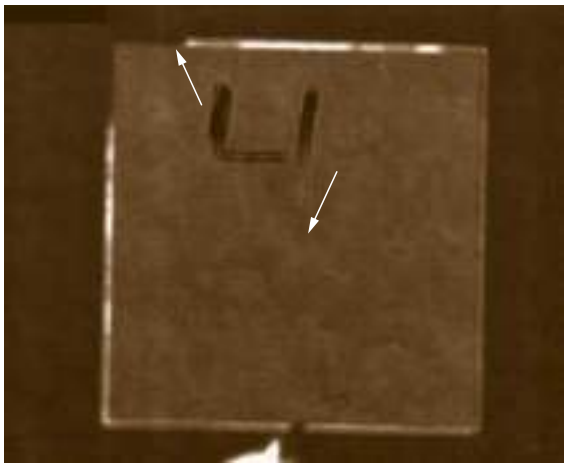

Fig. 40.34 SAM picture of a Si cap bonded to a Si wafer using polymer. The *black areas* indicate positions where the bond failed (*arrows*) (after [40.97])

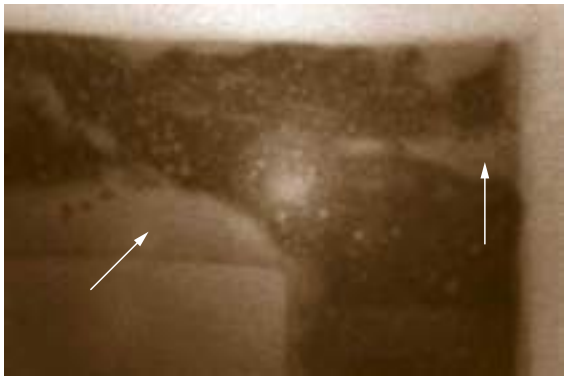

Fig. 40.35 X-ray image of a solder-sealed Si package. *White areas* are assumed to be solder oxide (unbonded areas)

in the solder ring are visible, and the lighter areas are assumed to be oxidized solder areas, and thus potential leaky paths.

Cross sectioning is of course destructive for the package, but it can also be used to investigate the bond quality, as shown in the example of Fig. 40.36. In this picture, voids in the sealing layer are clearly visible, and are potential source of gross leaks.

Conclusion

Investigating the failure mechanisms of the package is at least as important as for the MEMS itself, because without a good and robust package, most MEMS devices cannot survive operating or storage conditions. Understanding why a package failed will help to improve the next generation of MEMS. A lot of development still has to be done in packaging reliability testing, and this requires dedicated methods of investigation, which is now slowly emerging.

40.4 Conclusions

We have seen that a lot about the reliability of MEMS/NEMS is already known, and that in some cases even macroscopic principles can be applied to improve the reliability of micromachines over the state of the art. The fact that reliability is such a problem is not because MEMS/NEMS are intrinsically unreliable. They are not, and in fact – due to the low mass and high strength of materials on a microscale – the reliability that can be attained is even higher than in many macroscopic situations. The reason that reliability is hampering the commercialization of MEMS has already briefly been addressed in the creep section: to produce any MEMS at all is already a considerable feat, so that reliability issues are often not taken into account in the early stages of development. In the macroscopic world, instead, reliability is one of the key design issues of almost any product.

This sense still has to pervade the MEMS society, although things are changing. Especially in commercial laboratories, *design for reliability* is the new mantra, and independent research and development labs have set up dedicated groups to study fundamental issues in microscale reliability, such as stiction, charging, creep, fatigue, wear and packaging. If this trend continues over the coming years, MEMS may become just as pervasive as microelectronics is now.

41. Mechanical Properties of Micromachined Structures

Harold Kahn

To be able to accurately design structures and make reliability predictions, it is first necessary to know the mechanical properties of the materials that make up the structural components. In the fields of microelectromechanical systems (MEMS) and nanoelectromechanical systems (NEMS), the devices are necessarily very small. The processing techniques and microstructures of the materials in these devices may differ significantly from bulk structures. Also, the surface area to volume ratio in these structures is much higher than in bulk samples, and so the surface properties become much more important. In short, it cannot be assumed that mechanical properties measured using bulk specimens will apply to the same materials when used in MEMS and NEMS. This chapter will review the techniques that have been used to determine the mechanical properties of micromachined structures, especially residual stress, strength, and Young's modulus. The experimental measurements that have been performed will then be summarized, in particular the values obtained for polycrystalline silicon (polysilicon).

41.1 Measuring Mechanical Properties of Films on Substrates

In order to accurately determine the mechanical properties of very small structures, it is necessary to test specimens made from the same materials, processed in the same way, and of the same approximate size. Not surprisingly, it is often difficult to handle specimens this small. One solution is to test the properties of films remaining on substrates. Micro- and nanomachined structures are typically fabricated from films that are initially deposited onto a substrate and are subsequently patterned and etched into the appropriate shapes, and then finally released from the substrate. If the testing is performed on the continuous film, before patterning and release, the substrate can be used as an effective *handle* for the specimen (in this case, the film). Of course, since the films are adhered to the substrate, the types of tests that are possible are severely limited.

41.1.1 Residual Stress Measurements

One common measurement that is easily performed on films attached to substrates is that of residual film stress. The curvature of the substrate is measured prior to and after film deposition. Curvature can be measured in a number of ways. The most common technique is to scan a laser across the surface (or scan the substrate beneath the laser) and detect the angle of the reflected signal. Alternatively, profilometry, optical interferometry, or even atomic force microscopy (AFM) can be used. As expected, tools that map a surface or perform multiple linear scans can give more accurate readings than tools that measure only a single scan.

Assuming that the film is thin compared to the substrate, the average residual stress in the film, σ_f, is given

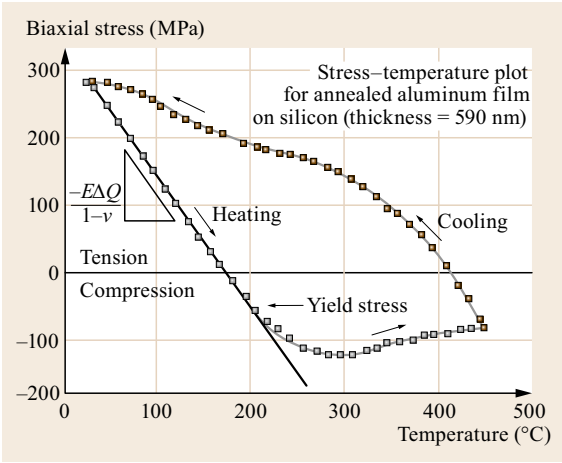

Fig. 41.1 Typical results for residual stress as a function of temperature for an aluminum film on a silicon substrate (after [41.1]). The stresses were determined by measuring the curvature of the substrate before and after film deposition, using the reflected signal of a laser scanned across the substrate surface

by the Stoney equation,

$$\sigma_f = \frac{1}{6}\frac{E_s}{(1-\nu_s)}\frac{t_s^2}{t_f}\left(\frac{1}{R_1}-\frac{1}{R_2}\right), \qquad (41.1)$$

where the subscripts f and s refer to the film and substrate, respectively; t is thickness, E is Young's modulus, ν is Poisson's ratio, and R is radius of curvature before (R_1) and after (R_2) film deposition [41.2]. For the typical (100)-oriented silicon substrate, $E/(1-\nu)$ (also known as the biaxial modulus) is equal to 180.5 GPa, independent of in-plane rotation [41.3]. This investigation can be performed on the as-deposited film or after any subsequent annealing step, provided no changes occur to the substrate.

This measurement will reveal the average residual stress of the film. Typically however, the residual stresses of deposited films will vary through the film thickness. One way to detect this, using substrate curvature techniques, is to etch away a fraction of the film and repeat the curvature measurement. This can be iterated any number of times to obtain a residual stress profile for the film [41.4]. Alternatively, tools have been designed to measure the substrate curvature during the deposition process itself, to obtain information on how the stresses evolve [41.5].

An additional feature of some of these tools is the ability to heat the substrates while performing the stress measurement. An example of the results obtained in such an experiment is shown in Fig. 41.1 [41.1], for an aluminum film on a silicon substrate. The slope of the heating curve gives the difference in thermal expansion between the film and the substrate. When the heating curve changes slope and becomes nearly horizontal, this indicates that the yield strength of the film has been reached.

41.1.2 Mechanical Measurements Using Nanoindentation

Besides residual stress, it is difficult to measure mechanical properties of films adhered to substrates, without the measurement being affected by the presence of the substrate. Recent developments in nanoindentation equipment have allowed this technique to be used in some cases. With specially designed tools, indentation can be performed using very low loads. If the films being investigated are thick enough and rigid enough, measurements can be made that are not influenced by the presence of the substrate. This can be verified by depositing the same film onto different substrates. By continuously monitoring the displacement as well as the load during indentation, a variety of properties can be measured, including hardness and Young's modulus [41.6]. This area is covered in more detail in a separate chapter.

For brittle materials, cracks can be generated by indentation, and strength information can be gathered. However, the exact stress fields created during the indentation process are not exactly known, and therefore, quantitative values for strength are difficult to determine. Anisotropic etching of single-crystal silicon has been done to create 30 μm tall structures which were then indented to examine fracture toughness [41.7], but this is not possible with most materials.

41.2 Micromachined Structures for Measuring Mechanical Properties

Certainly, the most direct way to measure the mechanical properties of small structures is to fabricate structures that would be conducive to such tests. Fabrication techniques are sufficiently advanced that virtually any design can be realized, at least in two dimensions. There are two basic types of devices used for mechanical property testing: *passive* structures and *active* structures.

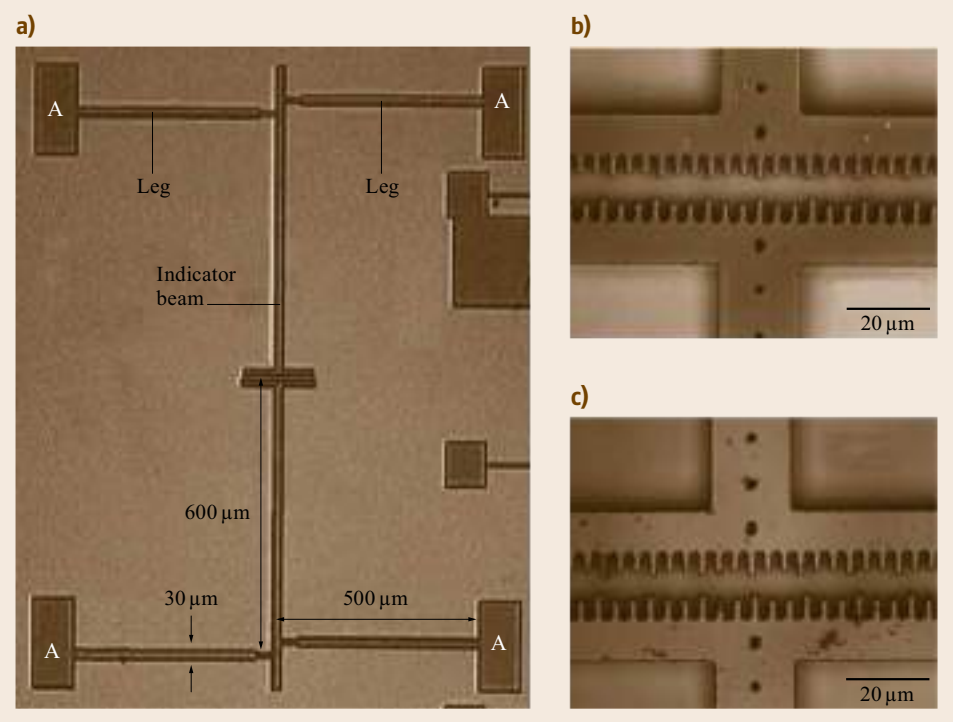

Fig. 41.2 (a) Microstrain gauge fabricated from polysilicon. (b) shows a close-up of the Vernier scale before release, and (c) shows the same area after release

41.2.1 Passive Structures

As mentioned previously, the main difficulty in testing very small specimens is in handling. One way to circumvent this problem is by using passive structures. These structures are designed to act as soon as they are released from the substrate and to provide whatever information they are designed to supply without further manipulation. For all of these passive structures, the forces acting on them come from the structural materials' own internal residual stresses. For devices on the micron scale or smaller, gravitational forces can be neglected, and therefore internal stresses are the only source of actuation force.

Stress Measurements

Since the internal residual stresses act upon the passive devices when they are released, it is natural to design a device that can be used to measure residual stresses. One such device, a rotating microstrain gauge, is shown in Fig. 41.2. There are many different microstrain gauge designs, but they all operate under the same principle. In Fig. 41.2a, the large pads, labeled A, will remain anchored to the substrate when the rest of the device is released. Upon release, the device will expand or contract in order to relieve its internal residual stresses. A structure under tension will contract, and a structure under compression will expand. For the structure in Fig. 41.2, a compressive stress will cause the legs to lengthen. Since the two opposing legs are not attached to the central beam at the same point, but are offset, when these legs expand, they will cause the central beam to rotate. The device in Fig. 41.2 contains two independent gauges that point at one another. At the ends of the two central beams are two parts of a Vernier scale. By observing this scale, the rotation of the beams can be measured.

If the connections between the legs and the central beams were simple pin connections, the strain ε of the legs (the fraction of expansion or contraction) could be determined simply by the measured rotation and the geometry of the device, namely

$$\varepsilon = \frac{(d_{\text{beam}} d_{\text{offset}})}{(2L_{\text{central}} L_{\text{leg}})} , \tag{41.2}$$

where d_{beam} is the lateral deflection of the end of one central beam, d_{offset} is the distance between the connections of the opposing legs, L_{central} is the length of the central beam (measured to the center point between the leg connections), and L_{leg} is the length of the leg. However, since the entire device was fabricated from a single polysilicon film, this cannot be the case; there must be some bending occurring at the connections. As a result, to get an accurate determination of the strain relieved upon release, finite element analysis (FEA) of

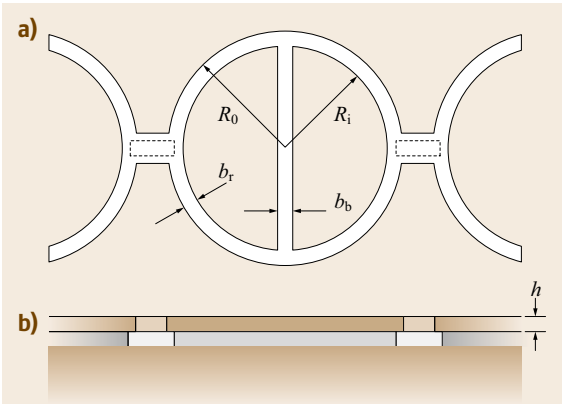

Fig. 41.3a,b Schematic **(a)** top view and **(b)** side view of Guckel ring structures (after [41.8]). The *dashed lines* in **(a)** indicate the anchors

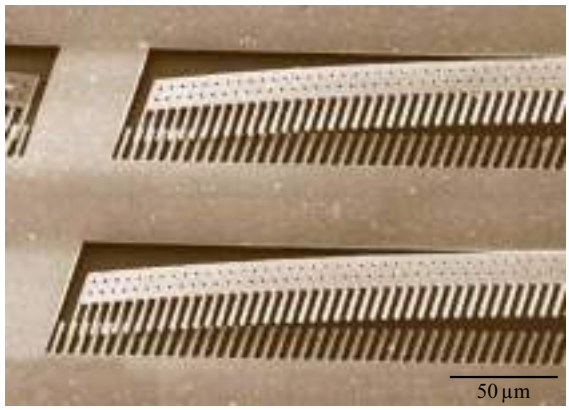

Fig. 41.4 Scanning electron micrograph (SEM) of a portion of a silicon microactuator. Residual stress gradients in the silicon cause the structure to bend

the structure must be performed. This is a common situation for microdevices. FEA is a powerful tool for determining the displacements and stresses of nonideal geometries. One of the drawbacks is that Young's modulus of the material must be known in order to do the FEA, as well as to convert the measured strain into a stress value. However, Young's moduli for many micromachined materials are known, or can be measured using other techniques.

Besides rotating strain gauges there are other devices designed to measure residual stresses. One of the most simple is a doubly clamped beam, that is, a long, narrow beam of constant width and thickness which is anchored to the substrate at both ends. If the beam contains a tensile stress, it will remain straight. However, if the beam contains a compressive stress, it will buckle if its length exceeds a critical value l_{cr} according to the Euler buckling criterion [41.8],

$$\varepsilon_r = -\frac{\pi^2}{3}\left(\frac{h}{l_{cr}}\right)^2 , \qquad (41.3)$$

where ε_r is the residual strain in the beam, and h is the width or thickness of the beam, whichever is less. To determine the residual strain, a series of doubly clamped beams are fabricated of varying lengths. In this way, the critical length l_{cr} for buckling can be deduced after release. One problem with this technique is that during the release process, any turbulence in the solution will lead to enhanced buckling of beams, and a low value for l_{cr} will be obtained.

For films with tensile stresses, a similar analysis can be done using ring-and-beam structures, also called Guckel rings after their inventor, Henry Guckel. A schematic of this design is shown in Fig. 41.3 [41.8].

A tensile stress in the outer ring will cause it to contract. This will lead to a compressive stress in the central beam, even though the material was originally tensile before release. The amount of compression in the central beam can be determined analytically from the geometry of the device and the residual strain of the material. Again, by changing the length of the central beam, the l_{cr} will be determined, and then the residual strain can be deduced.

Stress Gradient Measurements

For structures fabricated from thin deposited films, the stress gradient can be just as important as the stress itself. Figure 41.4 shows a portion of a silicon microactuator. The device is designed to be completely planar. However, stress gradients in the film cause the structures to bend. This figure illustrates the importance of characterizing and controlling stress gradients, and it also demonstrates that the easiest structure for measuring stress gradients is a simple cantilever beam. By measuring the end deflection δ, of a cantilever beam of length l, and thickness t, the stress gradient, $d\sigma/dt$ is determined by [41.9]

$$\frac{d\sigma}{dt} = \frac{2\delta}{l^2}\frac{E}{(1-\nu)} . \qquad (41.4)$$

The magnitude of the end deflection can be measured by microscopy, optical interferometry, or any other technique.

Another useful structure for measuring stress gradients is a spiral. For this structure, the end of the spiral that is not anchored to the substrate will move out-of-plane. Also, the diameter of the spiral will contract, and the free end of the spiral will rotate when released [41.10].

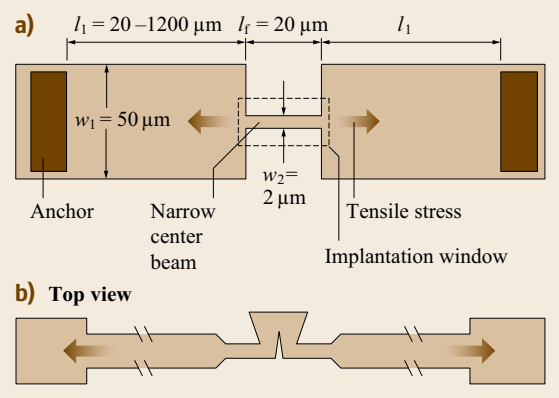

Fig. 41.5a,b Schematic designs of doubly clamped beams with stress concentrations for measuring strength. **(a)** was fabricated from polysilicon (after [41.11]) and **(b)** was fabricated from Si_xN_y (after [41.12])

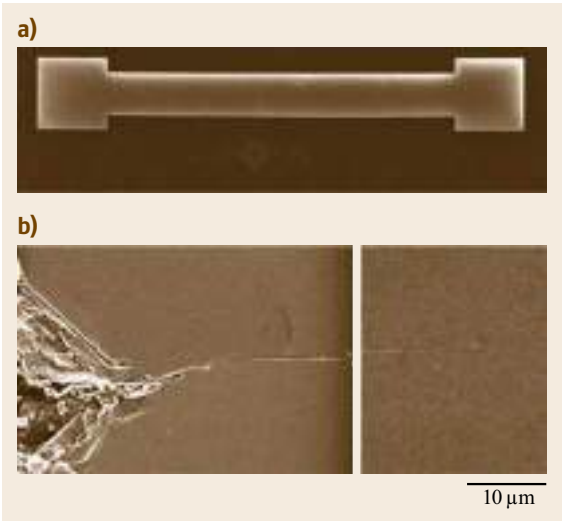

Fig. 41.6 **(a)** SEM of a 500 μm long polysilicon beam with a Vickers indent placed near its center; **(b)** higher magnification SEM of the area near the indent showing the precrack traveling from the substrate into the beam (after [41.14])

Strength and Fracture Toughness Measurements

As mentioned above, if a doubly clamped beam contains a tensile stress, it will remain taut when released, because it cannot relieve any of its stress by contracting. This tensile stress can be thought of as a tensile load that is being applied at the ends of the beam. If this tensile load exceeds the tensile strength of the material, the beam will break. Therefore, since the tensile stress can be measured, as discussed above, this technique can be used to gather information on the strength of materials. Figure 41.5 shows two different beam designs that have been used to measure strength. The device shown in Fig. 41.5a was fabricated from a tensile polysilicon film [41.11]. Different beams were designed with varying lengths of the wider regions (marked l_1 in the figure). In this manner, the load applied to the narrow center beam was varied, even though the entire film contained a uniform residual tensile stress. For l_1 greater than a critical value, the narrow center beam fractured, giving a measurement for the tensile strength of polysilicon.

The design shown in Fig. 41.5b was fabricated from a tensile Si_xN_y film [41.12]. As seen in the figure, a stress concentration was designed into the beam, to ensure the fracture strength would be exceeded. In this case, a notch was etched into one side of the beam. Since the stress concentration is not symmetric with regard to the beam axis, this results in a large bending moment at that position, and the test measures the bend strength of the material. Again, like the beams shown in Fig. 41.5a, the geometry of various beams fabricated from the same film were varied, to vary the maximum stress seen at the notch. By seeing which beams fracture at the stress concentration after release, the strength can be determined.

Through a similar technique, but by using an atomically sharp precrack instead of a stress concentration, the fracture toughness of a material can be determined. Sharp precracks can be introduced into micromachined structures before release by placing a Vickers indent on the substrate, near the device; the radial crack formed by the indent will propagate into the overlying structure [41.13]. Accordingly, the beam with a sharp precrack shown in Fig. 41.6, was fabricated using polysilicon [41.14]. Because of the stochastic nature of indentation, the initial precrack length will vary from beam to beam. Because of this, even though the geometry of the beams remains identical, the stress intensity, K, at the precrack tip will vary. Upon release, only those precracks whose K exceeds the fracture toughness of the material, K_{Ic}, will propagate, and in this way upper and lower bounds for K_{Ic} for the material can be determined.

For materials that do not normally contain residual tensile stresses, composite beams can be fabricated. In this technique, a portion of the beam length is fabricated from a highly tensile material, and the rest of the beam from the material to be tested. The two materials must exhibit perfect adhesion. When released, the tensile material will tend to contract, putting the rest of the beam in tension. This has been demonstrated for evaporated Al films with highly tensile CVD (chemical vapor deposition) SiN [41.15, 16].

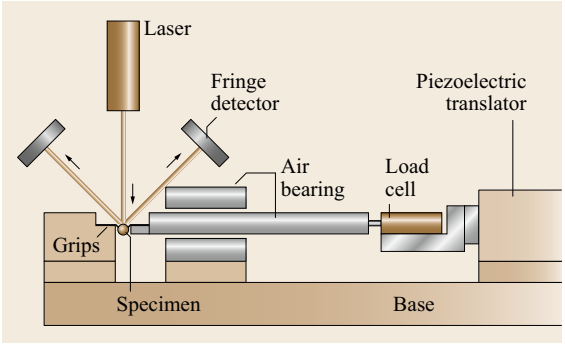

Fig. 41.7 Schematic of a measurement system for tensile loading of micromachined specimens (after [41.17])

For all of the beams discussed in this section, finite element analysis is required to determine the stress concentrations and stress intensities. Even though approximate analytical solutions may exist for these designs, the actual fabricated structure will not have idealized geometries. For example, corners will never be perfectly sharp, and cracks will never be perfectly straight. This reinforces the idea that FEA is a powerful tool for determining mechanical properties of very small structures.

41.2.2 Active Structures

As discussed above, it is very convenient to design structures that act upon release to provide information on the mechanical properties of the structural materials. However, this is not always possible. For example, those passive devices just discussed rely on residual stresses to create the changes (rotation or fracture) that occur upon release, but many materials do not contain high residual stresses as-deposited, or else the processing scheme of the device precludes the generation of residual stresses. Also, some mechanical properties, such as fatigue resistance, require motion in order to be studied. Therefore, active devices are used. These are acted upon by a force (the source of this force can be integrated into the device itself, or can be external to the device) in order to create a change, and by the response to the force, the mechanical properties are studied.

Young's Modulus Measurements

Young's modulus E is a material property that is critical to any structural device design. It describes the elastic response of a material and relates stress σ and strain ε by

$$\sigma = E\varepsilon \,. \tag{41.5}$$

In bulk samples, E is often measured by loading a specimen in tension and measuring displacement as a function of stress for a given length. While this is considerably more difficult for small structures, such as those fabricated from thin deposited films, with careful experimental techniques, it can be achieved. Figure 41.7 shows the schematic of one such measurement system [41.17]. The fringe detectors in the figure detect the reflected laser signal from two gold lines that are deposited onto the polysilicon specimen, which act as gauge markers. In this manner, the strain in the specimen during loading can be monitored. Besides gold lines, Vickers indents placed in a nickel specimen can also serve as gauge markers [41.19], or else a speckle interferometry technique [41.20] can be used to determine strain in the specimen. Once the stress versus strain behavior is measured, the slope of the curve is equal to E. By use of a constant load, such as a dead weight, and resistive heating, high temperature creep can also be investigated with this method [41.21].

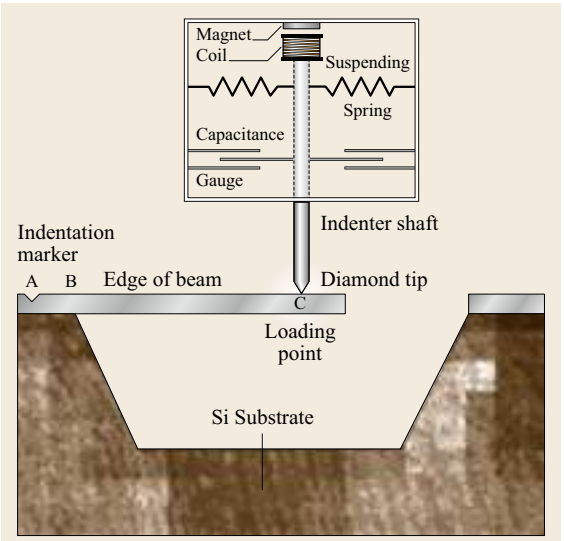

Fig. 41.8 Schematic of a nanoindenter loading mechanism pushing on the end of a cantilever beam (after [41.18])

Besides the tensile test, Young's modulus can be determined by other measures of stress–strain behavior. As seen in Fig. 41.8, a cantilever beam can be bent by pushing on the free end with a nanoindenter [41.18] or profilometer [41.22] or AFM probe [41.23]. The nanoindenter can monitor the force applied and the displacement, and simple beam theory can convert the displacement into strain, to obtain E. A similar technique, shown schematically in Fig. 41.9 [41.24], involves pulling downwards on a cantilever beam by means of an electrostatic force. An electrode is fabricated into the substrate beneath the cantilever beam, and a voltage is applied between the beam and the bottom electrode. The force acting on the beam is equal

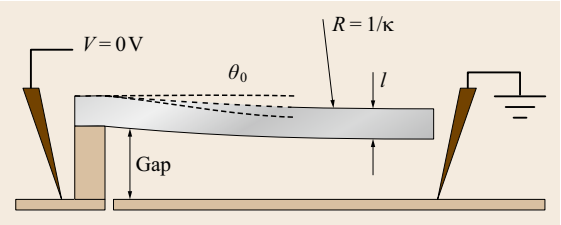

Fig. 41.9 Schematic of a cantilever beam bending test using an electrostatic voltage to pull the beam toward the substrate (after [41.24])

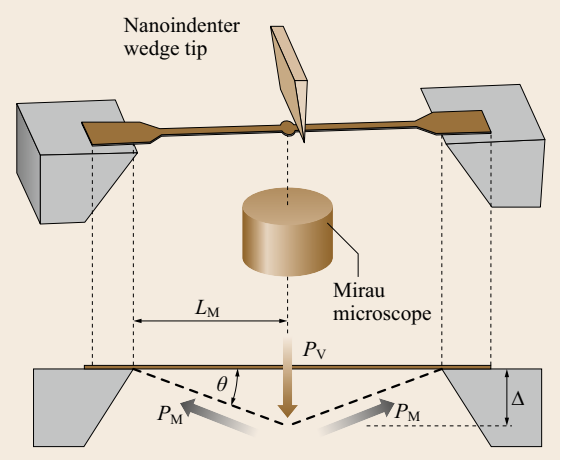

Fig. 41.10 Schematic of an externally loaded doubly clamped beam (after [41.25])

to the electrostatic force corrected to include the effects of fringing fields acting on the sides of the beam, namely

$$F(x) = \frac{\varepsilon_0}{2}\left(\frac{V}{g+z(x)}\right)^2\left(1+\frac{0.65[g+z(x)]}{w}\right), \tag{41.6}$$

where $F(x)$ is the electrostatic force at x, ε_0 is the dielectric constant of air, g is the gap between the beam and the bottom electrode, $z(x)$ is the out-of-plane deflection of the beam, w is the beam width, and V is the applied voltage [41.24]. In this work, the deflection of the beam as a function of position is measured using optical interferometry. These measurements combine to give stress–strain behavior for the cantilever beam. An extension of this technique uses doubly clamped beams instead of cantilever beams. In this case, the deflection of the beam at a given electrostatic force depends on the residual stress in the material as well as Young's modulus. Therefore, this method can also be used to measure residual stresses in doubly clamped beams.

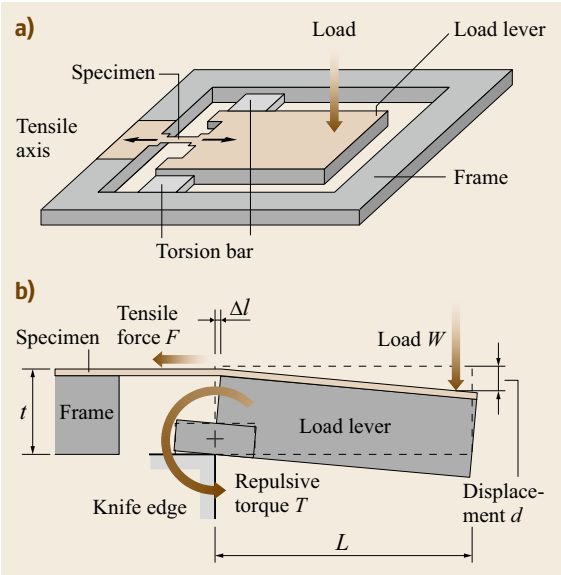

Fig. 41.11a,b Schematic of a device that transfers external vertical loads to in-plane tensile loads in deposited films (after [41.27])

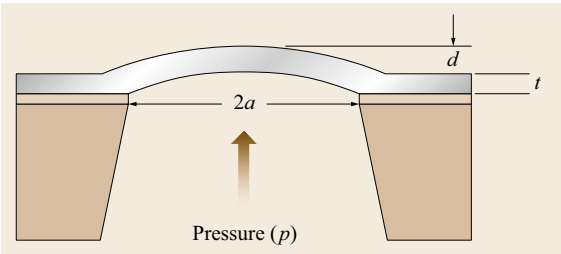

Fig. 41.12 Schematic cross section of a microfabricated membrane (after [41.28])

Similarly, an external load can be applied to the center of the doubly clamped beam, instead of using an electrostatic force, as shown in Fig. 41.10 [41.25]. The beam deflection is monitored using optical interferometry. If a profilometer is used to generate the downward force, the deflection can be measured along the entire length [41.26]. Yet another variation is illustrated in Fig. 41.11 [41.27]. In this technique, the externally applied downward force is transferred to a film of any material deposited onto the device.

Another device that is possible to fabricate from a thin film and also to use for investigating stress–strain behavior is a suspended membrane, seen in Fig. 41.12 [41.28]. As shown in the schematic figure, the membrane is exposed to an elevated pressure on one side, causing it to bulge out in the opposite direction. The deflection of the membrane is measured by optical or other techniques and related to the strain in the mem-

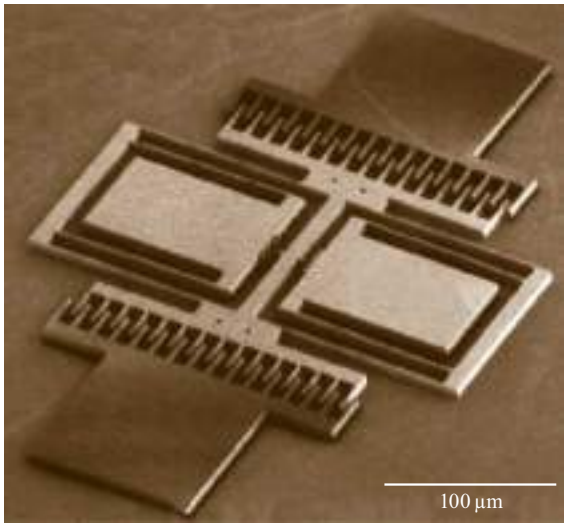

Fig. 41.13 SEM of a polysilicon lateral resonator (after [41.32])

brane. These membranes can be fabricated in any shape, typically square or circular. Both analytical solutions and finite element analyses have been done to relate the deflection to the strain. Like the doubly clamped beams, both Young's modulus and residual stress play a role in the deflected shape. Therefore, both of these mechanical properties can be determined by the pressure versus deflection performance of the membrane.

Besides stress–strain behavior, another measurement that can reveal Young's modulus of a material is to determine the natural resonance frequency. For a cantilever, the resonance frequency f_r for free undamped vibration is given by

$$f_r = \frac{\lambda_i^2 t}{4\pi l^2}\left(\frac{E}{3\rho}\right)^{1/2}, \tag{41.7}$$

where ρ, l, and t are density, length, and thickness of the cantilever; λ_i is the eigenvalue, where i is an integer that describes the resonance mode number; for the first mode $\lambda_1 = 1.875$ [41.29]. Therefore, by measuring f_r and knowing the geometry and density, E can be determined. The cantilever can be vibrated by a number of techniques, including a laser, loudspeaker, or piezoelectric shaker [41.30, 31]. The frequency that produces the highest amplitude of vibration is the resonance frequency.

A micromachined device that uses an electrostatic comb drive and an AC signal to generate the vibration of the structure is known as a lateral resonator [41.33]. One example is shown in Fig. 41.13 [41.32]. When a voltage is applied across either set of interdigitated comb fingers shown in Fig. 41.13, an electrostatic attraction will be generated due to the increase in capacitance as the overlap between the comb fingers increases. The force F generated by the comb drive is given by

$$F = \frac{1}{2}\frac{\partial C}{\partial x}V^2 = n\varepsilon\frac{h}{g}V^2, \tag{41.8}$$

where C is capacitance, x is distance traveled by one comb-drive toward the other, n is the number of pairs of comb fingers in one drive, ε is the permittivity of the fluid between the fingers, h is the height of the fingers, g is the gap spacing between the fingers, and V is the applied voltage [41.33]. When an AC voltage at the resonance frequency is applied across either of the two comb drives, the central portion of the device will vibrate. In fact, since force depends on the square of the voltage for electrostatic actuation, for a time t, dependent drive voltage $v_D(t)$ of

$$v_D(t) = V_P + v_d\sin(\omega t), \tag{41.9}$$

where V_P is the DC bias and v_d is the AC drive amplitude, the time-dependent portion of the force will scale with [41.33]

$$2\omega V_P v_d\cos(\omega t) + \omega v_d^2\sin(2\omega t). \tag{41.10}$$

Therefore, if an AC drive signal is used with no DC bias, at resonance, the frequency of the AC drive signal will be one half the resonance frequency. For this device, the resonance frequency f_r will be

$$f_r = \frac{1}{(2\pi)}\left(\frac{k_{sys}}{M}\right)^{1/2}, \tag{41.11}$$

where k_{sys} is the spring constant of the support beams and M is the mass of the portion of the device that vibrates. The spring constant is given by

$$k_{sys} = 24\frac{EI}{L^3}, \tag{41.12}$$

$$I = \frac{hw^3}{12}, \tag{41.13}$$

where I is the moment of inertia of the beams, and L, h, and w are the length, thickness, and width of the beams. Therefore, by combining these equations and measuring f_r, E can be determined.

One distinct advantage of the lateral resonator technique and the electrostatically pulled cantilever technique for measuring Young's modulus is that they require no external loading sources. Portions of the devices are electrically contacted, and a voltage is applied. For the pure tension tests, such as shown in Fig. 41.7,

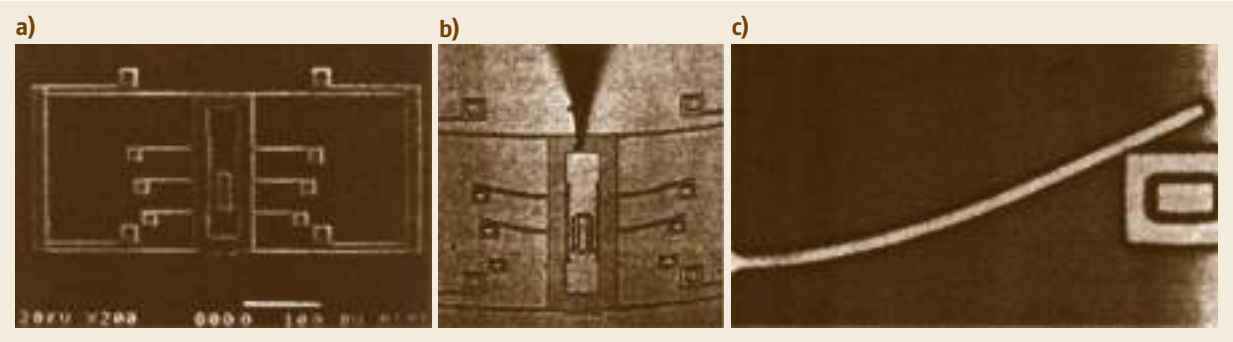

Fig. 41.14 **(a)** SEM of a device for measuring bend strength of polysilicon beams; **(b)** image of a test in process; **(c)** higher magnification view of one beam shortly before breaking (after [41.34])

the specimen must be attached to a loading system, and for the very small specimens discussed here, that can be extremely difficult and any misalignment or eccentricity in the test could lead to unreliable results. However, the advantage of the externally loaded technique is that there are no limitations on the type of materials that can be tested. Conductivity is not a requirement, nor is any compatibility with electrical actuation.

Strength and Fracture Toughness Measurements

As might be expected, any of the techniques discussed in the previous section that strain specimens in order to measure Young's modulus, can also be used to measure fracture strength. Simply, the load is increased until the specimen breaks. As long as either the load or the strain is measured at fracture, and the geometry of the specimen is known, the maximum stress required for fracture σ_{crit} can be determined, either through analytical analysis or FEA. Depending on the geometry of the test, σ_{crit} will represent the tensile or bend strength of the material.

If the available force is limited, or if it is desired to have a localized fracture site, stress concentrations can be added to the specimens. These are typically notches that are micromachined into the edges of specimens. Focused ion beams have also been used to carve stress concentrations into fracture specimens.

All of the external loading schemes, such as those shown in Figs. 41.7 and 41.8, have been used to measure fracture strength. Also, the electrostatically loaded doubly clamped beams can be pulled until they fracture. In this case, there is one complication. The electrostatic force is inversely proportional to the distance between the electrodes, and at a certain voltage, called the *pull-in voltage*, the attraction between the beam and the substrate will become so great that the beam will immediately be pulled into contact with the bottom electrode. As long as the fracture takes place before the pull-in voltage is reached, the experiment will give valid results.

There are other loading techniques that have been used to generate fracture of microspecimens. Figure 41.14 [41.34] shows one device which is designed to be pushed by the end of a micromanipulated needle. The long beams that extend from the sides of the central shuttle come into contact with anchored posts, and at a critical degree of bending, the beams will break off. Since the applied force cannot be measured in this technique, the experiment is optically monitored continuously during the test, and the image of the beams just before fracture is analyzed to determine σ_{crit}.

Another loading scheme that has been demonstrated for micromachined specimens utilizes scratch drive actuators to load the specimens [41.35]. These types of actuators work like inchworms, traveling across a substrate in discrete advances as an electrostatic force is repeatedly applied between the actuator and the substrate. The stepping motion can be made in the nm scale, depending on the frequency of the applied voltage, and so it can be an acceptable approximation to continuous loading. One advantage of this scheme is that very large forces can be generated by relatively small devices. The exact forces generated cannot be measured, so like the technique that used micromanipulated pushing, the test is continuously observed to determine the strain at fracture. Another advantage of this technique is that, like the lateral resonator and the electrically pulled cantilever, the loading takes place on-chip, and therefore, the difficulties associated with attaching and aligning an external loading source are eliminated.

Another on-chip actuator that is used to load microspecimens is shown in Fig. 41.15, along with three different microspecimens [41.13]. Devices have been fabricated with each of the three microspecimens integrated with the same electrostatic comb-drive actuator. In all three cases, when a DC voltage is applied to the

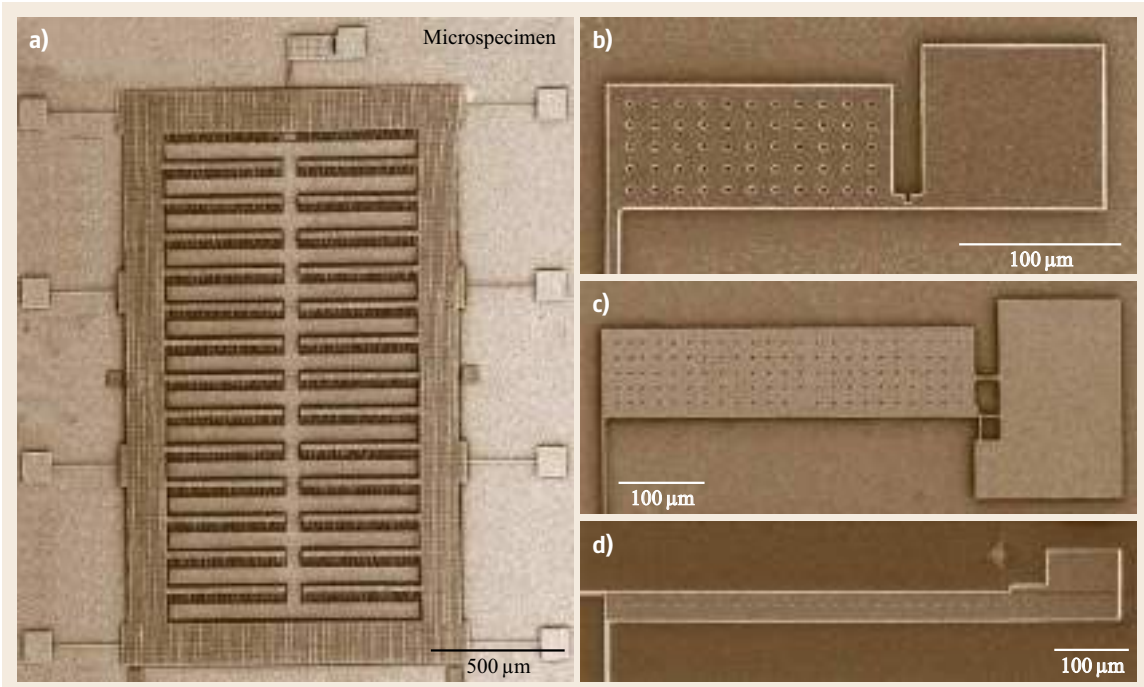

Fig. 41.15 **(a)** SEM of a micromachined device for conducting strength tests; the device consists of a large comb drive electrostatic actuator integrated with a microspecimen; **(b–d)** SEMs of various microspecimens for testing bend strength, tensile strength, and fracture toughness, respectively (after [41.13])

actuator it moves downward, as oriented in Fig. 41.15. This pulls down on the left end of each of the three microspecimens, which are anchored on the right. The actuator contains 1486 pairs of comb fingers. The maximum voltage that can be applied is limited by the breakdown voltage of the medium in which the test takes place. In air, that limits the voltage to less than 200 V. As a result, given a finger height of 4 µm and a gap of 2 µm, and using (41.8), the maximum force generated by this actuator is limited to about 1 mN. Standard optical photolithography has a minimum feature size of about 2 µm. As a result, the electrostatic actuator cannot generate sufficient force to perform a standard tensile test on MEMS structural materials such as polysilicon. Therefore, the microspecimens shown in Fig. 41.15 are designed such that the stress is amplified.

The specimen shown in Fig. 41.15b is designed to measure bend strength. It contains a micromachined notch with a root radius of 1 µm. When the actuator pulls downward on the left end of this specimen, the notch serve as a stress concentration, and when the stress at the notch root exceeds σ_{crit}, the specimen fractures. The specimen in Fig. 41.15c is designed to test tensile strength. When the left end of this specimen is pulled downward, a tensile stress is generated in the upper thin horizontal beam near the right end of the specimen. As the actuator continues to move downward, the tensile stress in this beam will exceed the tensile strength, causing fracture. Finally, the specimen in Fig. 41.15d is similar to that in Fig. 41.15b, except that the notch is replaced by a sharp precrack that was produced by the Vickers indent placed on the substrate near the specimen. When this specimen is loaded, a stress intensity K is generated at the crack tip. When the stress intensity exceeds a critical value K_{Ic} the crack propagates. K_{Ic} is also referred to as the fracture toughness.

The force generated by the electrostatic actuator can be calculated using (41.8). However, (41.8) assumes a perfectly planar, two-dimensional device. In fact, when actuated, the electric fields extend out of the plane of the device, and so (41.8) is just an approximation. Instead, similar to many of the techniques discussed in this section, the test is continuously monitored and the actuator displacement at the time of fracture is recorded. Then, FEA is used to determine the magnitude of the stress or stress intensity seen by the specimen at the point of fracture. To generate sufficient force to conduct tensile tests, a similar device to that shown in Fig. 41.15 has been designed which uses an array of parallel plate capacitors to provide the force,

instead of comb-drives [41.38]. In this way the available force is increased, but the maximum stroke is severely limited. Similar devices have also been designed for in situ testing in the SEM or TEM (transmission electron microscope) [41.39, 40].

Fatigue Measurements

A benefit of the electrostatic actuator shown in Fig. 41.15 is that, besides monotonic loading, it can generate cyclic loading. This allows the fatigue resistance of materials to be studied. Simply by using an AC signal instead of a DC voltage, the device can be driven at its resonant frequency. The amplitude of the resonance depends on the magnitude of the AC signal. This amplitude can be increased until the specimen breaks; this will investigate the low-cycle fatigue resistance. Otherwise, the amplitude of resonance can be left constant at a level below that required for fast fracture, and the device will resonate indefinitely until the specimen breaks; this will investigate high-cycle fatigue. It should be noted that the resonance frequency of such a device is about 10 kHz. Therefore, it is possible to stress a specimen over 10^9 cycles in less than a day. In addition to simple cyclic loading, if a DC bias is added to the AC signal, a mean stress can be superimposed on the cyclic load. In this way, nonsymmetric cyclic loading (either with a large tensile stress alternating with a small compressive stress, or vice versa) can be studied.

Another device that can be used to investigate fatigue resistance in MEMS materials is shown in Fig. 41.16 [41.36]. In this case, a large mass is attached

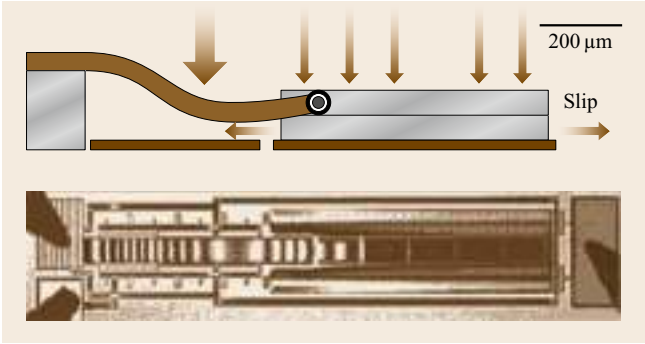

Fig. 41.18 Schematic cross-section and top-view optical micrograph of a hinged-cantilever test structure for measuring friction in micromachined devices (after [41.41])

to the end of a notched cantilever beam. The mass contains two comb drives on opposite ends. When an AC signal is applied to one comb drive, the device will resonate, cyclically loading the notch. The comb drive on the opposite side is used as a capacitive displacement sensor. This device contains many fewer comb fingers than the device shown in Fig. 41.15. As a result, it can apply cyclic loads by exploiting the resonance frequency of the device, but cannot supply sufficient force to achieve monotonic loading.

Fatigue loading has also been studied using the same external loading techniques shown in Fig. 41.7. In this case, the frequency of the cyclic load is considerably lower, since the resonance frequency of the device is not being utilized. This leads to longer high-cycle testing times. However, since the force is essentially unlimited, this technique allows a variety of frequencies to be studied, to determine their effect on the fatigue behavior.

Friction and Wear Measurements

Friction is another property that has been studied in micromachined structures. To study friction, of course, two surfaces must be brought into contact with each other. This is usually avoided at all costs for these devices because of the risk of stiction (stiction is the term used when two surfaces that come into contact adhere so strongly that the surfaces cannot be separated.) Even so, there have been a few devices designed to investigate friction. One of these is shown schematically in Fig. 41.17 [41.37]. It consists of a movable structure with a comb drive on one end and a cantilever beam on the other. Beneath the cantilever, on the substrate, is a planar electrode. The device is moved to one side using the comb drive. Then a voltage is applied between the cantilever beam and the substrate electrode. The voltage on the comb drive is then released. The device would normally return to its original position, to relax the

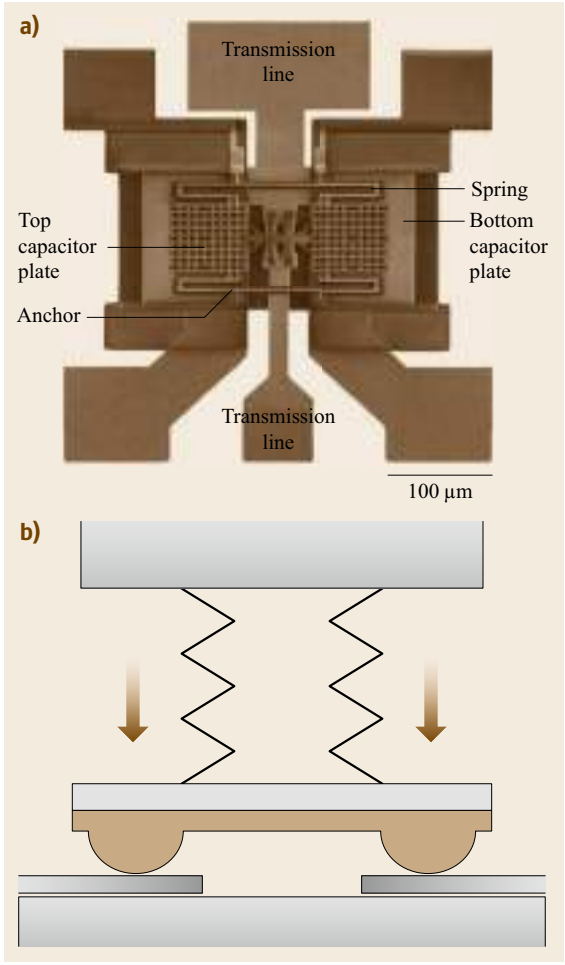

Fig. 41.19 **(a)** Micrograph of an RF MEMS switch designed by Rockwell Scientific, and **(b)** schematic drawing showing the movement of the metal bridge as it comes into contact with the underlying metal plate during switch operation (after [41.42])

deflection in the truss suspensions, but the friction between the cantilever and the substrate electrode holds it in place. The voltage to the substrate electrode is slowly decreased until the device starts to slide. Knowing the electrostatic force generated by the substrate electrode and the stiffness of the truss suspensions, the static friction can be determined. For this device, bumps were fabricated on the bottoms of the cantilever beams. This limited the surface area that came into contact with the substrate, and so lowered the risk of stiction.

Another device that has been designed to study friction is shown in Fig. 41.18 [41.41]. This technique uses a hinged cantilever. The portion near the free end acts as the friction test structure, and the portion near the anchored end acts as the driver. The friction test structure

is attracted to the substrate by means of electrostatic actuation, and when a second electrostatic actuator pulls down the driver, the friction test structure slips forward by a length which is proportional to the forces involved, including the frictional force. This distance, however, has a maximum of 30 nm, so all measurements must be exceedingly accurate in order to investigate a range of forces. This test structure can be used to determine the friction coefficients for surfaces with and without lubricating coatings.

Wear can occur whenever friction between two contacting components is nonzero. Wear mechanisms can entail plastic deformation or brittle fracture. Adhesive wear involves fusion between asperities of two different components, followed by fracture. Wear in polysilicon devices has been investigated using transmission electron microscopy [41.43].

Metal-to-Metal Contact

Recently, radiofrequency (RF) MEMS switches have been developed that are vast improvements over conventional technology. During operation, these devices endure unique mechanical metal-to-metal contacts that can be serious reliability concerns. An example of an RF MEMS switch is shown in Fig. 41.19 [41.42]. As illustrated in Fig. 41.19b, to close the switch the metal bumps are brought into contact with a metal plate, creating a short circuit. When this occurs, significant pressures are developed, depending on the roughness and asperity heights on the metal surfaces. Also, if currents are flowing, Joule heating and arcing can also take place. If the contact area becomes large, through surface roughness modification during operation, the adhesive forces between the two metal components can exceed the restoring force of the springs, and the switch can become stuck in the closed position. Alternatively, high currents can result in melting and short circuits [41.44]. To investigate this mechanical deformation during repeated impact, the RF switches themselves are usually examined before and after operation. A separate testing device has not been designed that could provide any accelerated testing conditions.

41.3 Measurements of Mechanical Properties

All of the techniques discussed above have been used to measure the mechanical properties of MEMS and NEMS materials. As a general rule, the results from the various techniques have agreed well with each other, and the argument becomes which of the measurement techniques is easiest and most reliable to perform. It is crucial to keep in mind, however, that certain properties, such as strength, are process dependent, and so the results taken at one laboratory will not necessarily match those taken from another.

41.3.1 Mechanical Properties of Silicon and Polysilicon

In current MEMS technology, the most widely used structural material is silicon: either single-crystal silicon or polysilicon deposited by low-pressure chemical vapor deposition (LPCVD). One reason for the prevalence of silicon and polysilicon is the large body of processing knowledge for this material that has been developed by the integrated circuit community. Another reason is that silicon possesses a number of qualities beneficial for MEMS devices, particularly its high strength and Young's modulus. As a natural result, most of the mechanical properties investigations on MEMS materials have focused on silicon and polysilicon.

Residual Stresses in Polysilicon

The residual stresses of LPCVD polysilicon have been thoroughly characterized using both the wafer curvature technique and the microstrain gauges. The results from both techniques give consistent values. Figure 41.20 summarizes the residual stress measurements as a function of deposition temperature taken from five different investigations at five different laboratories [41.45]. All five sets of data show the same trend. The stresses change from compressive at the lowest deposition temperatures to tensile at intermediate temperatures and back to compressive at the highest temperatures. The exact transition temperatures vary somewhat among the different investigations, probably due to differences in the deposition conditions:

- The silane or dichlorosilane pressure
- The gas flow rate
- The geometry of the deposition system
- The temperature uniformity.

However, in each data set the transitions are easily discernible. The origin of these residual stress changes lies with the microstructure of the LPCVD polysilicon films.

As with all deposited films, the microstructure of LPCVD polysilicon films is dependent on the deposition conditions. In general, the films are amor-

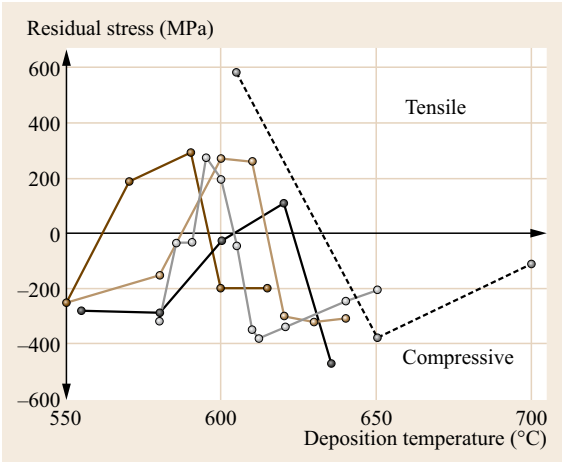

Fig. 41.20 Results for residual stress of LPCVD polysilicon films taken from five different investigations (after [41.45]). The data from each investigation are connected by a *line*

phous at the lowest growth temperatures (lower than $\approx 570\,^{\circ}\mathrm{C}$), display fine ($\approx 0.1\,\mu\mathrm{m}$ diameter) grains at intermediate temperatures (≈ 570–$610\,^{\circ}\mathrm{C}$), and contain columnar (110)-textured grains with a thin fine-grained nucleation layer at the substrate interface at higher temperatures (≈ 610–$700\,^{\circ}\mathrm{C}$) [41.45]. The fine-grained microstructure results from the homogeneous nucleation and growth of silicon grains within an as-deposited amorphous silicon film. In this regime, the deposition rate is just slightly faster than the crystallization rate. The as-deposited films will be crystalline near the substrate interface and amorphous at the free surface (the amorphous fraction can be quickly crystallized by annealing above $610\,^{\circ}\mathrm{C}$). The columnar microstructure seen at the higher growth temperatures results from the formation of crystalline silicon films as-deposited, with growth being fastest in the ⟨110⟩ directions.

The origin of the tensile stress in the fine-grained polysilicon arises from the volume decrease that accompanies the crystallization of the as-deposited amorphous material. The origins of the compressive stresses in the amorphous and columnar films are less well understood. One proposed explanation for compressive stress generation during thin film growth postulates that an increase in the surface chemical potential is caused by the deposition of atoms from the vapor; the increase in surface chemical potential induces atoms to flow into newly formed grain boundaries, creating a compressive stress in the film [41.46]. Investigations of PECVD (plasma-enhanced chemical vapor deposition) silicon films associates an increase in compressive stress with the presence of hydrogen [41.47], which may also be the origin of the compressive stresses in amorphous LPCVD silicon films.

Stress gradients are also typical of LPCVD polysilicon films. The partially amorphous films contain large stress gradients since they are essentially bilayers of compressive amorphous silicon on top of tensile fine-grained polysilicon. The fully crystalline films also exhibit stress gradients. The columnar compressive films are most highly stressed at the film–substrate interface, with the compressive stresses decreasing as the film thickness increases; the fine-grained films are less tensile at the film–substrate interface, with the tensile stresses increasing as the film thickness increases [41.45]. Both stress gradients are associated with microstructural variations. For the columnar films, the initial nucleation layer corresponds to a very high compressive stress, which decreases as the columnar morphology develops. For the fine-grained films, the region near the film-substrate interface has a slightly smaller average grain size, due to heterogeneous nucleation at the interface. This region displays a slightly lower tensile stress than the rest of the film, since the increased grain boundary area reduces the local density.

Young's Modulus of Silicon and Polysilicon

Young's moduli of polysilicon films have been measured using all the techniques discussed above. A good review of the experimental results taken from bulge testing, tensile testing, beam bending, and lateral resonators are contained in [41.48]. All of the reported results are in reasonable agreement, varying from 130–175 GPa, though many values are reported with a relatively high experimental scatter. The main origin of the error in these results is the uncertainties involving the geometries of the small specimens used to make the measurements. For example, from (41.13), the Young's modulus determined by the lateral resonators depends on the cube of the tether beam width, which is typically about $2\,\mu\mathrm{m}$. In general, the beam width and other dimensions can be measured with scanning electron microscopy to within about $0.1\,\mu\mathrm{m}$. However, the width of the beams is not perfectly constant along the entire length, or even through the thickness. These uncertainties in geometry lead to uncertainties in modulus.

The various experimental measurements lie close to the Voigt and Reuss bounds for Young's modulus calculated using the elastic stiffnesses and compliances for single-crystal silicon [41.48]. This strongly implies that Young's modulus of micro- and nanomachined polysilicon structures will be the same as for bulk samples made from polysilicon. This is not unexpected, since Young's modulus is a material property. It is related to the interatomic interactions and should have no dependence on the geometry of the sample. It should be

noted that polysilicon can display a preferred crystallographic orientation depending on the deposition conditions, and that this could affect the Young's modulus of the material, since the Young's modulus of silicon is not isotropic. Young's modulus of single-crystal silicon depends on the orientation of the crystal. Bulk measurements have been carried out and reviewed [41.49]. However, the anisotropy is fairly small for the cubic silicon.

An investigation that utilized electrostatically actuated cantilevers and interferometric deflection detection yielded Young's modulus of 164 GPa [41.24]. They found the grains in their polysilicon films to be randomly oriented, and calculated the Voigt and Reuss bounds to be 163.4–164.4 GPa. This appears to be a very reliable value for randomly oriented polysilicon.

Fracture Toughness and Strength of Silicon and Polysilicon

Using the device shown in Fig. 41.15a and the specimen shown in Fig. 41.15d, the fracture toughness, K_{Ic}, of polysilicon has been shown to be $1.0 \pm 0.1\,\mathrm{MPa\,m^{1/2}}$ [41.50]. Several different polysilicon microstructures were tested, including fine-grained, columnar, and multilayered. Amorphous silicon was also investigated. All of the microstructures displayed the same K_{Ic}. This indicates that, like Young's modulus, fracture toughness is a material property, independent of the material microstructure or the geometry of the sample.

A tensile test, such as shown in Fig. 41.7, but using a sample with indentation-induced sharp precracks reveals a K_{Ic} of $0.86\,\mathrm{MPa\,m^{1/2}}$ [41.51]. The passive, residual stress-loaded beams with sharp precracks, shown in Fig. 41.6, gave a K_{Ic} of $0.81\,\mathrm{MPa\,m^{1/2}}$ [41.14].

Given that K_{Ic} is a material property for polysilicon, measured fracture strength, σ_{crit}, is related to K_{Ic} by

$$K_{Ic} = c\sigma_{crit}(\pi a)^{1/2}\,, \tag{41.14}$$

where a is the crack-initiating flaw size, and c is a constant of order unity. The value for c will depend on the exact size, shape, and orientation of the flaw; for a semicircular flaw, c is equal to 0.71 [41.52]. Therefore, any differences in the reported fracture strength of polysilicon will be due to changes in a.

A good review of the experimental results available in the literature for polysilicon strength is contained in [41.53]. The tensile strength data vary from about 0.5 to 5 GPa. Like many brittle materials, the measured strength of polysilicon is found to obey Weibull statistics [41.54, 55]. This implies that the polysilicon samples contain a random distribution of flaws of various sizes, and that the failure of any particular specimen will occur at the largest flaw that experiences the highest stress. One consequence of this behavior is that, since larger specimens have a greater probability of containing larger flaws, they will exhibit decreased strengths. More specifically, it was found that the most important geometrical parameter is the surface area of the sidewalls of polysilicon [41.53] and single-crystal silicon [41.56] specimens. The sidewalls, as opposed to the top and bottom surfaces, are those surfaces that are created by etching. This is not surprising, since LPCVD polysilicon films contain essentially no flaws within the bulk, and the top and bottom surfaces are typically very smooth.

As a result, the etching techniques used to create the structures will have a strong impact on the fracture strength of the material. For single-crystal silicon specimens it was found that the choice of etchant could change the observed tensile strength by a factor of two [41.57, 58], and by about 20% for polysilicon [41.59]. In addition, the bend strength of amorphous silicon was measured to be twice that of polysilicon for specimens processed identically [41.50]. It was found that the reactive ion etching used to fabricate the specimens produced much rougher sidewalls on the polysilicon than on the amorphous silicon.

An investigation using high-throughput devices achieved 1500 strength measurements in identical polysilicon specimens [41.60]. A strength threshold was detected, implying a maximum flaw size.

The tensile strength of single-crystal silicon has also been measured using a technique similar to that shown in Fig. 41.8. Sharp notches were introduced into the beams using a focused ion beam, and the apparent fracture toughness was measured for varying planes parallel to the notch front, along which the crack propagated. For the {110} notch plane, the fracture toughness was about $1\,\mathrm{MPa\,m^{1/2}}$ [41.61, 62], and for the {100} notch plane it was about $1\,\mathrm{MPa\,m^{1/2}}$ [41.62] or about $2\,\mathrm{MPa\,m^{1/2}}$ [41.61]. The suspended membrane technique has also been used to study creep in silicon at elevated temperatures [41.63].

Fatigue of Silicon and Polysilicon

Fatigue failure involves fracture after a number of load cycles, when each individual load is not sufficient by itself to generate catastrophic cracking in the material. For ductile materials, such as metals, fatigue occurs due to accumulated damage at the site of maximum stress, and involves local plasticity. As a brittle material, polysilicon would not be expected to be susceptible to cyclic fatigue. However, fatigue has been observed for polysilicon tensile samples [41.51], polysilicon bend specimens with notches [41.36, 64], polysilicon bend specimens with sharp cracks [41.65], and polysilicon

torsion specimens [41.66]. The exact origins of the fatigue behavior are still subject to debate. However, some aspects of the experimental data are that the fatigue lifetime does not depend on the loading frequency [41.51], the fatigue behavior is affected by the ambient [41.14, 65], fatigue occurs faster in higher humidities [41.67], and the fatigue depends on the ratio of compressive to tensile stresses seen in the load cycle [41.14].

Fatigue in polysilicon has been found to either cause thickening of the native oxide in the highly stressed regions [41.68], or to cause no thickening of the native oxide in the highly stressed regions [41.69]. Even more strangely, fatigue cycling under certain conditions can lead to apparent strengthening of the polysilicon [41.70, 71]. While the exact mechanism of fatigue in polysilicon is not known, dislocations have been observed in tensile fracture of polysilicon at room temperature [41.72], which implies a role for dislocations in fatigue behavior.

Fatigue in single-crystal silicon has also been found to be affected by humidity, and also by loading frequency [41.73, 74]. In an oxygen-free ambient, silicon devices with smooth sidewalls did not exhibit fatigue, while silicon devices with rough sidewalls covered with thin SiO_2 layers did [41.75]; the authors concluded that neither dislocations nor environmental reactions contributed to fatigue.

Friction of Polysilicon

The friction of polysilicon structures has been measured using the techniques described above. The measured coefficient of friction was found to vary from 4.9 [41.37] to 7.8 [41.41]. The static and dynamic friction of polysilicon coated with monolayer lubricants has been measured with a device similar to that shown in Fig. 41.17, but using a scratch-drive actuator instead of a comb-drive [41.76]. The dynamic friction at 0.2 m/s was approximately 80% of the static friction value; the static friction at zero applied load was due to an adhesive force of 0.95 nN μm^{-2}.

41.3.2 Mechanical Properties of Other Materials

As discussed above, of all the materials used for MEMS and NEMS, polysilicon has generated the most interest as well as the most research in mechanical properties characterization. However, there have been measurements done on other materials, and these are summarized in this section.

As discussed above, one advantage of the externally loaded tension test, as shown in Fig. 41.7, is that essentially any material can be tested using this technique. As such, tensile strengths have been measured to be 0.6–1.9 GPa for SiO_2 [41.77] and 0.7–1.1 GPa for titanium [41.78]. The yield strength for electrodeposited nickel was found to vary from 370 to 900 MPa, depending on annealing temperature [41.19]. In addition, the yield strength was strongly affected by the current density during the electrodeposition process. Both the annealing and current density effects were correlated to changes in the microstructure of the material. Tensile strength and grain size were also found to be affected by electrolyte bath composition [41.79], and strength is increased by the addition of 5–15% tungsten [41.80]. The fatigue behavior of electrodeposited Ni was also investigated [41.81]. Microstructual changes due to thermal treatments also caused the yield strength of AlCuMgMn films to vary from 400 to 1000 MPa [41.82]. Young's moduli were determined to be 100 GPa for titanium [41.78] and 215 GPa for electrodeposited nickel [41.19], and 96 GPa for permalloy [41.27]. Young's modulus for electrodeposited nickel was found to be 159 GPa, using a resonating beam technique [41.30]. The tensile strength, Young's modulus, and Poisson's ratio of silicon nitride were measured to be 5.9 GPa, 257 GPa, and 0.23, respectively [41.83], and the same properties of amorphous diamond-like carbon were found to be 7.3 GPa, 759 GPa, and 0.17, respectively [41.84], with a fracture toughness of 4.4 MPa $m^{1/2}$ [41.85]. Young's modulus and creep behavior of SiC was studied up to 1000 °C [41.86].

The technique of bending cantilever beams, shown in Fig. 41.8, can also be performed on a variety of materials. The yield strength and Young's modulus of gold were found to vary from 260 MPa and 57 GPa, respectively [41.18], to 300 MPa and 120 GPa, respectively [41.87], using this method. The same properties in Al were measured to be 150 MPa and 80 GPa, respectively [41.87], and in silicon nitride to be 6.9 GPa and 260 GPa, respectively [41.88]. Strength, Young's modulus, and maximum strain were determined in carbon-infiltrated carbon nanotube structures to vary from 102 MPa, 4.1 GPa, and 2.5% when stressed perpendicular to the nanotube growth direction to 903 MPa, 11.0 GPa, and 9.2% when stressed parallel to the nanotube growth direction [41.89]. Using a technique similar to that shown in Fig. 41.8, except that a doubly clamped beam was used instead of a cantilever beam, the fracture toughness of ultrananocrystalline diamond was measured as 4.5 MPa $m^{1/2}$ [41.25].

Resonating cantilever beams revealed a Young's modulus of gold of 47 GPa [41.90], and Young's moduli of 1.8 and 14.4 GPa of silica and alumina aerogel thin films, respectively [41.91]. Resonating

beams were also used to determine Young's moduli of GaN and AlN to be 261 and 339 GPa, respectively [41.92].

Another technique that can be used with a number of materials is the membrane deflection method, shown in Fig. 41.12. Silicon nitride measured with this technique revealed a Young's modulus of 258 [41.83] to 325 GPa and a burst strength of 7.1 GPa [41.93]. A polyimide membrane gave a residual stress of 32 MPa, a Young's modulus of 3.0 GPa, and an ultimate strain of about 4% [41.28]. Membranes were also fabricated from polycrystalline SiC films with two different grain structures [41.94]. The film with (110)-texture columnar grains had a residual stress of 434 MPa and a Young's modulus of 349 GPa. The film with equiaxed (110)- and (111)-textured grains had a residual stress of 446 MPa and a Young's modulus of 456 GPa. A separate investigation reported Young's moduli of 417 GPa for polycrystalline and 388 GPa for single-crystal SiC [41.95]. Al and Ni membranes revealed Young's moduli of 70 and 200 GPa, respectively [41.96]. Polymeric SU-8 displayed a fracture strength of 73 MPa and a very low creep rate [41.97]. Al_2O_3 membranes revealed a fracture strength of about 2.6 GPa [41.98].

Other devices that are used to measure mechanical properties require more complicated micromachining, namely patterning, etching, and release, in order to operate. These devices are more difficult to fabricate with materials that are not commonly used as MEMS structural materials. However, the following examples demonstrate work in this area. The structure shown in Fig. 41.5b was fabricated from Si_xN_y, and revealed an apparent fracture toughness of 1.8 MPa $m^{1/2}$ [41.12]. Devices shown in Fig. 41.6 revealed a fracture toughness of atmospheric-pressure CVD SiC of 3.1 MPa $m^{1/2}$ [41.99] and low-pressure CVD SiC of 2.9 MPa $m^{1/2}$ [41.100]. Similar composite beams gave a yield strength of 625 MPa and a strain at crack initiation of 0.3 for Al [41.15]. Devices as shown in Fig. 41.10 showed a fracture toughness of diamond of 4.6 MPa $m^{1/2}$ [41.25], Young's modulus of Cu of 115 GPa [41.101], and Young's modulus and yield strength of Mo of 231 and 1.76 GPa, respectively [41.102].

Lateral resonators of the type shown in Fig. 41.13 were processed using single-crystal and polycrystalline SiC, and Young's modulus was determined to be between 360 GPa [41.103] and 426 GPa [41.104]. Resonating beams revealed the temperature coefficient of Young's modulus to be $-53\,\text{ppm}\,\text{K}^{-1}$ [41.105]. The device shown in Fig. 41.14 was fabricated from polycrystalline germanium and used to measure a bend strength of 1.5 GPa for unannealed Ge and 2.2 GPa for annealed Ge [41.106]. The same device was also fabricated from SiC and revealed a bend strength of 23 GPa [41.107]. Devices similar to that shown in Fig. 41.15 revealed the tensile strength of silicon nitride to be 6.4 GPa [41.93], and the Young's modulus and yield strength of aluminum to be 74.6 GPa and 330 MPa, respectively [41.108]. Young's modulus of an Al-0.5%Cu thin film was measured to be 87 GPa, with a yield strength that depended on the specimen length and thickness [41.109]. The device shown in Fig. 41.16 was used to study the fatigue behavior of electrodeposited nickel [41.110].

The metal-to-metal contact RF switches, such as shown in Fig. 41.19 typically use Au as the contact metal, due to its low electrical resistance and high oxidation resistance. In these devices, adhesive forces were found to increase logarithmically with *cold* contact cycles (cycling with no current passing through the switch), consistent with creep as the underlying physical mechanism [41.42]. At high currents, no adhesion was found between the metal components, but melting led to extrusions and short circuits [41.44]. Both of these results are consistent with separate modeling investigations [41.111, 112].

41.4 Summary

The mechanical properties of the materials comprising MEMS and NEMS are critical to their performance and reliability. Some of these properties, such as stiffness and toughness, are inherent to the materials, while others, such as strength and residual stress, are strongly influenced by the processing techniques used to make and pattern the structures. Various methods have been developed to determine the mechanical properties of micromachined structures – some of them relatively simple and others quite complex. The resulting measurements can be used to design devices with optimal performance.

42. High Volume Manufacturing and Field Stability of MEMS Products

T. Kieran Nunan, Mark G. da Silva

Low-volume microelectromechanical systems (MEMS)/nanoelectromechanical systems (NEMS) production is practical when an attractive concept is implemented with business, manufacturing, packaging, and test support. Moving beyond this to high-volume production adds requirements on design, process control, quality, product stability, market size, market maturity, internal capacity, and capital investment or transfer to foundry and business systems. In a broad sense, this chapter uses a case study approach: It describes and compares the silicon-based MEMS accelerometers and gyroscopes that are in high-volume production. What is described here also applies to other MEMS products such as pressure sensors, image projection systems, microphones, etc. Although they serve several markets, these businesses have common characteristics. For example, the manufacturing lines use automated semiconductor equipment and standard material sets to make consistent products in large quantities. Standard well-controlled processes are sometimes modified for a MEMS product. However, novel processes that cannot run with standard equipment and material sets are avoided when possible. When transferring to an external foundry, existing processes are modified to utilize the foundry equipment and processes where possible. This reliance on semiconductor tools, as well as the organizational practices required to manufacture clean, particle-free products, partially explains why the MEMS market leaders are integrated circuit manufacturers. There are other factors. MEMS and NEMS are enabling technologies, so it can take several years for high-volume applications to develop. Indeed, market size is usually a strong function of price. This becomes a vicious circle, because low price requires low cost – a result that is normally achieved only after a product is in high-volume production. During the early years, IC companies reduce cost and financial risk by using existing facilities for low-volume MEMS production. As a result, product architectures are partially determined by capabilities developed for previous products. This chapter includes a discussion of MEMS product architecture with particular attention to the impact of electronic integration, packaging, and surfaces. Packaging and testing are critical, because they are significant factors in MEMS product cost. MEMS devices have extremely high surface-to-volume ratio, so performance and stability may depend on the control of surface characteristics *after packaging*. Looking into the future, the competitive advantage of IC suppliers is decreasing because MEMS foundries are growing and small companies are learning to integrate MEMS/NEMS devices with die from CMOS foundries in one package. Packaging challenges still remain, because most MEMS/NEMS products must interact with the environment without degrading stability or reliability.

This chapter builds on the summary presented in [42.1], and covers high-volume inertial MEMS manufacturing over the last 15 years. MEMS are not limited to inertial products, and there are many other products such as inkjet printers and optical MEMS devices such as optical switches for the telecommunications field and optical light projectors such as TI's Digital Light Processing (DLP) system that use MEMS technologies. Except for optical switches, the inkjet and DLP MEMS technologies are mature, with most of the business being captured by a few dominant players. Other high-volume MEMS products such as pressure sensors, microphones, and MEMS switches will not be mentioned, and the main focus will be on inertial sensors. Newer MEMS products such as biomedical microelectromechanical systems (bioMEMS), environmental and chemical sensors, energy harvesting, and energy storage devices will not be discussed, as such technologies are still in the early stages of adoption, although seen to be a growing business with the onset of the Internet of Things (IoT) [42.2]. Maybe some insight into the evolution of these newer sensors and devices can be gained from this review of the evolution of the inertial MEMS sensor business.

42.1 High-Volume Manufacturing Strategy

In our discussion of MEMS manufacturing strategy, we will use the Analog Devices Inc. (ADI) experience and how the manufacturing strategy at ADI evolved. We will also discuss the manufacturing strategy for other high-volume inertial MEMS manufacturing companies. We hope that, through this discussion, the reader will see how MEMS high-volume manufacturing is closely linked to the semiconductor IC high-volume manufacturing strategy and the importance of external foundries in high-volume manufacturing. We will also discuss the challenges in using external foundries for MEMS manufacturing. The biggest challenge is that MEMS products typically require their own technology platform or different process modules tailored to MEMS product performance needs.

42.1.1 Foundry versus Internal Fab

In the early 2000s, inertial MEMS were a commodity product for many applications, including inertial sensing and pressure sensing. MEMS microphones were also beginning to gain some traction. Currently, there are two major approaches for high-volume manufacturing, either using an internal fab, e.g., STM and Bosch, or using external MEMS foundries, e.g., companies such as Knowles, InvenSense, and mCube. The main foundries used were IC foundries in Asia (e.g., Knowles uses a MEMS foundry in China to make their MEMS microphone).

Large foundries offer MEMS foundry services in their older 6 inch and 8 inch fabs to help with fab utilization, as standard IC production in these fabs transitioned to processing more advanced submicron complementary metal-oxide-semiconductor (CMOS) technology. The preferred MEMS technologies that could utilize this model were inertial, microphone, and pressure sensor designs that could take advantage of the standard equipment set in these older IC fabs, thereby avoiding large investment in new capital, and that were compatible with the other IC processes running in the fabs.

42.1.2 The ADI Experience

Evolution of Inertial MEMS

ADI started out with integrated MEMS devices based on the iMEMS® process [42.3–5], see Fig. 42.1.

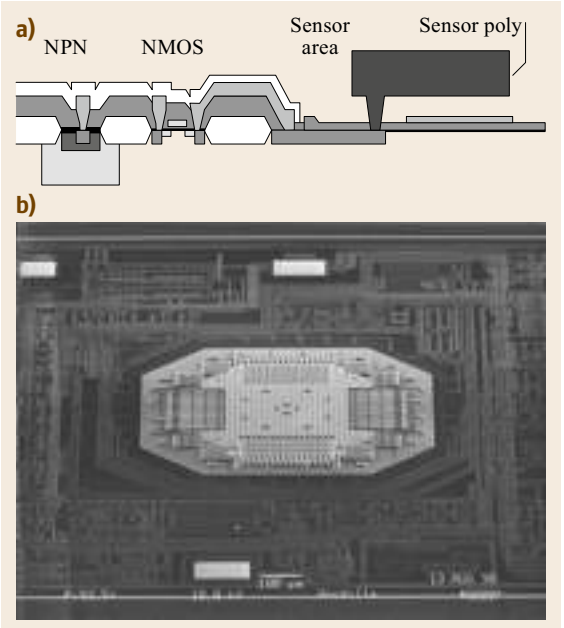

Fig. 42.1a,b iMEMS® sensor and signal processing devices on the same chip. **(a)** Cross section showing BIMOS circuit elements and sensor beam on the same chip. **(b)** Top down view of the integrated MEMS die with the sensor surrounded by the BIMOS circuits (courtesy of Analog Devices Inc.)

The evolution of this core technology was to increase the thickness of the MEMS element and reduce the parasitic capacitance to improve the signal-to-noise performance. The major changes were to replace the N^+ runners for the electrical connections between the sensor and electronics [42.6] with polysilicon runners that had lower series resistance and lower parasitic capacitance. At the same time, the sensor thickness was increased from 2 to 3 μm and eventually to 4 μm. Other changes centered on the packaging to drive down the cost and utilize original equipment manufacturer (OEM)-supplied packaging. This evolution went from metal can for the ADXL50 to ceramic and ceramic dual in-line package (CERDIP) cavity packages to eventually low-cost plastic overmolded packages. To enable overmold packaging, the sensor had to be capped [42.7, 8], see Fig. 42.2, and coated with antistiction coating technology [42.9] at wafer level, requiring development of a wafer-level antistiction coating process and a wafer-level capping technology.

The development of silicon-on-insulator microelectromechanical systems (SOIMEMS) technology [42.10–12], see Fig. 42.3, enabled MEMS integration with submicron CMOS technology and a 10 μm-thick sensor element.

So, the trend over the years has been to improve signal-to-noise performance and overload performance by increasing the sensor element thickness and reducing noise sources such as parasitic capacitance and Brownian noise while additionally reducing die size to reduce cost further.

ADI MEMS-Only Process

Before 2000, ADI MEMS products were manufactured using their integrated MEMS process flows such as *iMEMS*® and *SOIMEMS*. These integrated processes were highly customized to ADI internal IC processes as well as the unique MEMS process steps to integrate the MEMS element with the electronics directly on the same chip. As customers demanded greater functionality, including high-density digital signal processing, it became cost prohibitive to add the high-density circuity onto a single integrated chip. This resulted in a paradigm shift from discrete chip integration to newer products having two discrete chips in a single package: a MEMS chip with the front-end electronics for MEMS signal processing, and a second application-specific integrated circuit (ASIC) chip for additional high-density digital signal processing. This was still a very high-cost solution, so to drive down the cost, in particular for products targeted at high-volume commercial applications, ADI developed their first MEMS-only process, see Fig. 42.4a and 42.3b [42.13, 14].

ADI took some of the front-end poly interconnect and sensor anchor steps from the iMEMS® process and the process know-how for these steps and the back-end high-aspect-ratio deep silicon etch and sensor release steps from the SOIMEMS process to create the process flow for the MEMS-only process. The first MEMS-only process had two levels of poly interconnect and an 8 μm-thick polysilicon MEMS element. By using a thick substrate oxide, and two levels of poly interconnect with a low-pressure chemical vapor deposition (LPCVD) nitride etch-stop layer, the parasitic capacitance to the sensitive node in the MEMS device could be kept to a minimum, enabling manufacture of small high-performance inertial MEMS devices at relatively low cost.

Foundry MEMS at ADI

The next step in reducing the manufacturing cost was to transfer some if not all of the manufacturing steps to an external foundry capable of processing higher wafer volume rates. Other than the thick sensor polysilicon process that required careful control of the deposition conditions, all the other steps up to sensor element re-

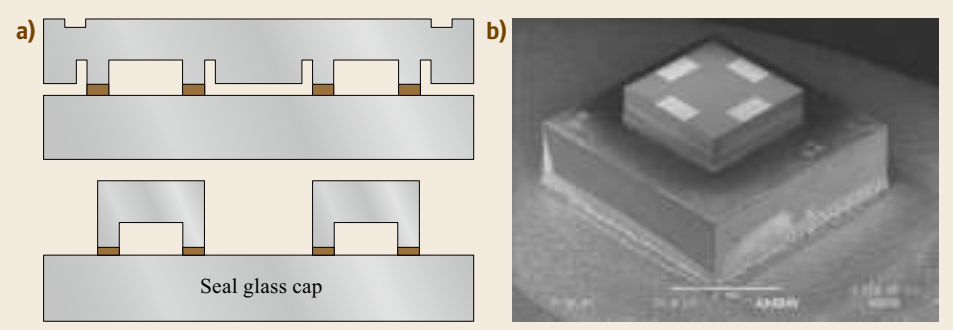

Fig. 42.2a,b Wafer-level seal glass frit capping process for MEMS devices using dicing for cap singulation (courtesy of Analog Devices Inc.); **(a)** cross section showing wafer level capping process using glass frit, **(b)** SEM image of finished capped MEMS devices after dicing

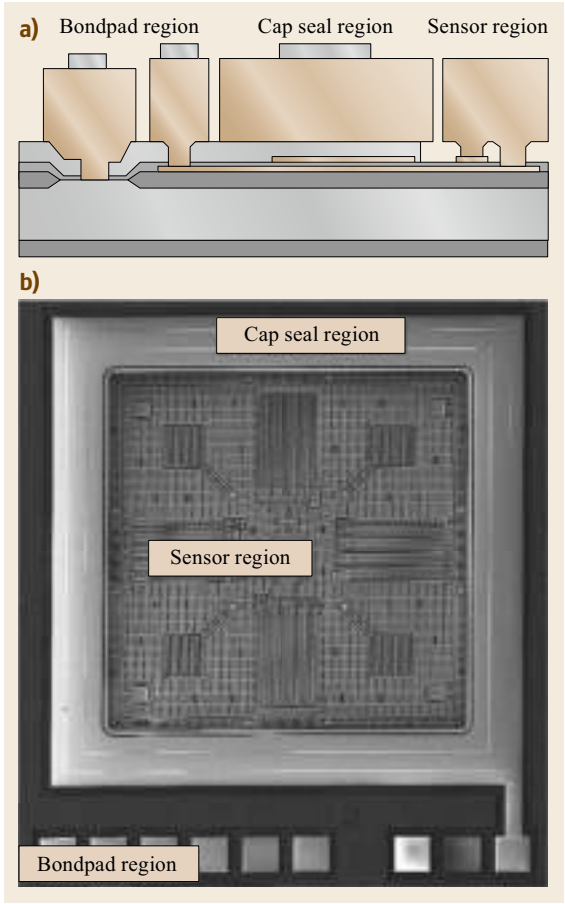

Fig. 42.4a,b MEMS-only process with 8 μm- or 16 μm-thick sensor polysilicon (courtesy of Analog Devices Inc.); **(a)** cross section showing the layers for the MEMS-only process, **(b)** top down view of the MEMS-only die before capping

lease were relatively standard processes available in a conventional IC foundry. ADI partnered with an external foundry to set up their first MEMS-only foundry process. This external foundry sent a team of engineers to work with the ADI MEMS engineers to understand all the process steps that were going to be run at the foundry, including the thick sensor polysilicon process. Every effort was taken to transfer the process as exactly as possible, but some process steps were changed to a different deposition tool but with similar film characteristics. The decisions to transfer exactly (as for the sensor poly process) or use similar but different films for other layers were made based on the expected impact on device properties and manufacturability. So, for a relatively small investment in capital, the ADI MEMS process up to the sensor element release step was transferred to the foundry with minimal impact on the other processes running in the same fab. This could be achieved as all the MEMS process steps up to the release step were compatible with the foundry fab and could use most of the existing equipment in the IC foundry fab.

For the first MEMS-only process to run at the foundry, this external foundry processed the MEMS wafers up to the sensor element release step and the cap wafers up to the seal glass frit application step to be ready to bond to the MEMS device wafers. ADI then completed the MEMS fabrication steps that included the proprietary sensor element release using a buffered oxide etch (BOE), and the application of the antistiction coating [42.9] to prevent in-use *stiction* on the MEMS device wafer. ADI also completed the processing steps on the cap wafer including the application of the seal glass frit bonding material, the wafer bonding, and final cap singulation to separate the individual die. These steps done at ADI are unique

MEMS steps requiring customized equipment and processes.

With the success of this first MEMS-only process foundry transfer, ADI and this external foundry partner continued to codevelop a full MEMS-only high-volume foundry process. This was done on 8 inch wafers on one of the 8 inch lines at the foundry. To do all the processing at the foundry, a number of process steps that would be compatible with the ADI MEMS-only process and design architectures had to be developed. This included an OEM-supplied vapor HF (vHF) release process and an OEM-supplied antistiction coating process for the MEMS element release. The cap process and the cap wafer for the MEMS wafer bonding were redesigned to take advantage of the fab equipment and process available at this foundry, such as the bonders for the bond step and the grind and polish tools for the cap singulation process, see Fig. 42.5.

ADI developed unit process steps for the vHF release process by working with an OEM supplier for the vHF step that would be compatible with the ADI MEMS-only process using a *low-stress nitride* (LSN) etch-stop layer. ADI also developed an antistiction coating process on an OEM-supplied antistiction coating tool as well as a new capping process that was compatible with a metal eutectic bond [42.15] and also compatible with the standard equipment and process steps in the CMOS fab. Further development was required for the cap singulation step to make it compatible with the new cap bonding process using equipment that was available at the foundry for the cap grinding steps. The bulk of the process development centered around integration of these new unit process steps to maintain sensor device performance and yield. Numerous adjustments or tweaks to the layout and process steps had to be made to address issues that surfaced with the integration of each of these new process steps. Process tweaks were made regarding the integrity of the etch-stop layer to the vHF and residues such as ammonium fluoride from the vHF release. Significant development effort went into achieving a predictable high-yielding metal bond process and a defect-free cap singulation process. There was heavy reliance on the foundry process development and manufacturing team to understand and optimize the process steps to fix the various issues that surfaced during the integration and manufacturing ramp-up. Through this close relationship between the foundry process teams and the ADI development team, a high-yielding and reliable MEMS-only process was qualified and released for manufacturing at the foundry. The strategy adopted and the key to success was redesigning the MEMS-only process to minimize the number of new processes and tools required for the foundry process and designing the process to be compatible with the existing cleanroom. Additional benefits were also realized; e.g., with the vHF release process, it was relatively easy to increase the sensor thickness from 8 to 16 µm, to increase the S/N performance and overload performance for the MEMS sensor element.

Strategy for Using MEMS Foundry Services

For a fabless company or organization looking to use external MEMS foundry services, there are two basic options or strategies. One option is to use a MEMS foundry process that the foundry owns and offers. The MEMS company may provide guidelines to the foundry to develop a MEMS process that is compatible with their MEMS designs. This works well for fabless MEMS companies (e.g., mCube). The approach is to obtain the design rules and design guide or process design kit (PDK) from the MEMS foundry and design the MEMS device using these. This is a well-established

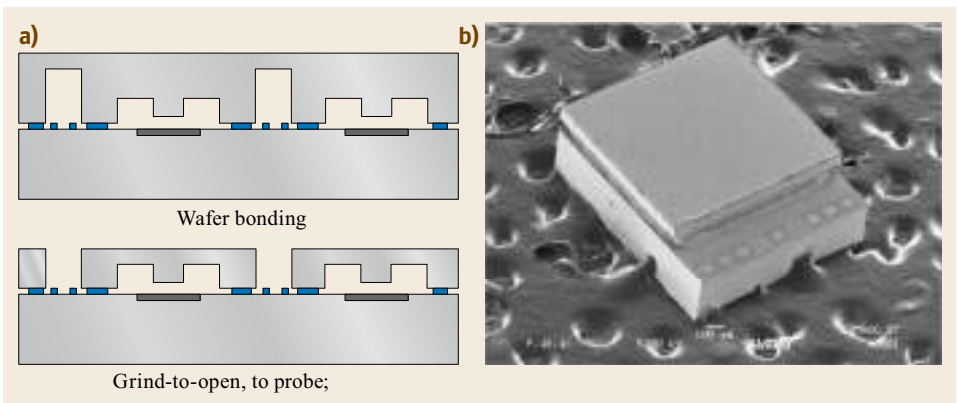

Fig. 42.5a,b MEMS cap process using grind-to-open for cap singulation (courtesy of Analog Devices Inc.); **(a)** cross section showing capping and cap grinding using Grind-to-open process, **(b)** SEM image of the 8"MEMS-only sensor die after dicing

methodology for semiconductor IC development, as the processes are well established and characterization data for individual active and passive devices manufactured using this foundry process are very well characterized and accurately simulatable. Also, the interaction of the IC devices when making a fully functional product is very well understood, so if the design does not violate any of the design rules, the product will with high likelihood operate as expected and pass qualification. The same approach for an off-the-shelf MEMS foundry process has been found to be not as predictable (Sect. 42.2). There are many variants in the sensor design between different MEMS sensor suppliers, and it is very challenging for a MEMS foundry to predict all the variants in the sensor design and how they will interact with the fabrication process flow. Typically, MEMS suppliers have developed models to predict the sensor performance and the effects of package stress and temperature on the sensor performance. These models are validated during characterization and qualification and are then adjusted (within statistical limits) to match the actual product performance. Package stress effects, anchor design, spring design, and surface parameters such as roughness and surface charge can all influence device performance. This takes a number of iterations to optimize (Robust Design for Volume Manufacturing methodology in Sect. 42.2), and often the process is modified to address issues found, in order to meet the target performance, as it may not always be possible to modify the sensor element design. In short, it has been the general experience that, to take advantage of the external foundry process, the product supplier will need a few cycles of learning to understand these interactions and implement a design for manufacturability (DfM) strategy to be successful. These process design iterations could result in a less optimal product in terms of cost, size, or performance in order to meet time-to-market requirements.

The other model for the MEMS product supplier is to develop a fabrication process internally (or at local R&D facilities) and then transfer the process to an external high-volume foundry, similar to the approach adopted by ADI and InvenSense. The difference between ADI and InvenSense is that ADI developed their MEMS processes in house using captive equipment sets and later transferred these individual process steps to the external foundry. In the case of InvenSense, the approach was to use many external MEMS foundry services to develop the process (short loop experiments and prototypes) and products and then transfer all of the processing know-how to a foundry for high-volume manufacturing. If the process is transferred exactly (including equipment utilized), then there can be high confidence that the designs will work as predicted using this process. Also, since the transferred process is proprietary to the MEMS product supplier, they have the flexibility to make modifications to the process for new products or features.

The foundry option has various advantages and disadvantages compared with using an internal fab dedicated to making MEMS devices in-house. The main advantage of internal manufacturing is the close working relationship between the MEMS designers, assembly and testing, and the fab and the flexibility to make process tweaks to address product issues as well as process changes to increase device performance and reduce cost for each product generation. Continuous constant feedback between the process and the MEMS design is critical for designing new MEMS products with quick design of experiments (DOE) cycle times. This freedom to adjust the process and add new process modules has significant advantages for new product generations. The disadvantage is the cost of maintaining a dedicated in-house wafer fab and maintain a positive variance by operating the fab close to capacity. In contrast, a dedicated MEMS fab relies on high-volume wafer starts, which is typically consumer products with lower margins. Furthermore, the consumer market is unpredictable due to its highly competitive nature and extremely short product cycles, so using a foundry service can help mitigate these risks.

42.1.3 Foundry Manufacturing

MEMS Industry Group (MIG) [42.16] provides a general guideline for anyone considering using a foundry service on their website [42.17].

In general, a statement of work (SOW) is agreed upon, which defines the scope of the work, the expected process flow and specifications, and either a timeline for product development, process transfer, and qualification, or a codevelopment agreement. The most straightforward development is a pure product development on an established *standard* MEMS fabrication process offered by the foundry, which is very rare. This will generally involve the foundry taking most of the responsibility for manufacturing the product and shipping the wafers when completed. Key items that need to be agreed upon include wafer cost, schedule, and intellectual property (IP) ownership. Both parties need to be aligned on general expectations regarding expected yield, reliability, and quality, since these can depend on unanticipated product–process interactions that will need to be resolved.

For a MEMS process transfer, additional items need to be included in the SOW and the contract. These will include setting up engineering teams at both the process owner(s) and foundry, to work out the details for

each of the fabrication steps and how each of these will be transferred or replicated at the foundry. This may involve adding some capital equipment and training and also includes sharing of equipment recipes, process specifications and control limits, and test structures. In practice, a sensor from an already released product is usually selected to qualify the process transfer and validate reliability and quality.

42.1.4 High-Volume Inertial MEMS Manufacturing Worldwide

Similar trends can be observed for other high-volume MEMS manufacturing companies. Referring to market research reports [42.18, 19], it can be observed that Bosch has also been making steady progress in increasing the sensor thickness as well as the dielectric thickness to increase the signal-to-noise performance. A review of tear down reports show that over time they have reduced the die size and increased the wafer size to reduce cost and add improved performance and functionality. Other trends include going from seal glass frit to metal bond for the capping process and combo devices in the same package. ST Microelectronics, another high-volume supplier of commodity MEMS inertial products, has made similar evolutions on a similar MEMS process. InvenSense and mCube are examples of two fabless MEMS companies that use foundries for their MEMS process for high-volume production. Their MEMS process architecture is quite different from those of ADI, Bosch, and ST, as they use a significantly different approach to make the MEMS sensor and the electrical interconnect between the ASIC and the MEMS. One of the main differences is that they use oxide chemical–mechanical polishing (CMP) and fusion bonding as some of the core process steps for building their MEMS devices. These process steps are similar to unit process steps in high-volume IC foundry fabs for making IC products, so it did not require significant process development or capital outlay to adapt them for MEMS products.

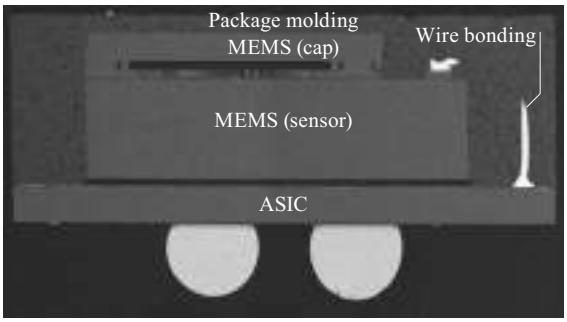

Fig. 42.6 Bosch BMA355 three-axis accelerometer cross section (courtesy of System Plus Consulting)

Bosch Sensor Fabrication Process

The Bosch version of the MEMS-only process [42.19] is an elegant process where a thick oxide is formed, using the first polysilicon layer (*poly1*) to route the electrical connections to the sensor and using a thick epi-polysilicon layer for the sensor. Figure 42.6 presents a typical example, showing a cross section of the construction of the Bosch three-axis accelerometer device.

Fig. 42.7 shows some of the sensor structure for the Bosch IMU product. Based on a previous review [42.18], the evolution of the process at Bosch is quite interesting, showing that early discrete MEMS sensor devices used 11 µm-thick sensor polysilicon with no etch-stop layer for sacrificial oxide removal. They also used conventional seal glass frit bonding for the wafer-level capping process to protect the MEMS device and enable low-cost plastic packaging. Later generations point to 20 µm epi poly and a second poly layer to improve device performance and decrease sensor size, while further driving down manufacturing

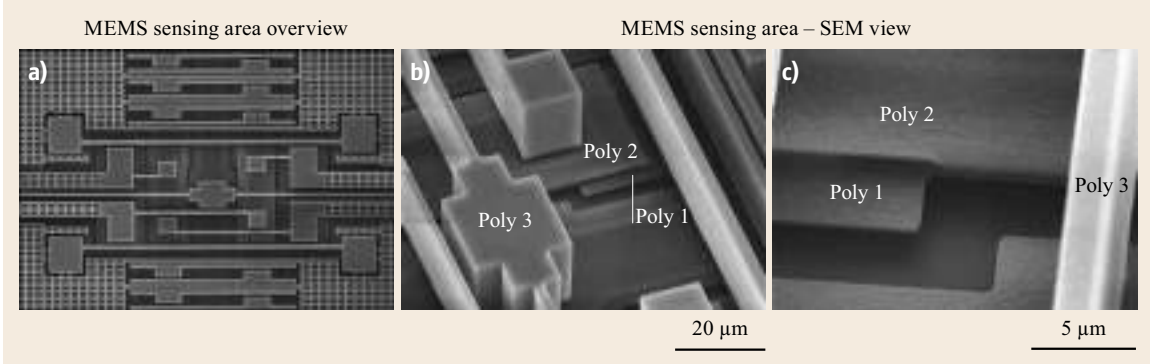

Fig. 42.7a–c Bosch SMI130 six-axis MEMS inertial measurement unit (IMU) (courtesy of System Plus Consulting); views **(a)**, **(b)** and **(c)** showing different details for the sensor poly (poly3) and the interconnect poly (poly1 and poly2)

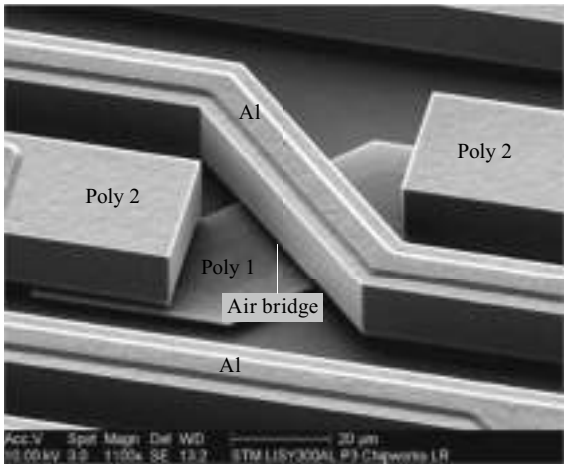
cost. Additional cost and size reduction was achieved in subsequent iterations, with a bumped ASIC with through-silicon via (TSV) through the ASIC die. This part was still plastic encapsulated, but at the wafer level, providing significant reduction in assembly and test costs if final testing was done on the bumped ASIC before dicing. Bosch was also one of the leaders in implementing Al-Ge eutectic bonding instead of seal glass frit to further decrease the die size and therefore die cost. In contrast, the discrete sensor gyro devices show that the sensor poly thickness was 10 µm with an Al-Ge eutectic bonding capping process implemented.



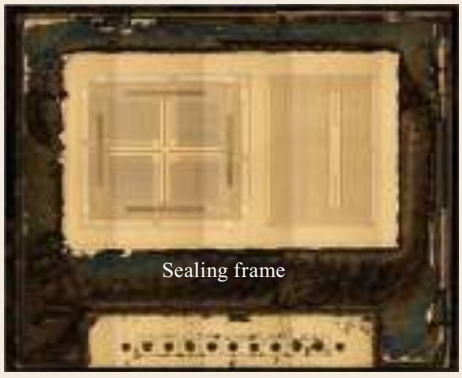


Fig. 42.8 ST LIS331DL three-axis accelerometer – metal on poly routing (courtesy of TechInsights Inc., formerly Chipworks)

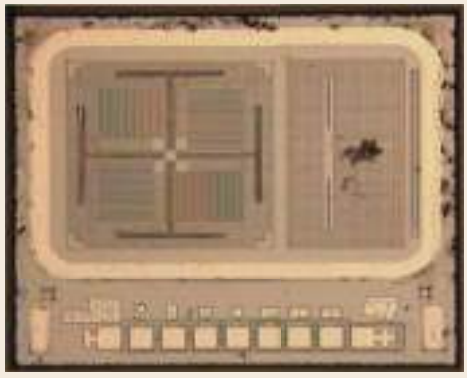
There is no *getter* layer evident in the construction, suggesting that the switch to Al-Ge may be to maintain low cavity pressure, which is needed for improved gyro performance. While increasing the sensor layer thickness and mass improves the S/N performance of accelerometer devices, provided that the Brownian noise is kept to a minimum, one does not get the same improvement in device performance for gyro designs, as they are influenced much more by the noise floor of the device. High-performance accelerometer devices can benefit directly in terms of both S/N and overload performance by increasing the sensor thickness and bonding at lower pressure to achieve cavity pressures in the range of 30–500 mbar. For gyro devices the Brownian noise has a greater effect, increasing in proportional to the sensor thickness, so there is not the same advantage with increasing the sensor thickness for gyro designs. Improvement in performance is mostly gained by decreasing the cavity pressure to below 10 mbar, which is very difficult to achieve with seal glass frit bonding, although such lower pressures can be achieved by using a metal eutectic bond (such as Al-Ge). This may explain why, for the multi-DOF (combined accelerometer and gyro die in the same package) designs, the manufacturer chose to use 10 µm sensor poly with Al-Ge metal eutectic bond for the gyro die while the accelerometer die in the same package has a 20 µm sensor layer with seal glass frit bonding [42.19].



ST Microsensor Fabrication Process

STM also have an elegant process for manufacturing discrete sensors, very similar to the Bosch process with

a thick substrate layer, polysilicon runners (signal routing), and a 15 μm-thick epi-polysilicon sensor layer in their early products. They also used conventional seal glass frit bonding for wafer-level encapsulation of the sensor to enable low-cost plastic packaging. Fig. 42.8 and Fig. 42.9 is a typical example showing some of the sensor structure of STM inertial sensors.

STM also use polysilicon for the sensor element, as well as additional polysilicon layers for signal routing and with an added metal layer (similar to the bond pad metal) on top of the thick polysilicon routing to further reduce the series resistance. For their later products, STM increased the sensor polysilicon to 24 μm and replaced the seal glass frit capping bond with a gold eutectic (Au-Au) thermal compression metal bond to reduce the die size (and cost) and also improve the accelerometer device performance. Other changes appear to be the use of materials such as tungsten silicide for the polysilicon routing layer to reduce the series resistance of the electrical connections. For their multi-DOF devices, the manufacturer chose to use the same polysilicon thickness of 24 μm for both the gyro and accelerometer sensor elements but added a *getter* layer to the capping process for the gyro sensor (deposited within the cap cavity) to maintain the cap cavity at very low pressure.

Interestingly, in other multi-DOF devices from the manufacturer, the decision was made to combine the accelerometer and gyro sensor elements on the same chip but with separate capped environments for each element; i. e., the cavity for the accelerometer and gyro is separated using a conventional seal glass frit bond. With a getter in the gyro sensor element cavity and no getter in the accelerometer cavity, both cavities can be fabricated at substantially different pressures. This highlights the simple fact that optimum performance for both the accelerometer and gyroscope cannot be achieved if the sensor thickness and cavity pressure are identical for both devices. Other process changes implemented in this fabrication flow include TSV through the sensor substrate to further reduce overall die size, and also added polysilicon layer routing paths in more recent products [42.19].

InvenSense Sensor Fabrication Process

InvenSense was one of the first fabless MEMS companies to make MEMS gyroscopic sensors using an external MEMS volume manufacturing foundry. Their first-generation MEMS gyro product was a two-axis device with a 35 μm sensor element layer using Al-Ge metal eutectic (likely related to manufacturability decisions at the external foundry) to bond the MEMS device to the ASIC and also to form the electrical connections between the sensor nodes and the ASIC. Fig. 42.10 and Fig. 42.11 shows some of the sensor details for the InvenSence products.

The process flow begins with a cap wafer with cavities etched into it, followed by silicon-to-silicon fusion bonding of the MEMS layer wafer to the cap wafer. The MEMS wafer is then ground back to the desired sensor thickness (35 μm), and germanium (Ge) is patterned on the previously bonded MEMS–cap stack. The sensor design is then formed within the 35 μm MEMS layer using a standard deep reactive-ion etch (DRIE). At this point, the capped MEMS wafer is combined with a conventionally fabricated standard CMOS ASIC wafer, but utilizing the top metal ASIC layer as the bonding nodes and the bond seal ring. Early device iterations had deep cavities etched into the ASIC die, which was likely not favored due to the necessary increase in the ASIC die size. However, more recent process iterations show that designs evolved to work without a cavity but used the top metal layer as a shield or sense node under the MEMS die.

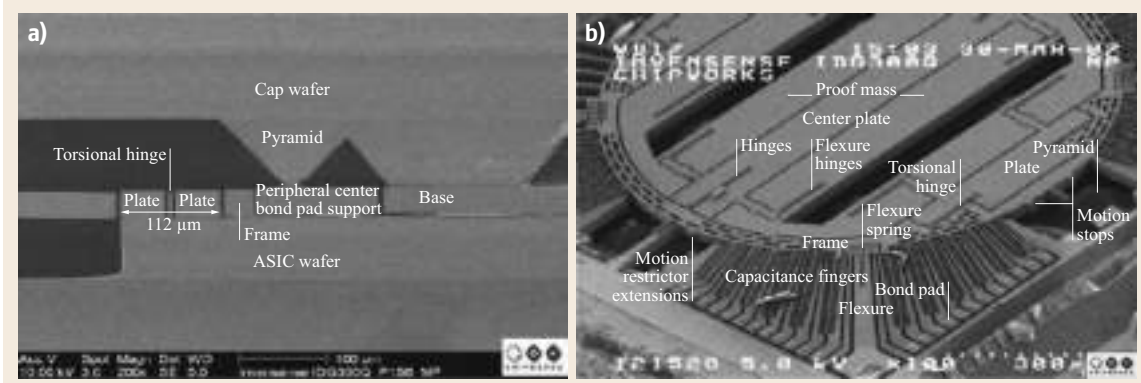

Fig. 42.10a,b InvenSense IDG-300 dual-axis MEMS gyroscope. **(a)** Cross sectional view and **(b)** top down view (courtesy of TechInsights Inc., formerly Chipworks)

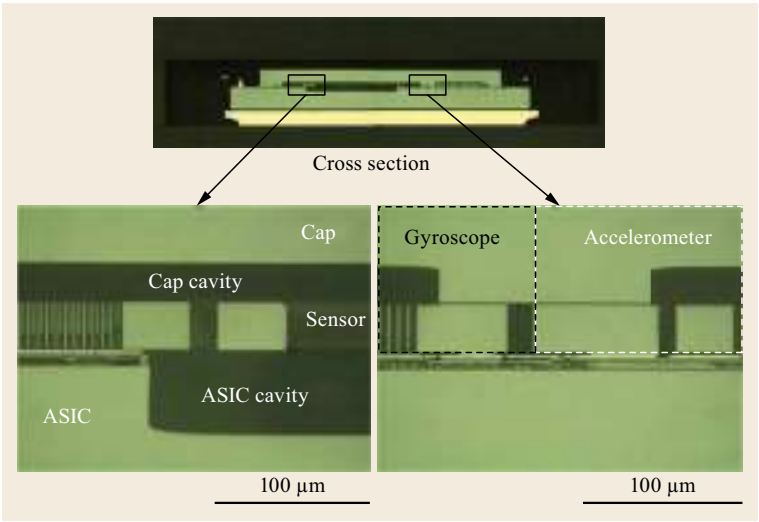

Fig. 42.11 InvenSense MPU-6000 three-axis accelerometer and three-axis gyro (courtesy of System Plus Consulting)

While there was some evolution in the process, like going from KOH etching to pattern the cap wafer to DRIE and using the top metal as an electrode for the MEMS sensing, most of the fabrication process evolution appears to have been directed towards the MEMS sensor element design and the ASIC technology nodes to shrink the die size and enable multi-DOF devices (combined three-axis gyroscope and three-axis accelerometer) on a single die.

mCube Sensor Fabrication Process

Another recent example of a company directly deploying their production to an external high-volume MEMS foundry is mCube, a new fabless inertial MEMS company. Reports [42.19] indicate that mCube appears to be using a fairly well-characterized MEMS process flow available to implement their own unique sensor design. Fig. 42.12 shows some of the sensor details for mCube process. The process has some similarities to the InvenSense sensor fabrication process and appears to use similar unit processes such as oxide-to-silicon fusion bonding and Al-Ge eutectic bonding. Both InvenSense and mCube processes do not require sacrificial oxide removal. Similar to earlier descriptions, the MEMS process uses fusion bonding to bond the MEMS wafer to the ASIC wafer, followed by a grind-back step of the MEMS wafer to the target sensor element thickness. Electrical connections through the sensor layers are realized using tungsten (W)-filled vias to make contact directly to the ASIC sensor nodes and interestingly to form the sensor anchors. The sensor element is patterned using a conventional DRIE, which also serves to isolate the sensor electrical connections, and finally the MEMS die is capped using a cavity cap wafer with metal Al-Ge eutectic bond.

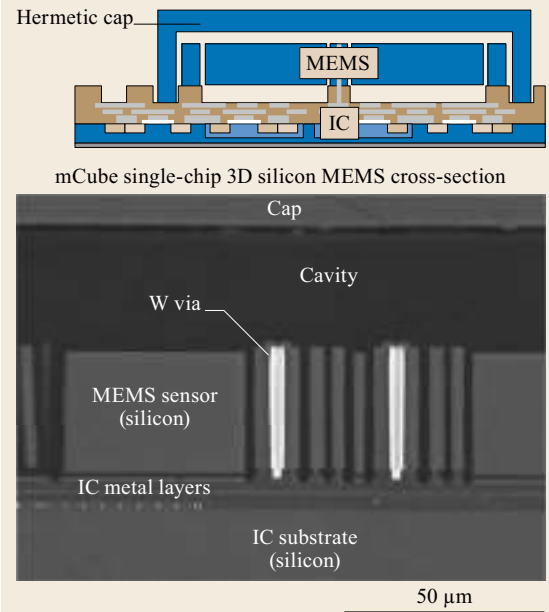

Fig. 42.12 mCube MC3635 three-axis accelerometer cross section (courtesy of System Plus Consulting in "mCube MC3635 Accelerometer Reverse Costing, 2006"). The mechanical layer of the MEMS accelerometer is constituted of silicon layer fusion bonded on top of the metal layers of the CMOS IC. The silicon layer is patterned by DRIE to form the mechanical structure. The electrical connection between the MEMS silicon layer ($\approx 30\,\mu$m thick) and the IC metal layer is realized with tungsten

One significant difference emerging between the MEMS processes used by ADI, Bosch, and STM for inertial sensors compared with InvenSense and mCube is

that the former have the flexibility to make the MEMS die and ASIC die independently as small as possible without any constraints on the MEMS or ASIC, while for the latter the MEMS and the ASIC die size are constrained to be the same, which does imply some limitations in terms of potential for manufacturing cost reduction. The other limitation is that it is difficult to evolve the latter for multi-DOF combined products that take advantage of either different cavity pressures or different device layer thicknesses. InvenSense in particular has been able to work around these limitations by using smart sensor designs and have introduced both 6DOF and 9DOF products to the market.

42.2 Robust Design for Volume Manufacturing

Robust design for manufacturing of MEMS implies deploying a MEMS element design strategy that results in high-yielding, controllable fabrication processes that provide functional and reliable sensor chips, as directly measured as the percentage of chips in a finished lot that pass all tests and function as specified. As seen in the previous section, the main requirement to build reliable parts is well-qualified manufacturing processes (Sect. 42.1); however, in this section, we take a look at the design strategy and in particular design for manufacturability (DfM) and reliability (DfR) [42.20], which are equally important for high volume MEMS manufacturing. In the MEMS industry, the challenges encountered in volume manufacturing have generally been underestimated in terms of the technical challenges they present due to the level of custom process development needed (*one product – one process*), and the effort required to resolve failure modes due to the relative immaturity of the process integration required. Section 42.1 covered some ground in describing available MEMS high-volume processes and their advantages/disadvantages and limitations, so the focus for the next few pages will be on DfM techniques to ensure successful, robust high-volume production.

42.2.1 MEMS Design for Manufacturability (DfM)

Development of MEMS-enabled products has generally followed a *one product – one process* [42.21] paradigm. Although a transition to use or reuse of standard scalable platforms has begun [42.22], as described in the previous section, there still exists a significant challenge for developing manufacturable and reliable [42.23] MEMS-enabled sensor products. DfM as a product development philosophy is well known [42.20, 21, 23], but the application of some common DfM principles (such as use of modular components, design for reuse, etc.) faces adoption challenges for MEMS development in particular (DfM incorporates the manufacturing process as part of the design and development process, including concurrent engineering design principles to produce manufacturable designs for cost-effective volume production [42.20]). The benefits of incorporating DfM for MEMS-enabled products are numerous, but at the top of the list would be reduced product development costs and time, being essential to meet the increased pace of system solution (IoT) introduction and competition. These improvements in manufacturability are typically characterized by:

- Minimization of the number of components in the manufacturing flow – specifically use of fewer masks and process modules. As seen in the cases in Sect. 42.1.4, even necessary modifications to the sensor process flow can be time consuming.
- Use of standard design (e.g., CAD models, material properties) or process elements (e.g., tools, fabrication steps, and instrumentation). In Sect. 42.1.4, the manufacturers (e.g., Bosch, STM etc.) chose to use existing, available process elements (flow) and implemented their unique sensor design within in it to ensure manufacturability.
- Available process flows or platforms can be used for a portfolio of MEMS-enabled products, which can translate to enormous potential to cut costs and reduce time to market. As noted in Sect. 42.1.4, all the cited manufacturers adopted this approach, as it ensures expandability of the product portfolio with minimal manufacturing development risk.

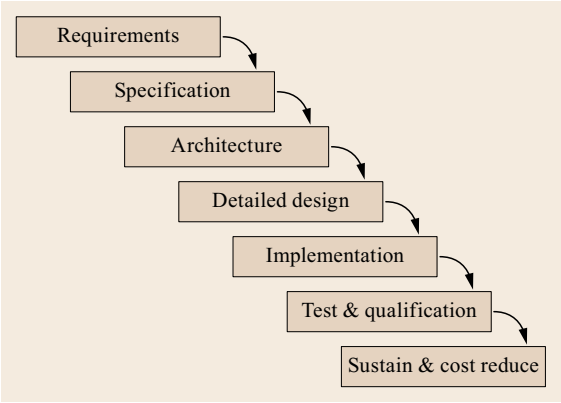

Fig. 42.13 *Waterfall* model for product development

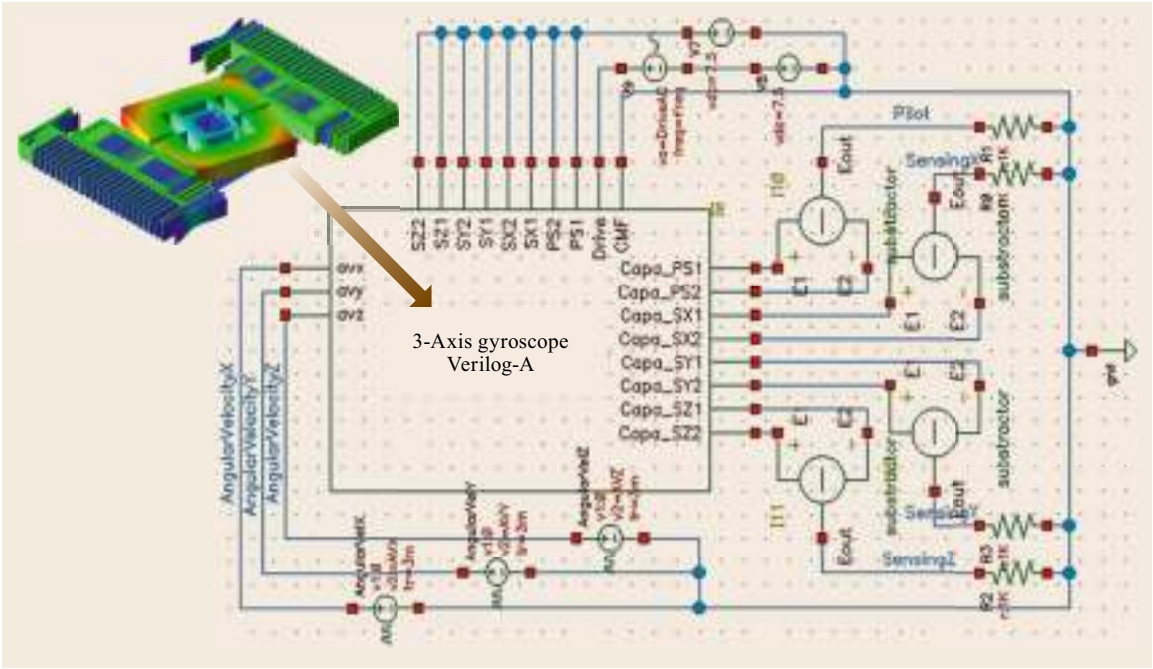

Fig. 42.14 Schematic model of a MEMS inertial sensor realized in MEMS+® (reprinted with permission from Coventor Inc. 2017)

In a typical MEMS component development flow, the product design phase has several overlapping phases that flow together, in what is widely referred to as the *waterfall* model (Fig. 42.13). Although this has been covered in significant detail elsewhere [42.23], it is worth highlighting that in the primary development stages, these phases have a significant impact on the course of product development and the robustness of the final product.

Technical Requirements and Architectural Design Phase, where the customer needs of performance, cost target, and component description are clearly articulated through the definition of a clear, detailed technical specification for the final product. This is a crucial step in the process, and one that can take many iterations. It typically involves data analysis, simulation, and even in some cases test chips to translate product requirements into precise engineering requirements and subsystem specifications that can serve as necessary inputs for the subsequent, more complex design phase.

Before any detailed design work can commence, the overall product architecture must be established. This is not a trivial task, as it has deep implications not only at the manufacturing level (which technology to employ, e.g., wafer-level chip-scale packaging (WLCSP), 0.18 μm CMOS, etc.) but also for the fundamental strategy at the design level (e.g., open/closed loop, power saving schemes, etc.), with the most critical issue being harmony between the design and process flow selected. As mentioned above, the down-selection process (especially for the sensor element design) often includes early evaluation of multiple sensor element designs [42.24], and this can typically result in evaluation of early test chips to identify critical limits of the design or process. Through iteration, once the system architecture has been established (based on general considerations of manufacturing availability; e.g., 0.18 μm CMOS ultralow leakage for the ASIC, or 30 μm-thick polysilicon for the sensor element are typical choices), evaluation of multiple design concepts needs to be completed in order to select candidate designs that are closest to meeting the required specifications. On the ASIC side, this translates to evaluating approaches for various subblocks (analog to digital converter (ADC), oscillator etc.), whereas on the sensor element side, this means understanding the design envelope available (spring constants, position of stoppers, etc.).

For the design of the ASIC signal chain, well-characterized PDKs are available from high-volume foundries (e.g., TSMC, Global Foundries, etc.) with well-characterized design rules, which makes it less burdensome as long as the design operates within established process limits. However, for MEMS element design, PDKs are not always available [42.25]. A MEMS foundry may make a limited set of design rules available, which sets design constraints for certain

but not all primary design parameters, and although this allows designers to proceed with the task of creating and evaluating multiple design concepts (using specialized design automation tools, e.g., CoventorWare™ or Intellisuite™), the interaction of the design and process (e.g., etch hole size, stopper shape, etc.) can have a significant impact on the robustness of the design once fabricated, and long-term reliability is virtually unknown without further characterization and testing. However, even with these limitations, this approach enables evaluation of sensor performance *and* to some extent manufacturability within a *set of constraints*, meaning that only designs that could potentially be manufactured within a particular process are evaluated.

Robust Design Phase: the primary goal in this phase is to thoroughly analyze and optimize the performance of the lead conceptual design(s) selected in the previous phase, using a variety of standard semi-analytical, analytical, and numerical techniques [42.26] to perform *optimization* studies, *tolerance-based design*, and *statistical design* to thoroughly evaluate the ability of the candidate designs to meet the required specifications. With modern design automation tools (e.g., MEMS+, Cadence; Fig. 42.14), *virtual manufacturing* analysis has become more widely available, and while only as accurate as the models used, it is gaining in importance as a necessary task, enabling optimization of device performance considering fabrication tolerances and process corners. Additionally, functional yield can be verified using a variety of techniques including *Monte Carlo* methods, and *sensitivity* analyses as shown in Fig. 42.15. At this stage, the focus of the designer is on quantifying the effects of *random variations* and *errors* on typical performance parameters (*sensitivity*, *cross-axis*, *dynamic range*, etc.) of the part [42.26] within the available process corners and operating ranges.

To the extent possible, determined of course by the manufacturing strategy decisions outlined above, it is beneficial to analyze the impact of manufacturing performance variations on the design *before* taping out any mask sets or fabrication of actual silicon. As discussed in Sect. 42.1, when an external foundry makes sufficient details regarding the established fabrication process(es) available, and the process is well controlled and characterized by available design rules, it becomes straightforward to predict functional yield and design sensitivities [42.26]. However, in cases where processes are not that well established, it is necessary to quantify achievable process limits before attempting such detailed designs [42.27]. The effort towards quantifying achievable limits overlaps with standardization efforts (either industry wide as has occurred in the IC industry and to a limited extent in MEMS, but also within a foundry) for measurement and characterization of material properties and process control parameters. The primary benefits are first-pass silicon success (design accuracy) and also more rapid development of new process technologies.

Package Design – The *co-design* of the package with the sensor element is critical, and preliminary assessment of the packaging options available must be initiated simultaneously with the *detailed design phase*. Ideally, the design team performs the package design as an *extension* of the sensor design to minimize the potential for redesign at a future stage. The performance of the part and potential sensor–package interaction failure modes that could arise (due to earlier sensor design decisions), as well as the package design and material selection and their impact on reliability and manufac-

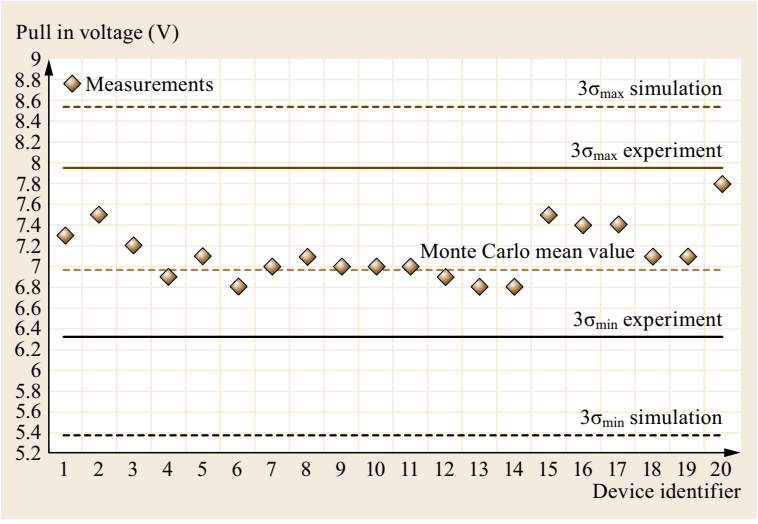

Fig. 42.15 Measured pull-in voltages for 20 suspended-plate variable capacitors in comparison with simulation results (after [42.24])

turability, has been described in detail elsewhere [42.23] but remains a critical factor, especially for the development of inertial sensors (Sect. 42.1). Today, low-cost plastic overmold packaging [42.28] is quite common (Fig. 42.16) for most MEMS inertial sensor products [42.18, 19]; however, in some cases, specialty packaging is needed (optical systems, Vital-Sign Monitoring (VSM) applications, or MEMS microphone packages), requiring additional development, and this necessary task must be factored into the overall development. Lastly, detailed decisions about the package design, especially pad configuration and placement, overall package dimensions and tolerances, maximum ratings, and even specific material choices, need to be made. At some level, similar choices face the design team, i. e., custom versus commercial off-the-shelf (COTS) package, highlighting that, in the development of MEMS products, using off-the-shelf packaging technologies will save development time and reduce overall risk.

Test (ATE) Development – The third important component of part design and one area that often gets overlooked during the design phase is the testability of the part, often referred to as design-for-test (DfT). The design team must also include robustness during final testing as part of the sensor–package design. In production, the part is handled by automated test equipment (ATE) and will experience unique thermomechanical forces due to handling and other back-end operations that may not be accounted for in the specification; For example, the packaged sensor could see higher than normal forces due to differences in the tolerances of the test socket compared with the package dimensional tolerances. Tolerance-based design practices must ensure survival of the component as well as no accumulated damage during this back-end stage.

Once the preliminary detailed design iteration has been completed and the design has successfully passed all available design rule checks (DRCs), the manufacturing stage can begin. In situations where process variability is still in question, the sensitivity of the design to these variations has to be quantified by collaborative effort between the design and process teams, resulting in the first tapeout of the design.

Manufacturing Phase: The manufacturing phase begins development of the MEMS sensor and ASIC fabrication process, as well as the assembly process for the product. Essential steps highlighted earlier (characterization of new process steps, etc.) involved in developing the sensor fabrication process must begin in parallel with the *detailed design* phase, and should include detailed process requirements and evaluation of available process platforms. Evaluation of available fabrication processes is necessary because there are basically three options with varying levels (as described in Sect. 42.1) of risk and cost structure: (a) available standard processes, generally found at captive foundries, (b) available standard processes with minor modifications, or even a well-established process transferred to another facility, or (c) a completely new process flow. One obvious consideration is ownership or control of the available process – as seen in Sect. 42.1 a majority of high-volume MEMS manufacturing process flows only exist in captive foundries, although this continues to evolve, and today there are multiple MEMS foundries that provide contract manufacturing services [42.29]. Each manufacturing platform process flow is composed of several unit process steps (that either add or remove material in a precise order [42.30]), and so in defining process requirements, it is necessary to factor in the tolerance limits and variations of these process characteristics such that specific performance parameters are constrained appropriately. In the situation where available platforms are either insufficient or require modification, validation of process development and integration experimental results must be performed to ensure manufacturability. Standardization efforts within the foundry should focus on identification and selection of relevant material properties and the conditions and metrology that influence these properties. Various approaches involving test structures (both in-line and monitor wafers) and material property measurements (off-line and small sample testing) have been employed with some success, but these approaches are by no means uniformly common in high-volume foundries. The goal of in-line measurements for MEMS process flows (similar to wafer acceptance test (WAT)

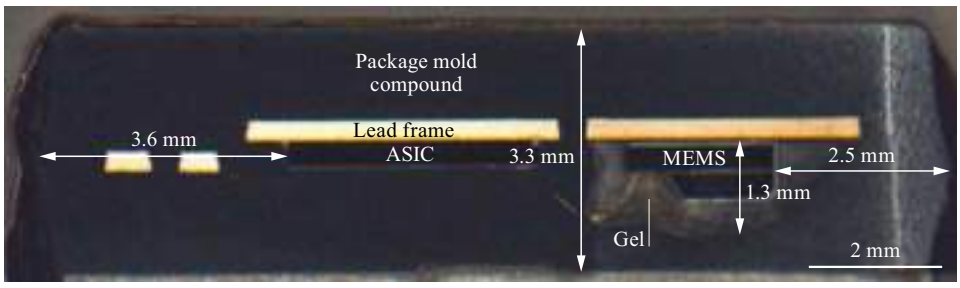

Fig. 42.16 Cross-section of a typical plastic overmolded MEMS sensor (courtesy of TechInsights Inc., formerly Chipworks)

structures used in IC fabrication) remains, and several industry groups including NIST continue to work on standardization. A table of material properties and process control parameters that are needed for MEMS is described in detail in [42.27] and replicated in Table 42.1 for convenience.

A manufacturing organization that is tasked with MEMS fabrication needs to ensure stable and reproducible fabrication processes to manufacture reliable products. As described above, fabrication of MEMS-enabled products requires in-depth analysis and review of product architecture and decisions regarding integration, size, and the process steps to use; the overall number of process steps and where they occur are among a large set of variables that affect the risk and cost of the end product, but more importantly determine success. A MEMS process is said to be stable when all of the parametric measures of the process have means, variances and distributions over time [42.31] leading to consistent chute yields over time. The path to achieving a high level of confidence in the manufacturing process is time consuming, requiring a step-by-step confidence building effort that begins with design of experiments (DOE) to identify significant process variables. The results of the DOE are then implemented on batches of validation material to confirm the outcome of the experiments and establish process baselines. Further DOEs may be needed to skew the primary variables to establish precise design rules that ultimately lead to a well-qualified, stable and reproducible process flow for future designs. It is generally true that, in the development or deployment of a completely new process flow, one is unlikely to achieve the low-ppm level of reliability within that process until a significant number of wafers have been processed. This sometime implies that the first designs released to the market using such a process may be vulnerable to field returns, but subsequent products using the same manufacturing flow will no doubt benefit. Over time, the process will mature to the point where it is possible to have extremely low field failure rates (a few ppm), and so the obvious challenge for the engineering team is to reach that level of field failures as soon as possible.

As described in earlier sections, the evolution of MEMS products has gone through several stages of integration. From the early days of integration of MEMS and signal processing side by side on the same die (e.g., iMEMS®) to discrete MEMS and ASIC die (e.g., integration through assembly) to the present-day wafer-level chip-scale packaging (WLCSP) integration of die by wafer bonding, the impetus has been to reduce size and cost by increasing the die per wafer (DPW) with fewer overall masks and process steps. Of course, this is dependent on the particular design and fabrication goals in each case, but design for manufacturability (*DfM*) is a powerful methodology that both the design and manufacturing teams need to adopt to improve manufacturing quality and yield of MEMS-enabled products.

Table 42.1 Material properties and process control parameters for MEMS fabrication (after [42.27])

42.3 Stable Field Performance

Field stability refers to the ability of a MEMS product to maintain stable performance parametrics, i. e., meet datasheet specifications, over the life of the component. Robust design of MEMS devices, and precisely controlled manufacturing processes, are needed to ensure stable field performance. However, even well-designed and well-fabricated parts can fail in-use due to a variety of factors that are usually considered out of bounds in terms of the design or process capability as well as use case. Typically, detailed analysis of the potential failure modes is performed using failure modes and effects analysis (FMEA) during the development cycle to try to anticipate and mitigate such failures. Clearly, there exists a strong linkage between design, manufacturing, and stable field performance [42.23], but a large proportion of MEMS product failures generally fall into two categories – electrical (e.g., dielectric charging and electrostatic discharge (ESD)) and mechanical (e.g., stiction, shock, and creep) failures. In this section, some of the primary failure modes within these categories are described, along with typical approaches to mitigate or prevent such failures.

42.3.1 Electric Field Stability

Due to the increased complexity of the ASIC signal chains in modern MEMS sensor products, field returns due to anomalous performance of specific ASIC functionality is not uncommon. Usually, these types of field returns are related to the sensitivity of the design to a process variable that may shift over time or from one lot to the next. By and large, the root cause of these failures can be reproduced by simulation and appropriate steps (and mitigated through either test-based screens or redesign), but for MEMS products, with the additional degree of freedom due to the sensor and package, the most common in-field failures experienced include dielectric charging and electrical breakdown (electrostatic discharge (ESD) or electrical overstress (EOS)) [42.23]. These electrical failure modes can play a significant role in a component's lifetime, and can cause unstable performance through either catastrophic failure or performance drift. The task of preventing these potential failure modes begins in the detailed design phase, but proper control of fabrication materials and surface chemistry control is also absolutely necessary for their mitigation.

Dielectric Charging: High electric fields (10^8 V/m) experienced across bulk and surfaces within some MEMS sensors can lead to charge injection resulting in trapped charges, and leakage currents, which are typically strong functions of temperature and humidity. Some dielectrics used in electrostatic MEMS are tailored to have low stress (as they are part of moving elements and have to have predictable behavior), and achieving this often requires a tradeoff with film electrical properties (reduced breakdown voltage, etc.). Charging of dielectrics is a complex phenomenon at the atomic scale and can be highly dependent on film composition and stoichiometry, deposition rates, times at temperature (as well as heating/cooling rates), and the specific techniques used for making the film. Mitigation of such charging effects involves a combination of design approaches such as geometry changes (removing dielectrics from certain areas, shielding, etc.) and material changes (i. e., composition of dielectrics) [42.32]. An example is deposition or growth of a thin conductive layer on top of a dielectric to bleed off surface charge, but this requires careful consideration of the design configuration and placement of various elements. Charging results in unpredictable spurious electrical fields that can disturb the stability of the moving MEMS element, leading to drift over time or even stiction. In accelerometers and gyros, this mechanism causes offset drift over time, leading to gradual loss of performance and eventually failure.

Electrostatic Discharge (ESD) and Electrical Overstress (EOS) – This refers to the sudden or instantaneous transfer of charge due to large potential differences between sensitive nodes in the component and can occur through a solid dielectric or through the gas (in between layers). In conventional ICs, protection against such failures is well established, but much less so for MEMS where ESD can cause both electrical (Fig. 42.17) and mechanical damage (pull-in or breakage of sensor element). Often, the mechanism can lead to catastrophic failure of the MEMS component, although less damaging erratic performance has also been observed in inertial sensors. Currently, techniques are available to quantitatively measure (human body model (HBM), machine model (MM), and charge discharge model (CDM)) and quantify device susceptibility, but they may not capture specific in-use situations encountered in the field.

Although there are clearly many design practices [42.23] that can be implemented to mitigate the harmful effects of ESD/EOS, from a manufacturing standpoint, the main choices are again geometrical (well-characterized design rules for spacings) and/or material (choice of appropriate materials). It is important to also mention the role of proper handling in the back-end of the production line so that opportunities for triboelectric charge generation are completely eliminated.

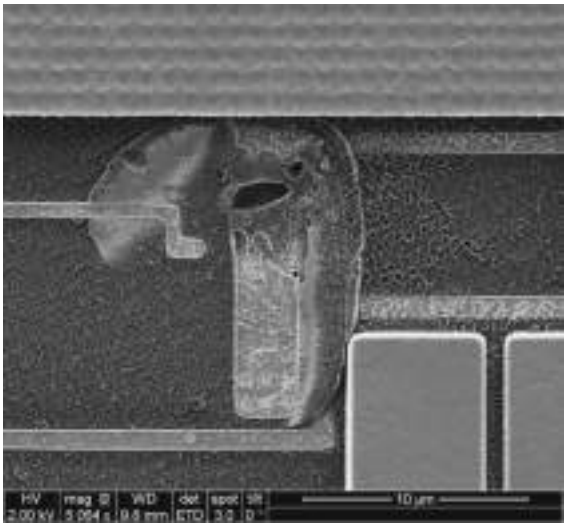

Fig. 42.17 EOS damage at ESD protection pad (courtesy of Analog Devices Inc.)

Fig. 42.18 Pinned and free-standing cantilever beams (reprinted with permission from [42.36, 37]. © 1993 IEEE)

The electric field stability of MEMS devices is also known to exhibit failure modes related to galvanic corrosion, anodic oxidation, pad damage, electrical discharge, etc., at either sensor die or package level, and these can be mitigated by proper control of fabrication steps (e.g., metal pad corrosion).

42.3.2 Mechanical Field Stability

Besides electrical field stability concerns, mechanical field stability concerns such as shock response, bias stability, noise stability etc. are often encountered in MEMS devices but the most common field stability issue in inertial MEMS is stiction. It is one of the primary tribological failure mechanisms in MEMS [42.33, 34], occurring when a suspended structure exhibits unexpected adhesion to adjacent contacting surfaces [42.34]. Although stiction usually manifests during fabrication, under certain circumstances it can also occur during use, i. e., *in-use* stiction.

Adhesion of two adjacent MEMS surfaces in contact occurs due to a combination of a variety of physical mechanisms such as van der Waals forces, electrostatic forces (trapped charge), and liquid capillary forces or a combination of these forces [42.35]. The use of wet chemical processes in MEMS fabrication is known to leave residual ions, dangling bonds, and even monolayer films of water and/or polymers. In such cases, adhesion predominantly occurs due to surface tension forces [42.38], although other triboelectric mechanisms can also influence this mechanism.

During component usage, the physical and chemical state of the contacting surfaces is a critical factor for the development of adhesive forces. A high-energy surface, which can evolve due to contamination, moisture, and film out-gassing during field use because of either known or unplanned failure modes (the surface energy can change over time due to repeated contact or due to a change in moisture levels, ambient gas, or surface roughness), can cause stiction to occur, leading to catastrophic failure of the component and potentially the system it resides within. Within the manufacturing process, it therefore becomes necessary to consider the balance and control of the process variables more precisely to prevent stiction [42.35]. In most inertial and optical MEMS devices where such failure modes are to be prevented, a combination of design and process modifications can be deployed to ensure mitigation of this failure mode. On the design side, it is relatively common to include bumps, stoppers, and other geometrical features to minimize contact surface areas. Additionally, the sensor element mechanics can be designed to ensure sufficient tolerance to applied voltages or displacements. On the process side, besides proper sequences of process steps to ensure low-energy surfaces, antistiction coatings are commonly used to further improve performance and eliminate stiction.

42.4 Internet of Things (IoT)

The IoT refers to the third wave of technology development, as depicted in Fig. 42.19. The mid 1950s saw the first wave with the development of solid-state devices and mainframe computers for businesses. The 1960–1970s saw a major growth period, which then began to level off as businesses and technology matured. The second wave was the development of personal computers, laptops, smartphones, and tablets. As the chart shows, there was a very rapid development of these devices starting in the 1980s and maturing in the 2000s. The connectivity offered by these devices, especially smartphones, has opened up a new area of technology development, which we call the Internet of Things or IoT. With the development of the internet and personal electronic devices, most of the modern world is now connected to the web and one another, providing ready access to information and the sharing of data. This provided a new opportunity to automate much of our daily activities, the methods we use to control our daily lives, and how we manage our personal tasks such as our health, finances, the efficiency of our homes, our communications, and work. To support this new paradigm of living, we will need ubiquitous sensing and signal processing to monitor our health and our environment, which can interface with our personal electronic devices, and the *intelligent* network to interpret and act on all this data as well as to provide a structure for the efficient use of this data. This will require multiple sensors, signal processing, wireless communication, cyber security, data analysis, storage, and applications as well as algorithms to manage and interpret all this data so that this information can help guide meaningful decisions.

Among the major areas where sensors will be used, smart agriculture, smart homes, and the smart environment are expected to be the industries seeing the greatest impact. The focus will be on developing systems to monitor our food for freshness, the cleanliness of the air we breathe, and the water we drink, as well as to detect hazardous chemicals or biological agents. In agriculture, soil quality, fertilizer concentrations, and insecticide levels will be monitored continuously to grow crops better and more efficiently. In the case of such systems deployed in homes, the goal would be to increase our energy efficiency by automatically turning on lights and other appliances in the most efficient manner and also to monitor our personal health in real time. It is predicted [42.2] that there will be 50 trillion connected devices with multiple sensors in the next 25 years. This includes wearables leading to e-health enabled by the mobile market as well as remote, fully contained systems for monitoring soil, clean food, air, water, roads, and building infrastructure. In our homes and workplaces, sensors will be used to monitor all our appliances, energy usage, security, etc. that are remotely accessed and monitored to reduce waste and improve their efficiency. In addition, a significant majority of these sensors will need energy-harvesting solutions for their (rechargeable) power source due to the size and cost of replacing disposable batteries.

All of this monitoring will demand a huge number of sensors of various types, including chemical, magnetic, inertial, and pressure sensors to name but a few, and MEMS manufacturing technology will need to scale significantly to meet the demand from such applications. To make these sensors, we need high-volume and low-cost sensor manufacturing technologies and likely novel three-dimensional (3-D) printer-based technologies to meet this huge demand at low cost.

While identification of this new massive business opportunity has generated lots of excitement and exploratory research and development work, there are significant challenges, specifically in evolving technologies and material science advances to provide solutions that meet the cost, manufacturability, reliability, and performance requirements. These challenges will require huge resources or individual companies to accurately predict narrow areas to focus on to develop new, profitable business directions. Over time, the materials and manufacturing technology approaches and strategies will determine winners and losers; at this point of time, the risks are still high, and it is not clear which direction IoT deployment (industry) will take to ensure success.

The IoT will require complete standalone system solutions; autonomous is another term that best describes such systems. So, in addition to the sensor, the

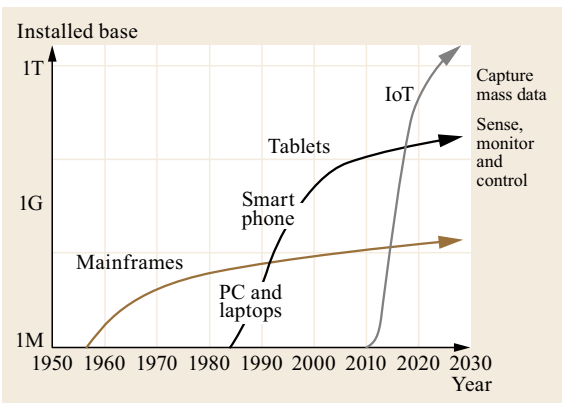

Fig. 42.19 Three waves of technology development. The IoT is predicted to have 1000× more devices compared with the second wave

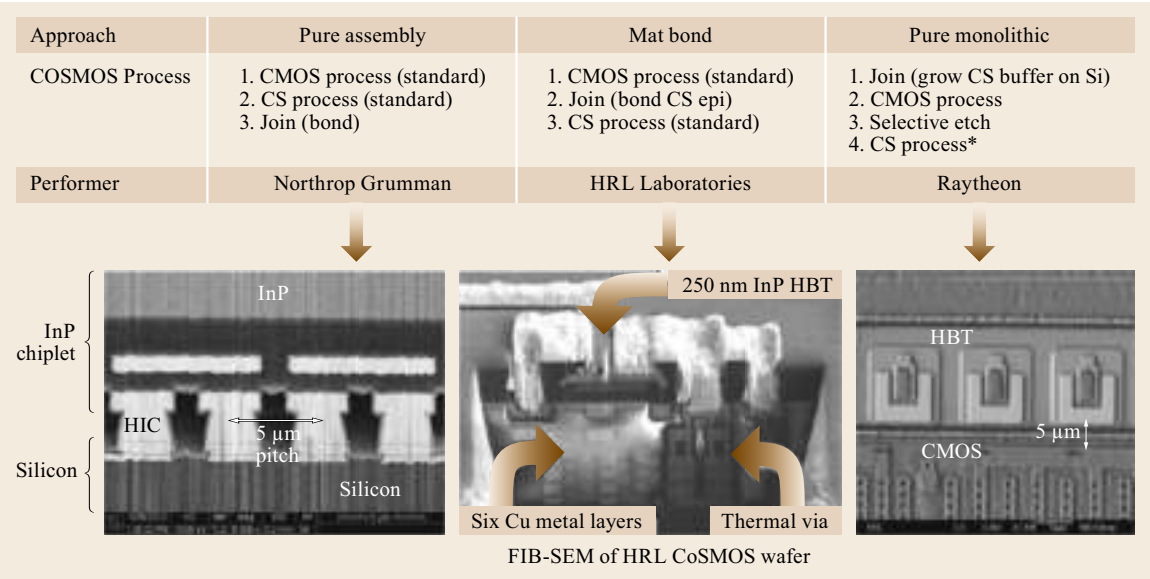

Fig. 42.20 Heterogeneous integration techniques funded by the DARPA COSMOS program (*CS*: chip scale)

system will need signal processing, wireless communication to your mobile device, and a renewable power source for implantable or remote location. MEMS devices and manufacturing technologies can be retooled and scaled to support this new sensor revolution. Many MEMS devices can be repurposed, and the fundamental science used for MEMS such as capacitive, piezoresistive, and piezoelectric sensors can be used to make a vast number of new IoT sensors. Also, MEMS unit processes such as bonding, deep silicon etching, depositing thick and thin films, and interfacing the device with the environment can be used as unit process steps in the development of the next generation of sensors, which suggests that existing MEMS manufacturers should have a head-start if not a clear advantage. In short, the requirements for the new IoT era that will be the main technology drivers are low-cost high-volume manufacturing, ultralow-power signal processing and networking, energy harvesting, and energy storage for the power source and algorithms and software for data management, providing secure error-free standalone sensor systems.

42.4.1 Heterogeneous Integration

Initially, new sensors and systems for the IoT will be silicon based, building on the experience to date in MEMS technology, wireless communication, and recent development efforts for energy harvesters.

The IoT will require rethinking of conventional semiconductor packaging and manufacturing approaches. The emerging concept of *heterogeneous integration* will be an enabling technology for the IoT. Heterogeneous integration refers to technologies which closely combine different types of semiconductor devices in ways that push far beyond what is now done using traditional semiconductor packaging techniques; For example, future heterogeneous integration technologies will enable combination of III–V semiconductor devices with silicon semiconductor devices with micron-scale placement accuracy and interconnect parasitics approaching that of monolithic integration. This will enable solutions that use the *right junction for the function*; that is, the optimum semiconductor material will be used for each particular function in a system. ICs will be manufactured which consist of, for example, GaAs or InP low-noise and radiofrequency (RF) power amplifiers, highly scaled CMOS for data converters, logic, and memory, and piezoelectric materials for sensors, all integrated together into a single piece of silicon in a single package. Cost-effective realization of this vision will enable IoT nodes with size, weight, and power that are impossible with traditional monolithic manufacturing and die packaging technologies.

Heterointegration will be needed to integrate all these different technologies into one system solution. Heterointegration is the process of transferring devices from one wafer with devices built using one technology to another wafer with devices built using a completely different technology so that the individual devices that make up the complete system can be integrated together. Heterointegration takes the system in package (SIP) approach for individual integration of different chips to the wafer level.

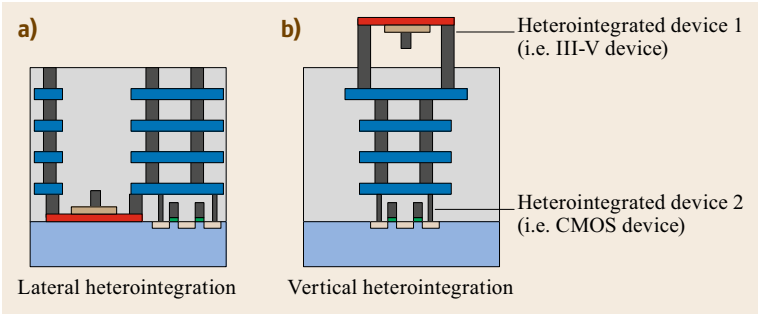

Fig. 42.21a,b Pictorial depiction of **(a)** lateral and **(b)** vertical heterointegration

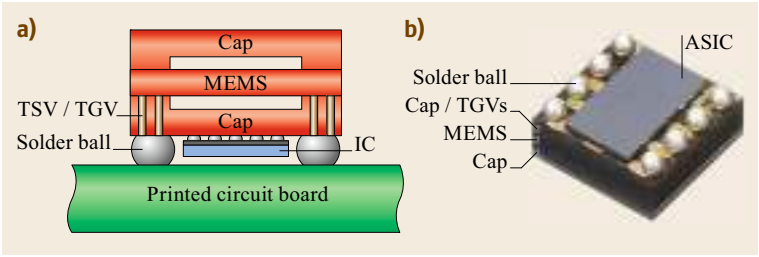

Fig. 42.22a,b Vertically integrated wafer bonding to integrate a MEMS device with a CMOS signal processing chip at wafer level (after [42.39]); **(a)** cross section, **(b)** image of diced device (*TGV*: through glass via)

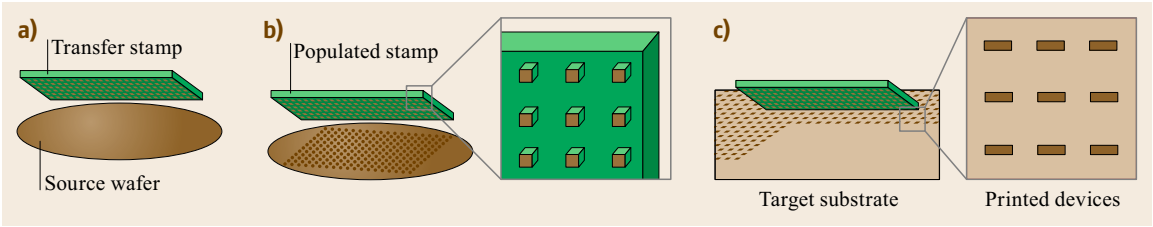

Fig. 42.23a–c Depiction of transfer printing process. A polymer stamp **(a)** is used to pick up large arrays of thin devices **(b)** and place them on a second wafer **(c)**

Heterointegration can take devices from a processed III–V wafer and integrate them with a foundry CMOS wafer. Another example could be a MEMS device on a MEMS wafer with either a processed III–V wafer, or both a III–V and a MEMS wafer to a foundry CMOS wafer. Heterointegration is highly flexible in enabling integration of different devices to provide a finished, self-contained product solution; For example, it can combine RF and high-frequency analog devices with foundry CMOS or any other unique process such as high-speed SiGe or InP devices, GaN high-speed high-power devices, photonics, or the new emerging technologies for energy storage or energy harvesters. So, developing heterointegration processes to mix many different types of chip at wafer level is one approach to develop a low-cost high-performance self-contained solution for emerging IoT products. Another advantage of heterointegration over SIP is that it allows microscale integration of different devices to reduce size and parasitic capacitance, resistance, and inductance between devices. With SIP integration, the minimum device sizes are relatively large and they have high interconnect parasitics. Heterointegration will enable integration of smaller devices and through parallel processing provide higher accuracy and matching of device placement and significantly lower manufacturing costs.

Many groups are pursuing different types of *heterogeneous integration*. The US Defense Advanced Research Program Agency (DARPA) funded a variety of these approaches in the COSMOS program. The different approaches taken in that work are shown in Fig. 42.20. Three different approaches were pursued. Raytheon pursued a heteroepitaxy approach to enable monolithic integration of InP devices with CMOS. Northrop Grumman pursued an approach which combines various *chiplets* on an interposer wafer. Hughes Research Labs used a wafer bonding approach. In all cases, III–V devices were joined with silicon devices with micron-scale spacing between the III–V device,

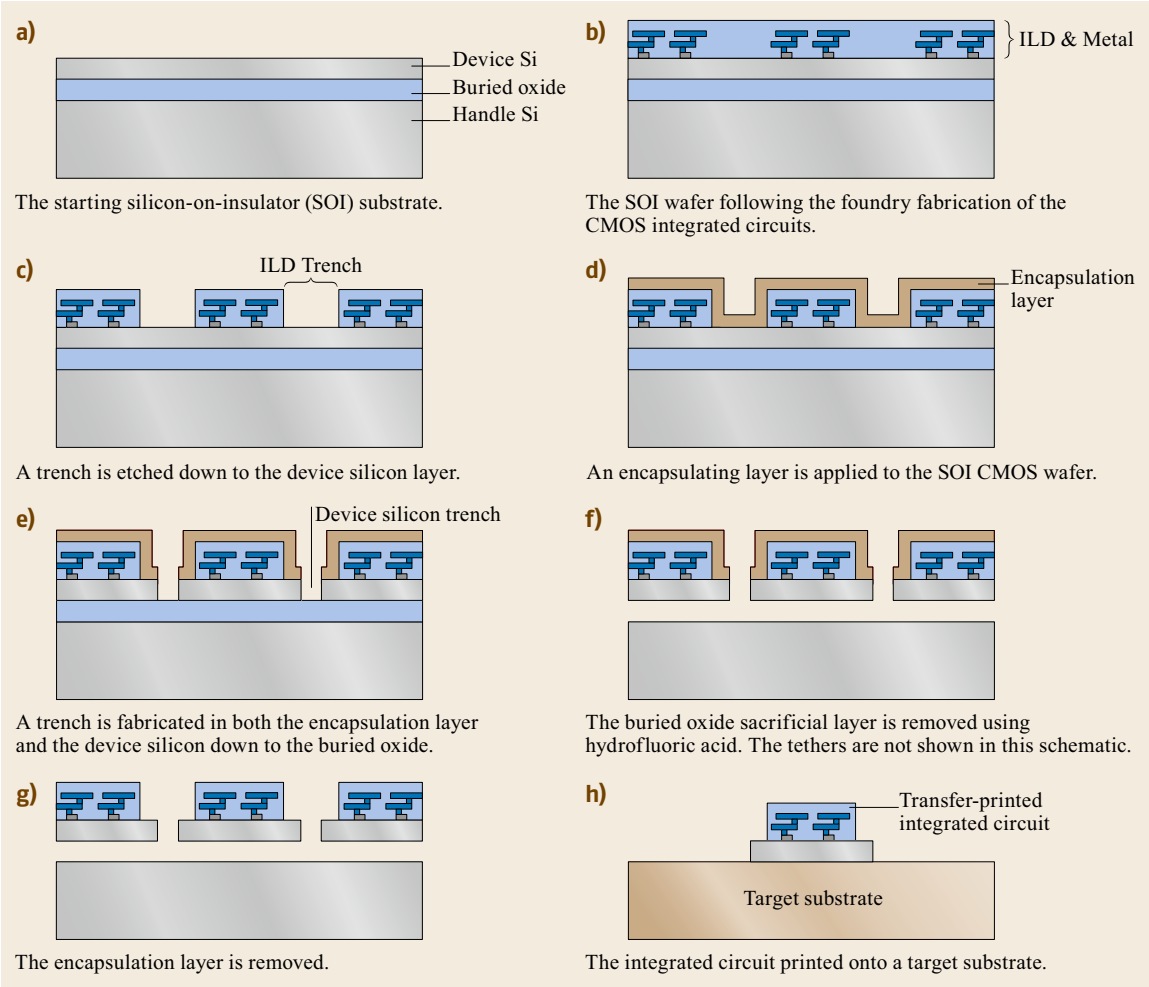

Fig. 42.24a–h Depiction of use of the transfer stamping process to transfer devices from an SOI wafer to a quartz wafer for display back-plane applications (*ILD*: inter level dielectric)

and with interconnect parasitics which approach what can be achieved in a monolithic process.

There are two basic modes of heterointegration, i. e., lateral (side by side) and vertical (stacked), as shown in Fig. 42.21.

Wafer-to-wafer bonding with TSVs is one way to integrate a MEMS wafer with submicron CMOS (Fig. 42.22). Here, Al-Ge eutectic bonding is used to form the electrical interconnect between the two different wafers, and a second major advantage is that it serves to form the cap for the MEMS device as well. TSVs through the CMOS or MEMS wafer act as input and output connections for the vertically heterointegrated device. The main advantages of this style of wafer bonding are close lateral alignment and the ability to form a large

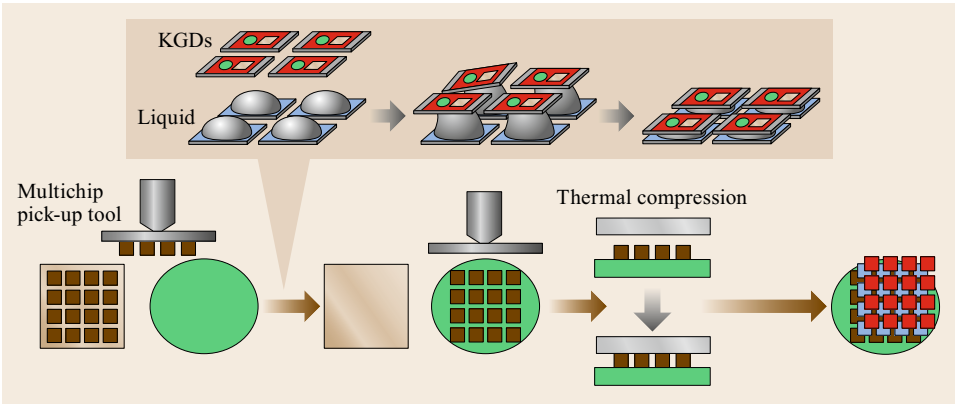

Fig. 42.26 Self-assembly-based multi-chip-to-wafer bonding (SA-MCtW)

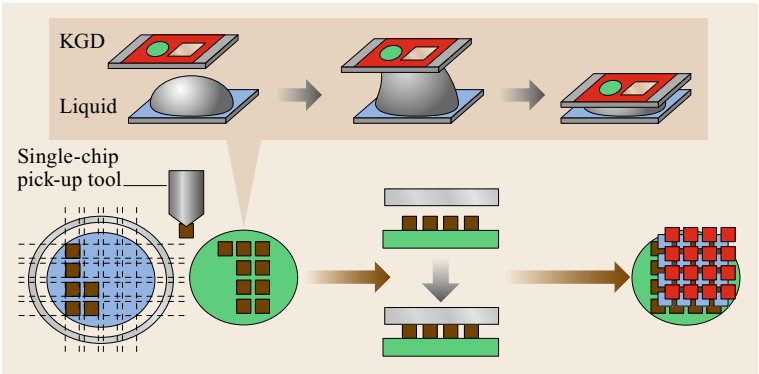

Fig. 42.27 Hybrid self-assembly-based chip-to-wafer bonding (HAS-CtW)

number of interconnects, but the main disadvantage is that one cannot easily integrate wafers of different sizes, and that the overall size is now determined by the size of the largest active device (which could leave valuable space unused).

This is a great example of vertical heterointegration. Another technique that is worth considering is microscale transfer printing [42.40], where a polymer array is used to pick up chiplets from one wafer and transfer them to a second wafer, as shown in Fig. 42.23.

Transfer stamping is another variant of this technology, as depicted in Fig. 42.24 and Fig. 42.25. Both approaches take chiplets from one wafer and transfer them to receptor regions on a second wafer.

Other approaches involve die to wafer transfer, where a pick and place tool can take individual die and flip them to align and bond with interconnects on the acceptor wafer.

This could be scaled up to take an array of singulated die and flip and bond to the acceptor wafer. Here once again, additional processing is performed to form electrical interconnects between the die that has been transferred and the die on the receiving wafer.

A variant on die to wafer transfer is a process that uses self-assembly techniques [42.41]. This technique requires special treatment of the acceptor wafer to obtain regions with specific surface tension to attract the chiplets and then uses thermocompression for bonding the die to the wafer. Two examples are shown in Figs. 42.26 and 42.27. One technique developed by Tohoku University [42.42] is to place a droplet of water on the receiving wafer where the chiplets are to be placed and use a pick and place tool to take singulated die from the donor wafers and place them on the water droplets. The chiplets self-align on the water droplets due to the surface tension of the water droplet and are then fixed in place using a thermocompression bond.

There are other ways to achieve heterointegration, but they lie outside the scope of this chapter. The aim of this discussion of heterointegration is to show that wafer-level bonding is currently used for heterointegration of MEMS with foundry CMOS, and that this and other heterointegration techniques are expected to gain momentum with the development of new sensors for the IoT.

42.5 Conclusions and Outlook

In this chapter we have discussed the evolution of MEMS high-volume manufacturing at ADI and some other high-volume MEMS manufacturing companies. There are two basic approaches. One is to make the MEMS device using a separate process and wafer and then connect the MEMS die with a signal processing die in a two- or multichip package using wire bonding. Future trends will be to use heterointegration to connect the MEMS die with the signal processing die through conductive bonding. Both the MEMS and CMOS processing can be done internally or using an external MEMS foundry. The second approach is monolithic integration of the MEMS device with the CMOS using fusion bonding followed by postprocessing. This approach generally requires that all the processing be done either internally or using an external foundry. The InvenSense process is a hybrid between these two approaches. The MEMS industry has been around for over 30 years now, and we are beginning to see commoditization of many MEMS products such as inertial sensors, microphones, and pressure sensors. Just as the semiconductor industry was the core technology to build MEMS devices, MEMS technology will become the core technology for new IoT sensors and devices.

43. Packaging and Reliability Issues in Micro/Nano Systems

Yu-Chuan Su, Jongbaeg Kim, Yu-Ting Cheng, Mu Chiao, Liwei Lin

The potential of microelectromechanical systems (MEMS)/nanoelectromechanical systems (NEMS) technologies has been viewed as a revolution comparable to or even greater than that of microelectronics. The scientific and engineering advancements in MEMS/NEMS could enable applications that were previously unthinkable, from space systems, environmental instruments, to appliances for use in daily life. As presented in previous chapters, development of core MEMS/NEMS processes has already demonstrated many commercial applications as well as potential for advanced functionality in the future. However, low-cost and reliable packaging for protection of these MEMS/NEMS products remains a very difficult challenge. Without addressing these packaging and reliability issues, no commercial products can be sold on the market. Packaging design and modeling, packaging material selection, packaging process integration, and packaging cost are the main issues to be considered when developing a new MEMS packaging process. In this chapter, we present the fundamentals of MEMS/NEMS packaging technology, including packaging processes, hermetic and vacuum encapsulation, wafer-level packaging, three-dimensional (3-D) packaging, polymer-MEMS assembly and encapsulation, thermal issues, packaging reliability, and future packaging trends. Specifically, development of MEMS packaging will rely on successful implementation of several unique techniques, including packaging design kits for system and circuit designers, low-cost and high-yield wafer-level, chip-scale packaging techniques, effective testing techniques at wafer level to reduce overall testing costs, and reliable fabrication of an interposer [43.1] with vertical through interconnects for device integration.

43.1 Introduction to MEMS Packaging

MEMS are miniaturized systems of micrometer to millimeter size, integrating mechanical, chemical, or biomedical features with IC circuitry for sensor or actuator applications [43.2]; For example, pressure [43.3], temperature, flow [43.4], acceleration [43.5], gyroscopic [43.6], and chemical sensors [43.7] can be fabricated using MEMS technologies for sensing applications, while fluidic valves [43.8], pumps [43.9], and inkjet printer heads are examples of actuation devices for medical, environmental, office, and industrial applications. Silicon is typically used as the primary substrate material for MEMS fabrication, because of its unique electrical, thermal, and mechanical properties as well as its easy micromachining in batch processing and

B. Bhushan (Ed.), *Springer Handbook of Nanotechnology*, DOI 10.1007/978-3-319-49347-3_43

potential incorporation with microelectronic circuitry mostly using conventional semiconductor manufacturing processes and tools. The resulting MEMS devices offer the advantages of smaller size, lighter weight, lower power consumption, and lower fabrication cost compared with existing macroscale systems offering similar functionality. With the advances of MEMS fabrication technology in recent decades, the MEMS market at component level now exceeds 5 billion, driving end-product markets of more than 100 billion [43.10].

Nevertheless, the road to commercialization of MEMS does not look as promising as expected. Many industrial companies have taken advantage of MEMS technology due to the high production volumes and high added value resulting from product integrations. Therefore, cost-efficiency has become the major factor driving MEMS toward commercialization. Several MEMS devices have been developed for and applied in the automotive industry and information technology field, dominating the MEMS market due to their high production volumes. However, custom-designed MEMS products remain very diverse, aiming for different applications, and their initial costs in small- to medium-scale production are still much higher than market-acceptable levels. In this regard, high packaging and testing costs have hindered MEMS commercialization. Furthermore, based on past experience in the IC industry, the cost of packaging processes is about 30% and can sometimes be more than 70% of total production costs. MEMS packaging processes are expected to be even more costly, because of the challenging and stringent packaging issues related to the MEMS components, in addition to microelectronic circuitry, in a typical MEMS product [43.11].

43.1.1 MEMS Packaging Fundamentals

Sealing or encapsulation is an important step in either integrated circuit (IC) or MEMS packaging processes, to protect devices during operation. In traditional IC packaging procedures, the overall packaging steps often involve [43.12, 13]:

1. Wafer dicing
2. Pick-and-place
3. Electrical connections, such as wire bonding
4. Plastic molding or housing for the sealing process.

With the increasing requirement for high-performance and multifunctional consumer electronic products, IC packaging processes have incorporated more complex designs and advanced fabrication technologies, such as Cu interconnects [43.14], flip-chip bonding [43.15], ball grid array [43.16], wafer-level chip-scale packaging [43.17], 3-D packaging [43.18], etc. to satisfy the needs for high I/O density, large die area, and high clock frequency. The functions of conventional IC packaging are to protect, power, and cool the microelectronic chips or components and provide electrical and mechanical connection between the microelectronic part and the outside world. Unlike regular ICs, the diversity of MEMS products complicates the sealing issue. MEMS packaging processes cannot directly follow the procedures applied in the IC packaging industry due to inclusion of free-standing physical microstructures or chemical substances which cannot survive dicing or pick-and-place steps before the sealing process. Moreover, MEMS components may need to interface with the outside environment (for example, fluidic interconnectors [43.19]), while other components may need to be hermetically sealed (for example, accelerometers [43.5]) in addition to the need for electrical interconnects. Therefore, MEMS packaging processes may have to provide more functionality, including better mechanical protection, thermal management, hermetic sealing, and complex electrical and signal distributions.

It has been suggested that MEMS packaging should be incorporated in the device fabrication stage as part of the micromachining process. Although this approach solves the packaging requirement for some specific devices, it does not address it for general microsystems. In particular, many MEMS devices are now fabricated using various foundry services [43.20, 21], and there is a tremendous need for a uniform packaging process. Figure 43.1 shows a typical MEMS device being encapsulated by a packaging cap. The most fragile part of this device is the suspended mechanical sensor, which is a freestanding mass–spring microstructure. This mechanical part should be protected during packaging and handling processes. Moreover, vacuum encapsulation may be required for such microstructures in applications including resonant accelerometers [43.5] or gyroscopes [43.6, 22]. A *packaging cap* with a properly designed microcavity should be fabricated to encapsulate and protect such fragile MEMS structures as a first-level postpackaging process. The wafer can then be diced and well-established packaging technology from the IC industry applied to complete the packaging. Additionally, a common packaging requirement for MEMS devices is hermetic sealing and sometimes vacuum encapsulation. Hermetic sealing is important to ensure that no moisture or contamination can enter the package and affect the functionality of microstructures. This increases the difficulty of common IC packaging processes tremendously. Although most single-function MEMS chips can employ typical IC packaging techniques, such as die-attachment pro-

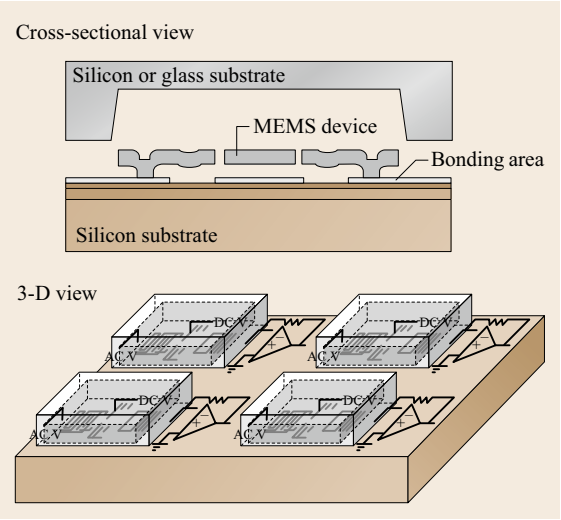

Fig. 43.1 Typical MEMS packaging with a MEMS structure encapsulated and protected by a packaging cap

cesses and wiring interconnects, using molded plastic, ceramic, or metal for packaging [43.12], the increasing complexity of MEMS devices requires more advanced packaging techniques, especially wafer-level packaging, for integration of multiple chips for multifunctional applications; for example, if chemical or biomedical substances are present [43.23], any sealing process must not exceed low processing temperatures. For optical devices [43.24], the sealing process should provide good optical paths. If mechanical resonators are included [43.25], vacuum sealing might be required to improve device performance, with the desired vacuum level depending on the device specification.

Before state-of-the-art MEMS packaging processes are discussed, several primary microfabrication processes for packaging applications are summarized. These processes include the flip-chip (FC) technique, ball grid array (BGA), through-wafer etching, and electroplating. Other silicon-based processes, such as thin-film deposition, wet and dry chemical etching, lithography, lift-off, and wire-bonding processes, are described in many textbooks [43.26].

Flip-Chip (FC) Technique

This technique is commonly used in the assembly process of a chip with microelectronics and a packaging substrate [43.15]. The microelectronic chip is *flip joined* with the packaging substrate, and metal solder bumps are used for both bonding and to form electrical paths between bond pads on the microelectronic chip and metal pads on the packaging substrate. Because the vertical bonding space may be very narrow, being controlled by the height of the solder bumps, and the bond pads can be distributed across the whole chip rather than only on the edge, this technique can provide high-density input/output (I/O) connections. In the FC technique, solder bumps are generally fabricated by means of electroplating. Before the bumping process, multiple metal layers, such as TiW-Cu, Cr-Cu, Cr-Ni, or TaN/Ta/Ni, are deposited to form a seed layer for electroplating and as a diffusion barrier to prevent diffusion of solder into underlying electrical interconnects.

Ball Grid Array (BGA)

This technology is very similar to the FC technique. An area array of solder balls on a single- or multichip module are used in the packaging process as electrical, thermal, and mechanical connects to join the module with the next-level package, usually a printed circuit board [43.16]. The major difference between typical BGA and FC chips is the size of the solder bumps; in a BGA chip, the bumps are in the order of 750 μm in diameter, which is 10 times larger than those commonly used in an FC chip.

Through-Wafer Etching

This is a chemical etching process to make through-wafer channels on a silicon substrate for fabrication of vertical through-wafer interconnects. The chemical etching can be either a wet or dry process. Anisotropic or isotropic etching solutions can be used in a wet etching process, while the dry etch process is based on plasma and ion-assisted chemical reactions, which can be either isotropic or anisotropic. To create high-density and high-aspect-ratio through-wafer vias, deep reactive-ion etching (DRIE) is typically used. Two popular DRIE approaches, Bosch and Cyro, are well described in literature [43.27].

Electroplating

Electroplating is another common microfabrication process. It can be used for deposition of an adherent metallic layer onto a conductive or nonconductive substrate. The process on a conductive substrate is called electrolytic plating, utilizing a seed layer as the anode to transfer metal ions onto the cathode surface when a DC current is passed through the plating solution. The plating process without use of an electrical current is called electroless plating and can be applied on both conducive and nonconductive surfaces. The electroless plating process requires a layer of noble metal such as Pd, Pt, or Ru on the substrate to catalyze the self-decomposition reaction in the plating solution. Electroplating processes are very important for fabrication of electrical interconnects and solder bumps for packaging applications, because of their low process temperature and cost. They are generally applied to pro-

vide electrical and thermal paths for various IC/MEMS packaging approaches.

43.1.2 Contemporary MEMS Packaging Approaches

Several MEMS packaging issues and approaches before 1985 were discussed in the book *Micromachining and Micropackaging of Transducers* [43.28], and researchers have been working on MEMS packaging approaches continuously since then; for example, *Senturia* and *Smith* [43.29] discussed packaging and partitioning issues for microsystems, and *Smith* and *Collins* [43.23] used epoxy to bond glass and silicon for chemical sensors. Several multichip module (MCM) methods have been proposed. *Butler* et al. [43.30] proposed adapting multichip module foundries using the chip-on-flex (COF) process. *Schuenemann* et al. [43.31] introduced a 3-D stackable packaging concept based on the top–bottom ball grid array (TBBGA) that includes electric, fluidic, optical, and communication interfaces. *Lee* et al. [43.32] and *Ok* and *Baldwin* [43.10] presented a direct-chip-attach MEMS packaging approach using through-wafer electrical interconnects. *Laskar* and *Blythe* [43.33] developed an MCM packaging process using epoxy. *Reichl* [43.34] discussed different materials for bonding and interconnection. *Grisel* et al. [43.35] designed a special process to package microchemical sensors. Special processes have also been developed for MEMS packaging, such as packaging for microelectrodes [43.36], packaging for biomedical systems [43.37], and packaging for space systems [43.38]. These specially designed, device-oriented packaging methods are aimed at individual systems. However, there are few reliable methods that would qualify as versatile MEMS postpackaging processes that meet the rigorous process requirements of low temperature, hermetic sealing, and long-term stability.

Several MEMS postpackaging processes have been proposed. *Butler* et al. [43.30] demonstrated an advanced MCM packaging scheme. It adopts the high-density interconnect (HDI) process consisting of embedding bare die into premilled substrates. Because MEMS structures have to be released after the packaging process, this scheme is undesirable for general microsystems. *Van der Groen* et al. [43.39] reported a transfer technique for complementary metal–oxide–semiconductor (CMOS) circuits based on epoxy bonding. This process overcomes the surface roughness problem, but epoxy is not a good material for hermetic sealing. In 1996, Cohn et al. demonstrated a wafer-to-wafer vacuum packaging process using silicon-gold eutectic bonding with a 2 μm-thick polysilicon microcap. However, experimental results showed substantial leakage after a period of 50 days. *Cheng* et al. [43.40] developed a vacuum packaging technology using localized aluminum/silicon-to-glass bonding. In 2002, *Chiao* and *Lin* [43.41] demonstrated vacuum packaging of microresonators by rapid thermal processing. These research efforts indicate the strong need for a versatile MEMS postpackaging process.

43.1.3 Bonding Processes for MEMS Packaging Applications

Silicon bonding technologies have been used in many MEMS fabrication and packaging applications, two types of which are commonly applied:

- Direct bonding processes such as anodic bonding and fusion bonding
- Bonding processes with intermediate layers, such as epoxy bonding, eutectic bonding, and solder bonding.

Direct wafer bonding processes are procedures that facilitate permanent attachment between two wafers without any intermediate layer. A permanent bond between two wafers can also be accomplished by using intermediate layers. Joining processes using intermediate layers have been extensively used in the ceramic industry to form metal-to-metal and metal-to-ceramic joints [43.42, 43] and can be characterized as [43.44]:

1. Fusion or melting of two materials to form a stable intermediate compound which facilitates the bond
2. Diffusion, in which pressurized joint parts are heated to 70% of the material's melting temperature to form a stable intermediate compound at the interface
3. Brazing, where a filler material is placed between the two parts to be joint, forming a stable intermediate compound upon heating.

These processes are commonly used when a lower bonding temperature or stronger bonding interface is required but cannot be achieved by a direct bonding process. Furthermore, the intermediate layers may reflow during the bonding process and fill the gaps between two bonding surfaces to overcome the surface roughness problem commonly encountered during direct wafer bonding processes. As such, the requirement for fine surface roughness for direct wafer bonding processes can be greatly relieved by using such intermediate layers.

Many MEMS applications have used both direct bonding as well as other bonding processes based on intermediate layers; For example, devices such as pressure sensors, micropumps, and biomedi-

cal or chemical sensors require mechanical interconnection when bonded onto the substrate [43.7, 19, 45]. Glass has been commonly used as the bonding material for anodic bonding at temperature of about 300–450 °C [43.46, 47]. *Klaassen* et al. [43.48] and *Hsu* and *Schmidt* [43.49] demonstrated different types of silicon fusion and Si–SiO_2 bonding processes at very high temperatures above 1000 °C. *Ko* et al. [43.28], *Tiensuu* et al. [43.50], *Lee* et al. [43.51], and *Cohn* et al. [43.52] used eutectic bonding for different applications. All of these bonding techniques have different mechanisms that determine the individual bonding characteristics and process parameters. This section discusses the details of these processes.

Fusion Bonding

Silicon fusion bonding is an important fabrication technique for silicon-on-insulator (SOI) technology. This method is based on the strong Si–O, Si–N, or Si–Si covalent bonds. However, very high bonding temperature (above 1000 °C) and flat bonding surfaces (below 6 nm) to ensure intimate contact are the two basic requirements for strong, uniform, and hermetic bonding. The common silicon-to-silicon fusion bonding process starts with wafer hydration (soaking in H_2O_2–H_2SO_4 mixture, diluted H_2SO_4, or boiling nitric acid, or use of oxygen plasma) to create a hydrophilic top layer consisting of O–H bonds [43.53]. Prebonding is accomplished when the two wafers are brought into intimate contact and van der Waals forces create a bond between the two wafers. An annealing step at elevated temperature is required to strengthen the bond. Although hydrophilic surface treatment can lower the bonding temperature, annealing above 800 °C is still required to prevent bubble formation at the bonding interface. *Bower* et al. [43.54] proposed that Si_3N_4 fusion bonding could be achieved at temperature below 300 °C. *Takagi* et al. [43.55] proposed that silicon fusion bonding could be achieved at room temperature by using Ar^+-beam treatment of the wafer surface with bond strength comparable to conventional fusion bonding. In summary, fusion bonding is a popular fabrication technique for MEMS fabrication and packaging.

Anodic Bonding

The invention of anodic bonding dates back to 1969, when *Wallis* and *Pomerantz* [43.56] found that glass and metal could be bonded together at about 200–400 °C below the melting point of glass with the aid of a high electrical field. This technology has been widely used for protecting onboard electronics in biosensors [43.57–59] and sealing cavities in pressure sensors [43.60]. Many reports have also discussed the possibility of lowering the bonding temperature using different approaches [43.61, 62]. Anodic bonding forms Si–O or Si–Si covalent bonds, some of the strongest chemical bonds available for silicon-based systems. The bonding process can be accomplished on a hot-plate at temperature of 180–500 °C in atmosphere or vacuum environment. When a static electrical field is applied between Pyrex glass and silicon, sodium ions in the glass migrate away from the silicon–glass interface, creating a locally high electrical field, and a bond forms due to electrochemical effects [43.56]. To create a high electrical field, a flat bonding surface with roughness of less than 50 nm is required. In addition, the electrical field required for bonding is larger than 3×10^6 V/cm [43.28]. Such a high electrical field is generated by a power supply of 200–1000 V. Figure 43.2 shows the setup for anodic bonding, where two bonding wafers are brought together and heated to an elevated temperature to supply the bonding energy. Care must be taken if there are free-standing, conductive micromechanical structures on either wafer to be bonded, as the high voltage tends to pull and may damage such structures. A thin metal film can be formed on the glass cap to provide shielding to solve this problem, as shown in Fig. 43.2. Furthermore, Corning 7740 Pyrex is commonly used in silicon-to-glass bonding systems, because it contains sodium ions and has a thermal expansion coefficient close to that of single-crystalline silicon in the range of 200–300 °C. The problem of induced residual stress can thereby be minimized in this temperature range. *Hanneborg* et al. [43.63] successfully bonded silicon with other thin solid films, such as silicon dioxide, nitride, and polysilicon, by using an intermediate glass layer with the anodic bonding technique. *Chavan* and *Wise* [43.64] reported absolute pressure sensors fabricated using the anodic bonding technique. In this process, a silicon cap with a thin, heavily doped boron layer and a recess cavity was bonded in vacuum environment to a glass substrate with prefabricated interconnection lines. However, the problem of oxygen outgassing due to the high electrical field in the anodic bonding process presents a challenge for the vacuum sealing process [43.65]. A thin Ti/Pt

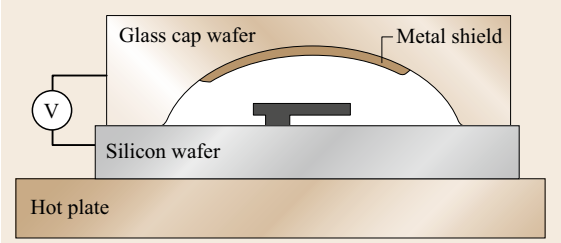

Fig. 43.2 Schematic diagram of setup for silicon-to-glass anodic bonding

layer predeposited on the glass surface has been shown to provide a good diffusion barrier, and the resulting pressure in the cavity can reach 200 mTorr [43.64]. In another example, microgyroscopes were fabricated using the anodic bonding technique by *Hara* et al. [43.66].

In practice, electrostatic bonding has become widely accepted for MEMS fabrication and packaging applications, as described above. Unfortunately, the possibility of contamination due to excessive alkali metal in the glass or damage to microelectronics due to the high electrical field, and the requirement for flat bonding surfaces limit application of anodic bonding for MEMS postpackaging [43.67].

Epoxy Bonding (Adhesive Bonding)

Epoxy comprises four major components: epoxy resin, filler-like silver slake, solvent or reactive epoxy diluent, and additives such as hardeners and catalysts [43.68, 69]. The bonding mechanism is very complicated, depending on the type of epoxy applied. In general, the main source of bonding strength is the van der Waals force. Because epoxy is a soft polymer material and its curing temperature for bonding is only around 150 °C, low residual stress and process temperature are the major advantages of epoxy bonding. However, the properties of epoxy can be easily changed by environmental humidity and temperature, so the bonding strength decays over time. In addition, epoxy bonding has low moisture resistance and is a dirty process due to its additives. These disadvantages make epoxy bonding unfavorable for special MEMS packaging requirements such as hermetic or vacuum sealing.

Eutectic Bonding

In many binary systems, there is a eutectic point corresponding to the alloy composition with the lowest melting temperature. If the environmental temperature is maintained above this eutectic point, two contacting surfaces containing the two elements with the eutectic composition can form liquid-phase alloy. Solidification of this eutectic alloy results in *eutectic bonding* at a temperature lower than the melting temperature of either element in the alloy. Eutectic bonding can form a strong metal bond; For example, in the case of the Au–Si alloy system, the eutectic temperature is only 363 °C for the composition with atomic ratio of 81.4% Au to 18.6% Si, and the bonding strength is above 5.5 GPa [43.70]. Because other alloy systems may have lower eutectic temperature than the Al–Si system, they have great potential for use in MEMS packaging applications. In addition to the Au–Si system, the Al–Ge, Au–SnSi, and Au–Ge–Si systems have been applied for MEMS packaging. Specifically, InvenSense has used the Al–Ge bonding process for their gyroscope products [43.71].

Solder Bonding

Solder bonding has been widely used in microelectronic packaging [43.72], offering the advantages of both low bonding temperature and high bonding strength for packaging applications. Furthermore, there are a variety of choices of solder material for specific applications. *Singh* et al. [43.73] successfully applied solder bump bonding for integration of electronic components and mechanical devices in MEMS fabrication [43.74]. In this case, indium metal was used to bond two separated silicon surfaces together by applying 350 MPa pressure, with bonding strength as high as 10 MPa. Glass frit can also be treated as a solder material and has been extensively used for vacuum encapsulation in the MEMS industry. Glass frits are ceramic materials that can provide strong bonding strength with silicon and good hermeticity. The bonding temperature is lower than 400 °C, suitable for electronic components. However, bonding width of greater than 200 μm is required to achieve good bonding results, which may become a drawback because area is a measure of manufacturing cost in the IC industry. Nevertheless, glass frit is the most popular bonding process used in current MEMS products.

Localized Heating and Bonding

Low bonding temperature and short process time are desirable process parameters for MEMS packaging fabrication, to decrease the thermal budget and increase throughput. However, most chemical bonding reactions require a minimum thermal energy to overcome the reaction energy barrier, or activation energy, to start the reaction and form a strong bond. As a result, high bonding temperature generally results in shorter processing time to reach the same bonding quality at a lower bonding temperature [43.75]. The common limitations of the bonding techniques described above are their individual bonding characteristics and temperature requirements. In general, MEMS packaging requires good bonding for hermetic sealing, while the processing temperature must be kept low at wafer level to have less thermal effects on devices that are already present; For example, a MEMS device may have prefabricated circuitry, biomaterial or other temperature-sensitive materials such as organic polymer, magnetic metal alloy, or piezoceramic. Since the packaging step comes after the MEMS device fabrication processes, the bonding temperature should be kept low to avoid effects of high temperature on the system. Possible temperature effects include residual stress due to thermal expansion coefficient mismatch between bonding materials and substrates, electrical contact failure due to atomic interdiffusion at the interface, and contamination due to outgassing or evaporation of materials. In addition to control of

Table 43.1 Summary of bonding mechanisms

Bonding method	Temperature	Roughness	Hermeticity	Postpackaging	Reliability

[b] No conclusive data

the bonding temperature, the magnitude of the force applied to create intimate contact for bonding and control of the atmospheric environment are other factors that should be considered. Based on heat transfer simulations [43.76], it is possible to confine the high-temperature area to a small region by using localized heating without heating the whole substrate. Therefore, assembly steps can always be applied after device fabrication without having detrimental effects. As such, localized heating and bonding techniques have been introduced and implemented as postprocessing approaches for fabrication of MEMS packaging [43.75, 77].

Table 43.1 summarizes these MEMS packaging technologies and their limitations, including the localized heating and bonding approach. The localized heating approach introduces several new opportunities. First, better and faster temperature control can be achieved. Second, higher temperature can be applied to improve the bonding quality. Third, new bonding mechanisms that require high temperature such as brazing [43.78] may now be explored for use in MEMS applications. As such, this approach has potential applications for a wide range of MEMS devices and is expected to advance the field of MEMS packaging.

43.2 Hermetic and Vacuum Packaging

Hermetic packaging is beneficial because it provides a moisture-free environment to avoid charge separation in capacitive devices, corrosion of metallization, and electrolytic conduction, thereby prolonging the lifetime of electronic circuitry. Especially for MEMS packaging, hermeticity is desirable in most cases since one of the main failure mechanisms for MEMS devices is humidity, and the surface tension of water can cause stiction of micromechanical structures, leading to malfunction. In several device applications, vacuum encapsulation is necessary but can be costly. Many surface-micromachined resonant devices need vacuum to improve their performance, such as comb-shaped μ-resonators and ring-type μ-gyroscopes, which have very high surface-to-volume ratio and vibrate in a very tight space [43.22, 79]. Two major approaches for hermetic and vacuum packaging of MEMS have been demonstrated and are discussed in this section:

- The integrated encapsulation approach
- The postprocess packaging approach.

Moreover, vacuum encapsulation by means of localized heating and bonding is discussed separately as another example of issues related to hermetic and vacuum packaging.

43.2.1 Integrated Micromachining Processes

Several hermetic and vacuum packaging processes for MEMS have been demonstrated based on integrated micromachining processes, where construction of sealing or protection caps is integrated with the MEMS device manufacturing process. This integrated approach has the advantage of sealing mechanical components in situ prior to the chip dicing and handling steps, to avoid contamination. An integrated vacuum sealing process using low-pressure chemical vapor deposition (LPCVD) is presented here as an illustrative example. This integrated process can encapsulate comb-shaped microresonators [43.80] in vacuum at wafer level. Figure 43.3 presents a cross-sectional view of the manufacturing process. First, a standard surface micromachining process [43.81] is conducted by using four masks to define a first polysilicon layer, anchors to the substrate, dimples, and a second polysilicon layer, as shown in Fig. 43.3a. The process so far is similar to the polyMUMPs process (MUMP: multi-user MEMS process) [43.21], and comb-shaped microstructures are fabricated at the end of these steps. In the standard surface micromachining process, the sacrificial layer (oxide) would be etched away to release the microstruc-

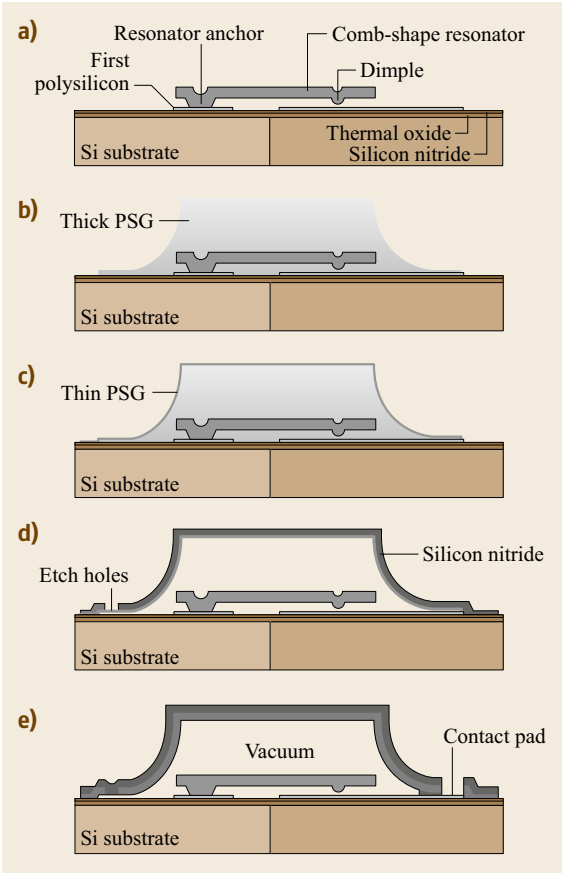

Fig. 43.3a–e Integrated vacuum encapsulation process using LPCVD nitride sealing to package micromechanical resonators. **(a)** Surface micromachining; **(b)** microshell; **(c)** etch channels; **(d)** etching and drying; **(e)** sealing (after [43.76])

tures. In the MEMS postpackaging process, a thick (7 μm) layer of phosphorus-doped glass (PSG) is deposited to cover the microstructure and patterned by using 5 : 1 buffered HF (BHF) to define a microshell area, as shown in Fig. 43.3b. A thin PSG layer of 1 μm is then deposited and defined to form etch channels, as illustrated in Fig. 43.3c. The microshell material, low-stress silicon nitride, is now deposited with thickness of 1 μm. Etch holes are defined and opened on the silicon nitride layer by using a plasma etcher. Silicon dioxide inside the packaging shell is now etched away using concentrated HF, and the wafer is dried by using the supercritical CO_2 drying process [43.82]. The result after these steps is shown in Fig. 43.3d. A 2 μm-thick LPCVD low-stress nitride is then deposited at pressure of 300 mTorr to seal the shell in the vacuum condition. Finally, the contact pads are opened, as shown in Fig. 43.3e. Figure 43.4 shows a scanning electron

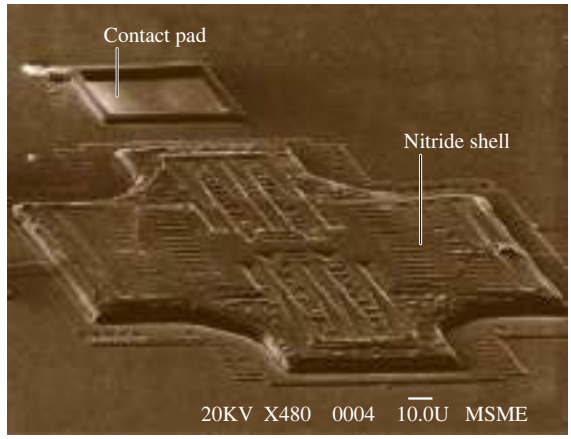

Fig. 43.4 SEM image showing a MEMS mechanical comb-shaped resonator vacuum-packaged using integrated LPCVD sealing as depicted in Fig. 43.3 (after [43.76])

microscopy (SEM) image of a finished device with a protective microshell on top. The total packaging area (microshell) has dimensions of about $400 \times 400\,\mu m^2$. A contact pad is shown with the covering nitride layer removed. The shape of the microresonator, with beams 150 μm long and 2 μm wide, is reflected on the surface of the microshell due to the integrated packaging process. The total height of the nitride shell is 12 μm, as seen standing above the substrate. Spectral measurements of the comb resonator inside the packaging revealed that a vacuum level of about 200 mTorr is accomplished using this method [43.83].

Similarly, *R. Aigner* et al. [43.84] reported a BiCMOS-compatible, integrated vacuum sealing process to package a polysilicon microaccelerometer. The protective shell was a polysilicon layer with supporting pillars anchored on the structural polysilicon. Release was achieved using a HF gas-phase etching process to remove the sacrificial oxide layer, and the release holes were sealed in a vacuum environment. The device was then injection molded into a plastic package at pressure of 100 bar. The supporting pillars were strong enough to hold the polysilicon shell under this high-pressure molding process.

An integrated sealing process based on evaporation of aluminum has also been reported [43.85]. A silicon substrate was deposited with a 4 μm-thick epitaxial n-type silicon layer. A controlled plasma etching and oxidation process formed a sharp tip, and a layer of borophosphosilicate glass (BPSG) was used to fill the trench as a sacrificial layer. The nitride sealing cap was deposited and patterned, and a 290 nm-thick PSG sacrificial release via was deposited and patterned, followed by deposition and patterning of the polysilicon anode. After the release etching process, aluminum evapora-

tion was applied in a 2×10^{-6} Torr vacuum chamber to deposit an 800 nm-thick aluminum layer to seal the release via. The resulting pressure was estimated as 1 mPa by measuring vacuum diode characteristics.

Other similar processes based on the integrated encapsulation concept have been demonstrated; For example, *Sniegowski* et al. [43.86] developed a reactive sealing method to seal vibratory micromachined beams; *Ikeda* et al. [43.79] used epitaxial silicon to seal microstructures; *Mastrangelo* et al. [43.87] used silicon nitride to seal mechanical beams as light sources; *Smith* et al. [43.88] used the approach of embedding microstructures and CMOS circuitry. All of these approaches integrate the encapsulation process within the MEMS fabrication process. The typical advantage of this approach is that such devices are ready for standard IC packaging processes such as dicing, pick-and-place, etc. once the wafer-level integrated sealing processes are completed. Specifically, SiTime has used a similar vacuum integration process to make their time-reference resonators [43.89].

Although the above vacuum sealing processes can successfully achieve MEMS hermetic and vacuum packaging, they suffer from some drawbacks; For example, these postpackaging processes are highly process dependent and are not suitable for generic MEMS postpackaging. MEMS companies or researchers have to adapt these postpackaging processes for their own device manufacturing process. Currently, standard MEMS foundry services do not support any of these integrated processes. Also, integrated encapsulation does not enable control of the cavity pressure, although it can achieve low pressure by wafer-level fabrication and provide lower manufacturing cost.

43.2.2 Postpackaging Processes

The second approach is defined as postpackaging processing. Such a packaging process starts when the device fabrication processes are completed, so this approach has high flexibility for various microsystems; For example, Fig. 43.5 shows a common industrial hermetic postpackaging technique called dual-in-line packaging (DIP) [43.90, 91]. A die is placed inside a ceramic holder covered by a sealing lid. Solder or ceramic joining is generally used for assembling the lid and holder under a pressure-controlled environment. High cost is the major drawback of this method, because of the expensive ceramic holder and low fabrication throughput. Another example postpackaging method is based on wafer bonding techniques combined with microshell encapsulation. Devices are sealed by stacking another micromachined silicon or glass substrate, as illustrated in Fig. 43.1. Integrated microsystems and

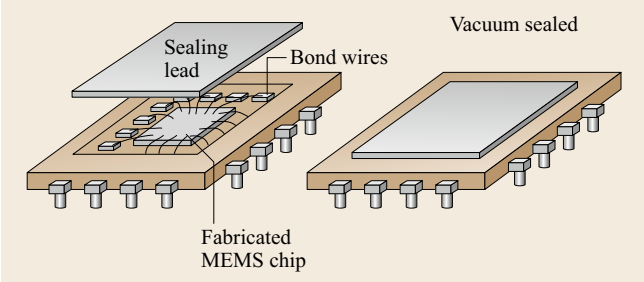

Fig. 43.5 Schematic of industrial post-packaging (DIPs) using a ceramic holder to be covered by a sealing lid

protection shells are fabricated on different wafers, either silicon or glass, at the same time. After the two substrates are assembled together using silicon fusion, anodic, or low-temperature solder bonding to achieve the final encapsulation, these microshells provide mechanical support, thermal paths, or electrical contact for the MEMS devices. Low packaging cost can be expected due to wafer-level processing.

A special heating method using rapid thermal processing (RTP) for wafer bonding applications is explained here to illustrate the roles of various control parameters such as temperature, time, and intermediate bonding materials. *Chiao* and *Lin* [43.92] reported a wafer bonding process by melting an intermediate filler material to facilitate sealing of micromechanical structures. Figure 43.6a shows the concept of the bonding and sealing scheme using an aluminum-to-glass bonding system, while Fig. 43.6b shows the experimental setup for aluminum-to-nitride bonding with integrated comb resonators inside. Aluminum with thickness of 3–4 μm was patterned to form sealing rings that surround the micromechanical structures on the device wafer. The width of a typical aluminum sealing ring was 100–200 μm, and the sealing area was $600 \times 600\,\mu m^2$. A glass (Pyrex, Corning 7740) wafer was used as the cap to cover the MEMS devices. The heating and bonding energy was provided by RTP; a typical heating history is shown in Fig. 43.7, where the overall heating process can be completed in 1 min, during which the temperature rises from room temperature to 990 °C then decreases to 350 °C. The aluminum-to-glass bonding and joining process was accomplished by heating at 990 °C for 2 s in the RTP chamber. It was shown that aluminum could extract oxygen to form aluminum oxide to create the bond [43.93]. Figure 43.8 shows a microheatuator successfully packaged using this bonding process; the surrounded liquid, isopropanol alcohol (IPA) in this case, was sealed without penetrating inside the package.

Other material systems have also been bonded using this RTP process, e.g., aluminum-to-silicon nitride

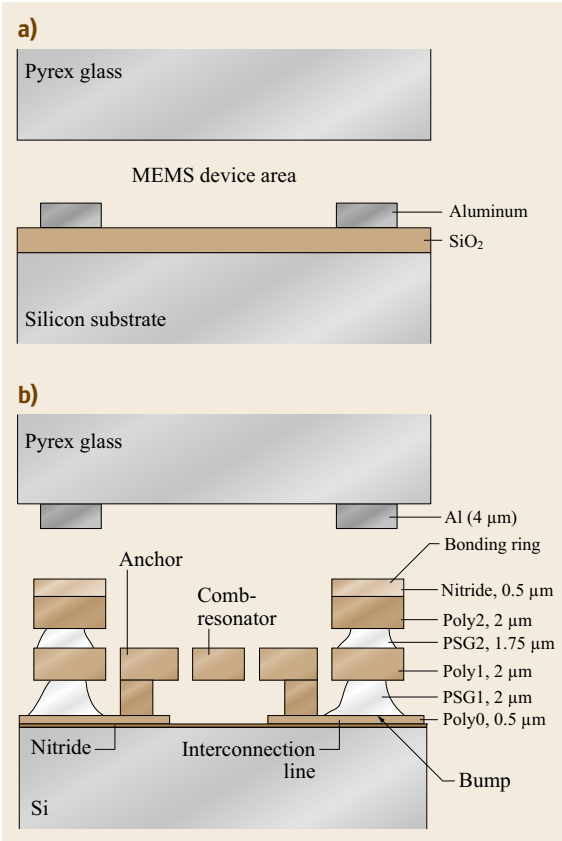

Fig. 43.6a,b Schematics of RTP bonding experiments: **(a)** the concept of aluminum-to-glass bonding, and **(b)** aluminum-to-nitride bonding with comb resonators

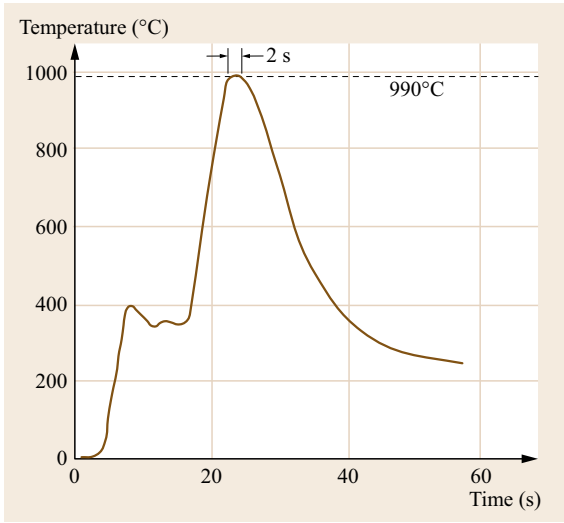

Fig. 43.7 Temperature history in an RTP bonding experiment

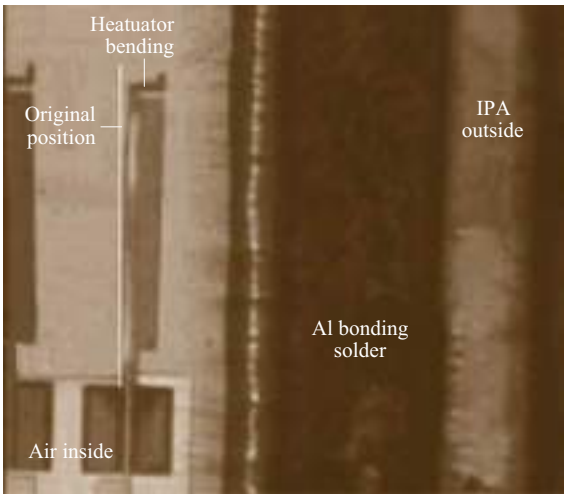

Fig. 43.8 A hermetically packaged microheatuator operating when immersed in liquid

joining (Fig. 43.6b) [43.94]. In this case, a 5000 Å-thick LPCVD silicon nitride layer was deposited and patterned on top of sealing ring structures that encompassed surface-micromachined comb-shaped resonators [43.81]. Using RTP with process time of 10 s at the peak temperature of 750 °C, a stable bond was formed at the aluminum–nitride interface. Figure 43.9 shows a packaged comb resonator that resonated at 19.6 kHz when immersed in deionized (DI) water, as seen under an optical microscope. The aluminum-to-nitride seal successfully blocked water from entering the package. To examine the bonding strength, the package was forcefully broken, as shown in Fig. 43.10. The glass debris was attached to the sealing ring surrounding the comb-drive resonator on the silicon substrate. This shows that the bonding strength of the aluminum-to-nitride system was greater than the glass fracture strength, which is estimated at around 270 MPa [43.95].

A vacuum sealing process using RTP bonding is discussed here in detail to address the technical issues in vacuum sealing processes. *Chiao* and *Lin* [43.96] reported a vacuum sealing process based on aluminum-to-nitride bonding using RTP. The RTP bonding process was conducted in a vacuum quartz tube, as shown in Fig. 43.11. Both device and cap wafers must be baked in vacuum at 300 °C for at least 4 h to drive out water and gas species that may adhere at the wafer surface [43.97]. This prebaking process in vacuum was necessary to minimize the outgassing effect during the bonding process in order to achieve high-quality vacuum. Afterwards, the device and cap wafers were immediately flip-chip-assembled, loaded into a sample holder, and placed inside a quartz chamber, as shown in Fig. 43.11. The system was then placed inside the RTP

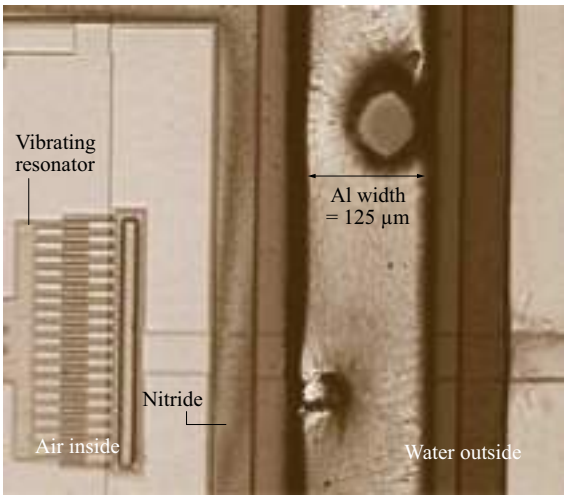

Fig. 43.9 A comb-drive resonator sealed in a a package chip and operating when the package was immersed in water

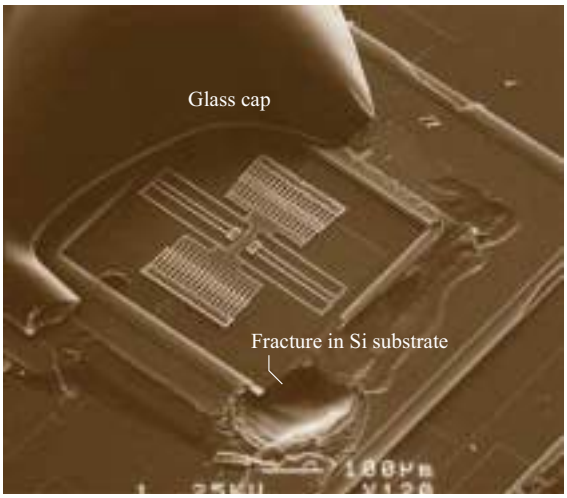

Fig. 43.10 SEM micrograph of a silicon substrate after forcefully breaking the aluminum-to-nitride bond. Glass debris was found attached to the silicon substrate

equipment, and the base pressure was pumped down to about 1 mTorr using a turbopump. The vacuum was held steady for 4 h to drive out gas trapped inside the package cavity [43.98]. The bonding and vacuum sealing process was achieved by RTP heating for 10 s at 750 °C to complete the bonding process.

Figure 43.12 shows the spectrum of a vacuum-packaged, double-folded beam comb-drive resonator measured using a microstroboscope. The central resonant frequency is at about 18 625 Hz, and the quality factor is extracted as 1800 ± 200, corresponding to a pressure level of about 200 mTorr inside the package [43.98]. This type of postpackaging process at wafer level has become the preferred approach for hermetic encapsulation, because it can provide lower cost and greater process flexibility. However, the packaging process relies on *good* bonding techniques. A strong and reliable bond between the two substrates should be provided, and the bonding procedure should be compatible with the other microsystem fabrication processes.

43.2.3 Localized Heating and Bonding Processes

The approach of MEMS postpackaging by localized heating and bonding is proposed to address the problems of global heating effects. In this section, resistive microheaters are used as an example to provide localized heating, although several other means of localized heating have also been demonstrated, including laser welding [43.99], inductive heating [43.100], and ultrasonic bonding [43.101]. The principle of localized

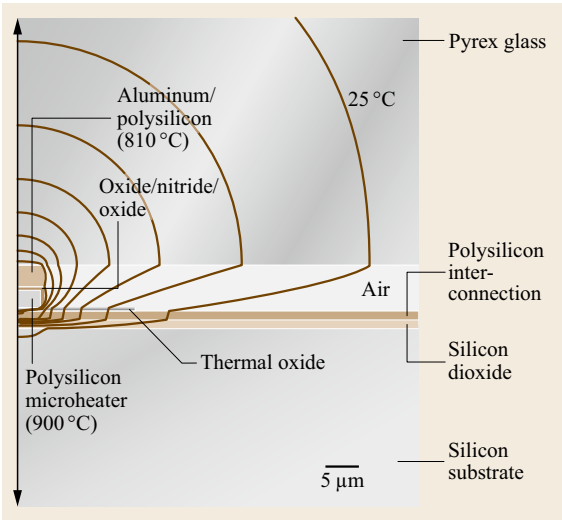

Fig. 43.13 Schematic of the 2-D heat transfer model with geometry and boundary conditions

heating is to achieve high temperature for bonding locally while maintaining low temperature globally at wafer level. Resistive heating by using microheaters on top of the device substrate is applied to form a strong bond with the silicon or glass cap. According to the results of two-dimensional (2-D) heat conduction finite element analysis (Fig. 43.13), the steady-state heating region of a 5 µm-wide polysilicon microheater capped with a Pyrex glass substrate can be confined locally as long as the bottom of the silicon substrate is constrained to ambient temperature. The physics of the localized heating behind this design can be understood by solving the governing heat conduction equations for the device structure without a cap [43.98]. As long as the width of the microheater and the thickness of the silicon substrate are much smaller than the die size and a good heat sink is placed underneath the silicon substrate, heating can be confined locally. The temperature of the silicon substrate can be kept low or close to room temperature. Several localized resistive heating and bonding techniques have been successfully developed for packaging applications, including localized silicon-to-glass fusion bonding, gold-to-silicon eutectic bonding, and localized solder bonding. Several solder materials have been successfully tested, including PSG, indium, and aluminum alloy [43.102].

The vacuum packaging example presented in this section is based on the localized aluminum/silicon-to-glass solder bonding technique. Built-in folded-beam comb drive μ-resonators are used to monitor the pressure of the package. Figure 43.14 shows the fabrication process for the package and resonators. Thermal oxide (2 µm) and LPCVD Si_3N_4 (3000 Å) are first deposited on a silicon substrate for electrical insulation, followed by deposition of 3000 Å LPCVD polysilicon. This polysilicon is used as both the ground plane and the electrical interconnect to the μ-resonators, as shown in

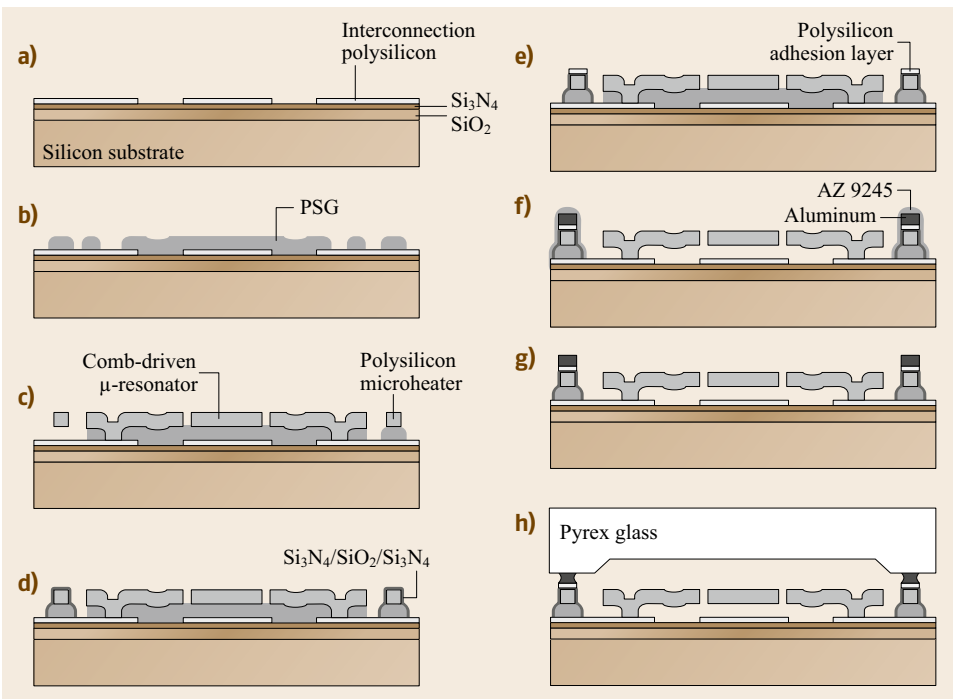

Fig. 43.14a–h Schematic process flow of vacuum encapsulation using localized aluminum/silicon-to-glass bonding. **(a)** Deposition and patterning; **(b)** sacrificial layer; **(c–g)** surface micromachining; **(h)** vacuum packaging

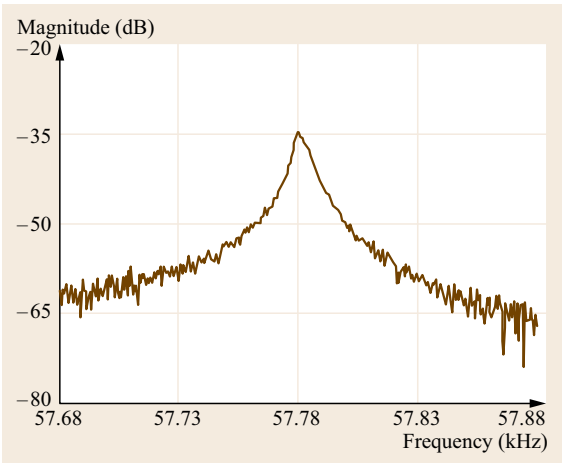

Fig. 43.16 Transmission spectrum of a glass-encapsulated μ-resonator after 120 min pump-down time in vacuum environment ($Q = 9600$)

Fig. 43.14a. Figure 43.14b shows a 2 µm LPCVD SiO_2 layer that is deposited and patterned as a sacrificial layer for fabrication of the polysilicon μ-resonators using a standard surface micromachining process. 2 µm-thick phosphorus-doped polysilicon is used as both the structural layer for the microresonators and the on-chip microheaters. This layer is formed over the sacrificial oxide in two steps to achieve a uniform doping profile. Lower input power and better process compatibility are two major advantages of using such on-chip microheaters for glass packages. The resonators are separated from the heater by a short distance of 30 µm, to effectively prevent their exposure to the high heater temperature, as shown in Fig. 43.14c. This concludes the fabrication of the μ-resonators.

To prevent the current supplied to the microheater from leaking into the aluminum solder during bonding, a LPCVD Si_3N_4 (750 Å)/SiO_2 (1000 Å)/Si_3N_4 (750 Å) sandwich layer is grown and patterned on top of the microheater, as shown in Fig. 43.14d. Figure 43.14e,f show how the aluminum (2.5 µm) and polysilicon (5000 Å) bonding materials are deposited and patterned. Sacrificial release is the final step to form the free-standing μ-resonators. Figure 43.14f shows how thick AZ 9245 photoresist is applied to cover the aluminum/silicon-to-glass bonding system to ensure that the system can withstand attack from concentrated hydrofluoric acid. After 20 min of sacrificial release in concentrated HF, the system as shown in Fig. 43.14g is ready for vacuum packaging. A Pyrex glass cap with a 10 µm-deep recess is then placed on top with applied pressure of ≈ 0.2 MPa under 25 mTorr vacuum, and the heater is heated using 3.4 W input power (the exact value depending on the design of the microheaters) for 10 min to complete the vacuum packaging process, as shown in Fig. 43.14h.

To evaluate the integrity of resonators packaged using such localized aluminum/silicon-to-glass solder bonding, the glass cap was forcefully broken and removed from the substrate. No damage was observed on the μ-resonator. A part of the microheater was stripped away, as shown in Fig. 43.15, demonstrating that a strong and uniform bond could be achieved

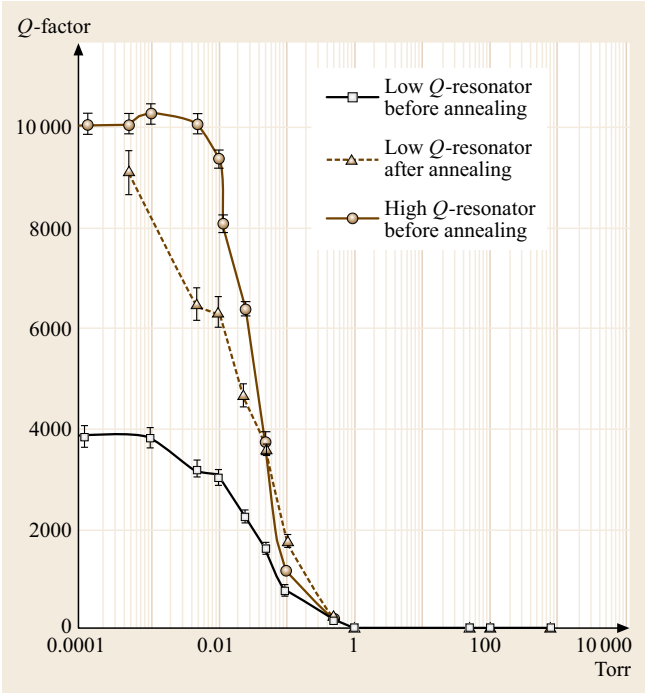

Fig. 43.17 Measured Q-factor versus pressure for unpackaged μ-resonators

without detrimental effects on the encapsulated device. Figure 43.16 shows a vacuum-encapsulated unannealed μ-resonator ($\approx$ 57 kHz) after 120 min of wait time. The Q-factor measured after packaging was 9600. Q versus pressure measurements for a high-Q unpackaged μ-resonator (Fig. 43.17) demonstrated that the pressure inside the package was comparable to the vacuum level in the packaging chamber.

Postprocess packaging using the localized heating and bonding technique includes four basic components:

1. An electrical and thermal insulation layer such as silicon dioxide or silicon nitride for localized heating
2. Resistive microheaters to provide the heating source for localized bonding
3. Bonding materials such as metal or polysilicon to provide good bonding and hermeticity with the silicon or glass substrate
4. A good heat sink under the device substrate to ensure localized heating during the bonding experiments.

MEMS devices are fabricated on the device chip then hermetically sealed in a cavity formed by the device chip, resistive microheaters, and protective cap. The process can be either die level or wafer level. A schematic design for the wafer-level packaging process is shown in Fig. 43.18. The resistive microheaters are parallel to each other and connected together to ensure that identical current density is applied for individual packages at the same time. These heaters can be fabricated on either the chip or protection cap and can be built on a larger wafer for current inputs. The interconnections for these packaging cavities can be built in the dicing area, such that no extra space is required for the packaging process.

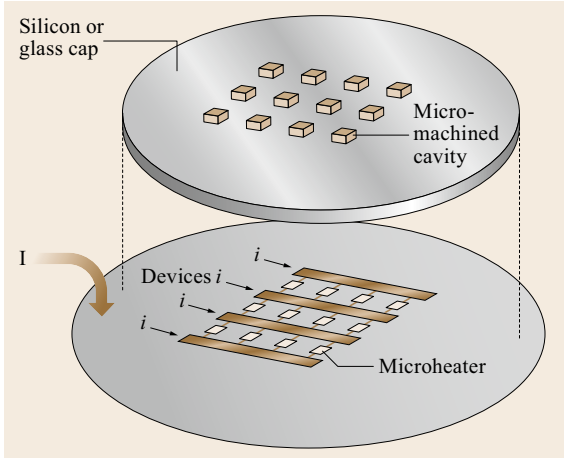

Fig. 43.18 Illustration of wafer-level vacuum packaging using the localized heating and bonding technique

43.3 Emerging Packaging Approaches

Wafer-level packaging and 3-D packaging have undoubtedly been the hottest emerging packaging technologies over the past few years and will be the trend in the near future [43.103, 104]. The process of packaging a wafer before dicing is called wafer-level packaging. Modern MEMS packaging usually involves at least three wafers, namely the application-specific integrated circuit (ASIC) wafer, the MEMS device wafer, and the cap wafer. These wafers are fabricated separately and bonded layer by layer to form the complete package. It is advantageous to encapsulate the MEMS devices early in the wafer processing to protect them mechanically and prevent contamination during subsequent fabrication and packaging processes. In this way, extra packaging equipment and repeated assembly processes can be largely eliminated. By dicing the bonded wafers at the end of the processes, one can obtain a large number of packaged chips with desired small footprint. For production of practical MEMS devices, this can reduce the cost of packaging and testing, and also improve yield and reliability. Meanwhile, 3-D packaging enables the combination of dissimilar classes of materials and components into a single system. Therefore, high-performance materials and subsystems can be combined in ways that would otherwise not be possible, thereby forming complex and highly integrated micro- or nanosystems; For example, polymers are being actively used for various MEMS sensors and actuators [43.105]. They provide many advantages in terms of cost, materials properties, and ease of processing. Integration of polymers for structural or functional purposes into microsystems is also a promising emerging technology with great potential for use in MEMS packaging.

43.3.1 Wafer-Level Packaging

Wafer-level packaging approaches for various applications can be classified into two categories:

- Interfacial bonding or bonding with intermediate melting materials
- Deposition sealing.

Mechanical protection of MEMS devices is realized by bonding a cap wafer on top of the device wafer, or by sealing of surface-micromachined cavities by deposition. Meanwhile, electrical feedthrough is needed for interconnection with the encapsulated MEMS. Normally, metal is used as the feedthrough material, while highly doped silicon can also be employed. In general, this is realized by either lateral feedthrough on the chip surface or vertical feedthrough using a through-hole via.

Wafer-Level Packaging by Interfacial Bonding

Transparent Pyrex glass wafers have thermal expansion coefficient similar to silicon wafers, and they are frequently used as cap wafers. In addition, interfacial bonding between metal and metal can also be employed. Electrical feedthrough is usually achieved using vias in the cap wafer. If silicon is used as the cap wafer, the thermal stress caused by thermal expansion mismatch between the device and cap wafers can be reduced, and holes in the cap wafer can be made using DRIE of silicon; For example, the fabrication process developed for film bulk acoustic resonator (FBAR) filters (RF MEMS devices) is shown in Fig. 43.19 [43.106]. Gold is electroplated using a photoresist mold, and the silicon substrate is etched by DRIE. The silicon cap wafer is bonded to the MEMS device wafer by Au–Au thermocompression bonding, and the etched holes are exposed by grinding the cap wafer. Finally, the packaged wafer is diced into individual chips, and wire bonding is carried out inside the exposed holes. In addition to Au–Au thermocompression bonding [43.107, 108], similar Al–Al [43.109] and Cu–Cu [43.110] thermocompression bonding can also be employed to achieve wafer-level packaging. Metal bonding surfaces are brought into contact with the application of force and heat simultaneously. Due to surface oxidation, high temperature is usually required to achieve high bonding quality, but MEMS packaging can be achieved at adequately low temperatures of about 300 °C or below. It has been demonstrated that Al-to-Al bonding can achieve wafer-level hermetic sealing and 3-D interconnects of MEMS devices [43.109]. Figure 43.20 shows wafer-level packaging processes employing Al-to-Al bonding and through-silicon vias (TSVs). After thermal oxidation for electrical isolation of the vias, highly doped poly-Si is deposited to fill the vias completely to form electrical signal paths. On the cap wafer, 2 μm-thick Al (with 2% Cu) is patterned at the perimeter of the individual dies as well as the input/output bond pads. On the MEMS device wafer, the seal rings and bond pads are also patterned using Al as described above. After cavity etching, the cap wafer is bonded to the MEMS wafer using Al bonding, creating both a hermetic seal around each die and conducting paths from the MEMS devices to the vias. The two wafers were bonded at ≈ 450 °C with various bond forces up to 80 kN. Leak detection on the capped device showed hermeticity of $\approx 10^{-12}$ cm^3 atm/s He leak rate with Al seal width as narrow as 3 μm. After back-grinding and polishing the bonded pair to expose the vias, new bond pads are formed on top of the cap wafer using standard passivation and redistribution layer (RDL) metallization. The electrical contact resistance of the Al-to-Al bonded interface was measured to be less than 1 Ω.

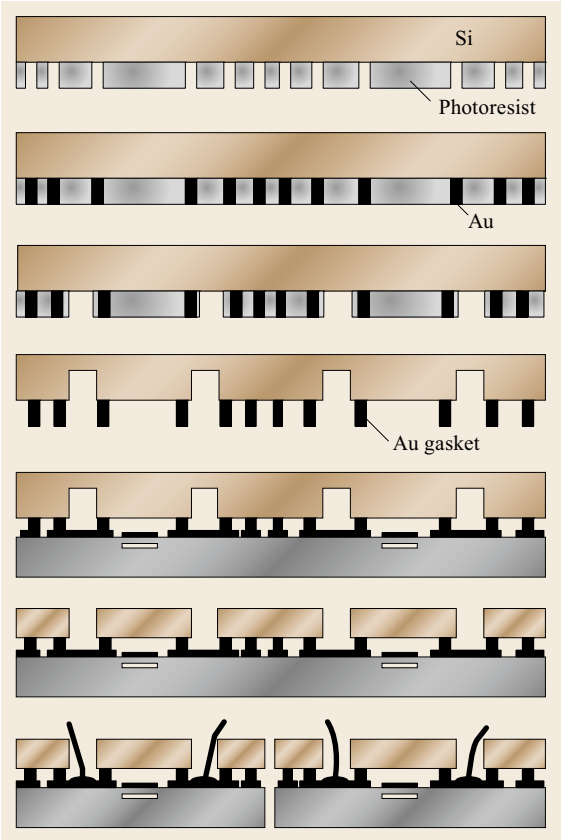

Fig. 43.19 Illustration of wafer-level packaging using metal-to-metal bonding (after [43.106])

Wafer-Level Packaging by Deposition Sealing

Narrow gaps for electrical feedthrough made between the MEMS wafer and the cap wafer can be sealed by depositing materials. Previously, an integrated process using surface-micromachined microshells was developed [43.111]. This process applies the concepts of sacrificial layer and low-pressure chemical vapor deposition (LPCVD) sealing to achieve wafer-level packaging. Similar processes have been

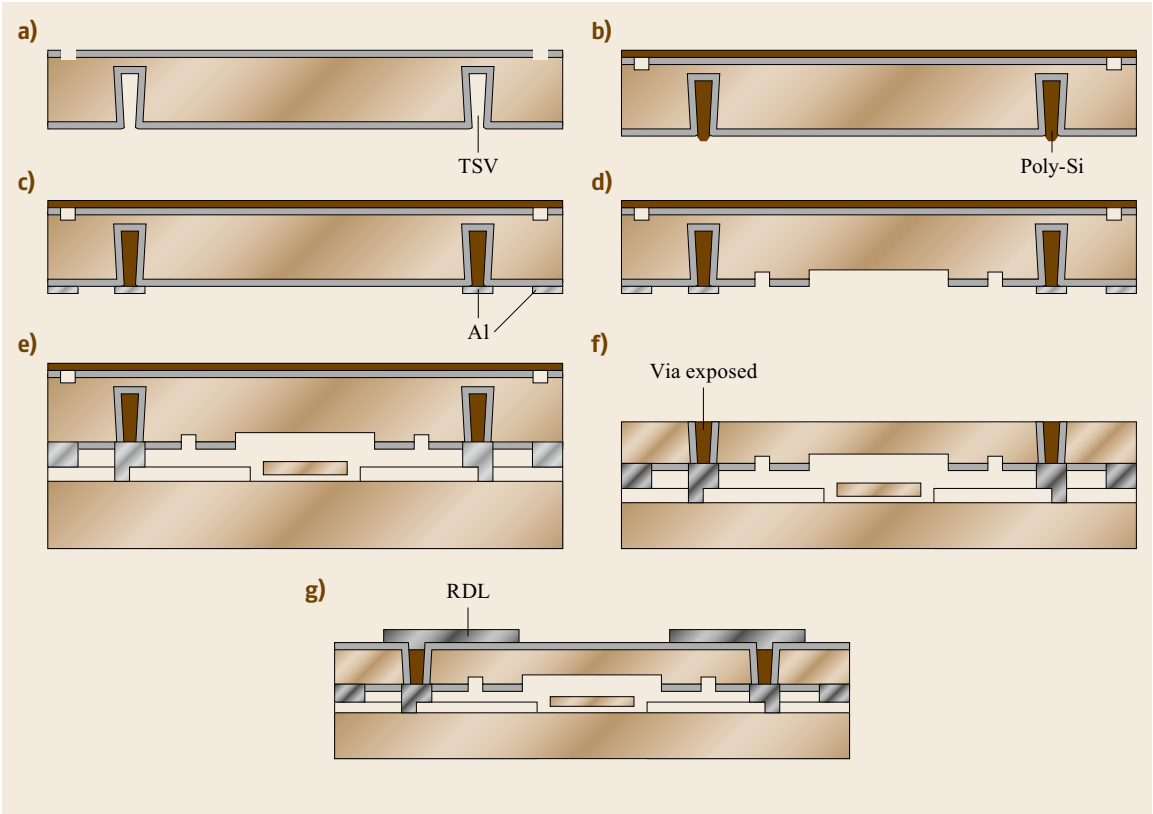

Fig. 43.20a–g Illustration of wafer-level hermetic packaging and 3-D interconnection using metal-to-metal bonding. **(a)** Etching and isolation; **(b)** filling and polishing; **(c)** deposition and patterning; **(d)** etching; **(e)** Al to Al thermocompression bonding; **(f)** back-grinding and polishing; **(g)** passivation and interconnection (after [43.109])

demonstrated; For example, *Guckel* et al. [43.112] and *Sniegowski* et al. [43.86] developed a reactive sealing method to seal vibratory micromachined beams. *Ikeda* et al. [43.79] adopted epitaxial silicon to seal microstructures. *Mastrangelo* and *Muller* [43.113] used silicon nitride to seal mechanical beams as light sources. *Smith* et al. [43.88] presented a new fabrication technology by embedding microstructures and complementary metal–oxide–semiconductor (CMOS) circuitry. All of these methods integrate the MEMS process with the packaging process so that no extra bonding process is required. However, these schemes are highly process dependent and not suitable for prefabricated circuitry.

Sacrificial etching can also be performed through porous materials such as porous poly-Si [43.115, 116] or through a gas-permeable membrane. Sealing can be achieved by depositing material on the porous material; For example, a permeable membrane is used in Fig. 43.21 for the following process sequence [43.114]: After forming the MEMS in the silicon wafer by etching, they are covered with patterned photoresist and a polymer overcoat. Since the photoresist thermally decomposes at 200 °C, the decomposed gas diffuses out through the polymer overcoat on heating. Finally, a thin metal layer is deposited on the surface of the polymer overcoat for hermetic sealing. In addition to deposition sealing, soldering can also be employed to seal MEMS; For example, a technique to premold and transfer lead-free solder balls for MEMS/electronics packaging applications has been demonstrated [43.117].

Electrical Feedthrough

Electrical feedthrough is needed for interconnection with the MEMS encapsulated in a cavity. Normally, metals are used as the feedthrough material, because of their low resistance, while highly doped silicon can also be used to reduce potential thermal stresses. Stray capacitance and stray inductance have to be taken into account for RF MEMS. Lateral feedthrough on a chip can be realized by embedding a thin metal layer in silicon dioxide and sealing the surface by anodic bonding with a glass cap wafer [43.118]. After etching the silicon dioxide on a silicon wafer, the etched groove is

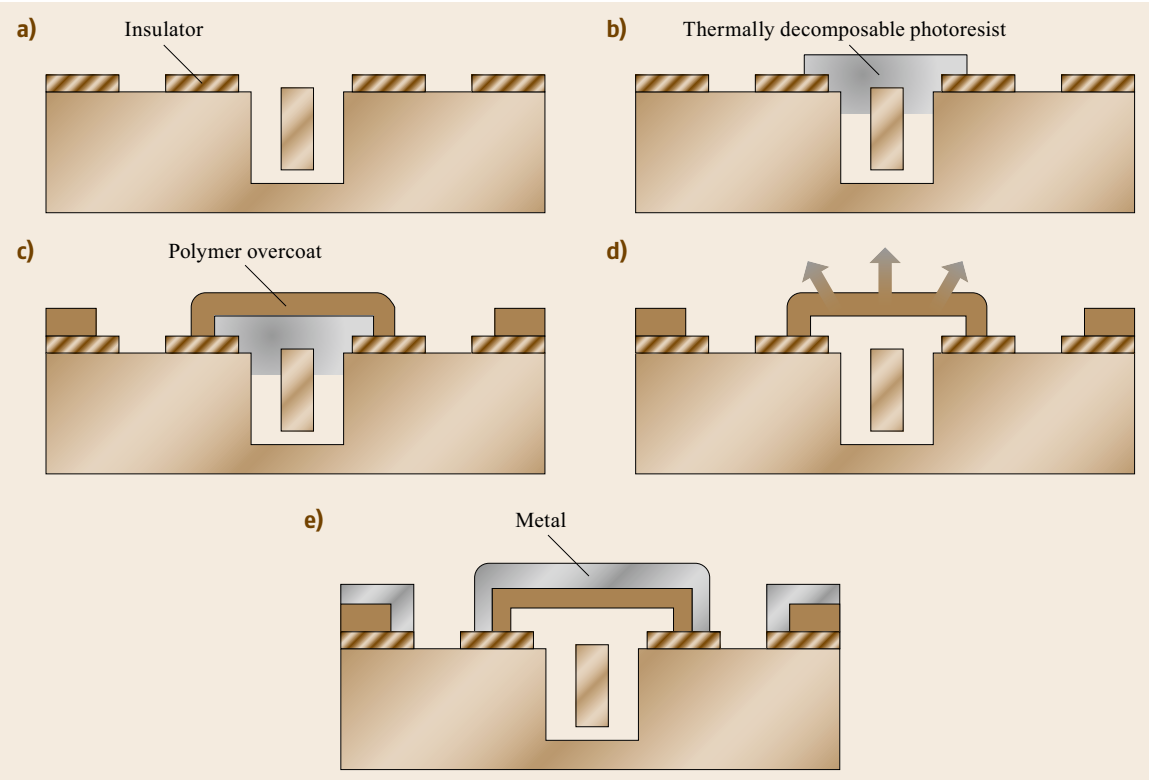

Fig. 43.21a–e Illustration of wafer-level packaging by deposition sealing. **(a)** Isolation; **(b)** cavity formation; **(c)** cap formation; **(d)** decomposition; **(e)** metallization (after [43.114])

filled with Cr–Al. The surface is coated with spin-on glass (SOG) to insulate and to make a planar surface, and silicon is sputter-deposited on it. This is anodically bonded to a Pyrex glass wafer. It was found that this lateral feedthrough is not as practically applicable compared with the vertical feedthrough described below, because the lateral feedthrough has to be fabricated on the same wafer as the MEMS.

Electrical interconnection can also be achieved using a through-hole via in the wafer, as shown in Fig. 43.22 [43.103]. The advantage of vertical feedthrough in the cap wafer is that the electrical interconnection can be fabricated on a different wafer from the MEMS wafer, so process compatibility is not required. For a glass cap wafer, it is not easy to make through holes. Meanwhile, vertical feedthrough can be achieved in a silicon wafer on which MEMS are fabricated [43.119].

43.3.2 3-D Packaging

Three-dimensional (3-D) packaging is an emerging technology that vertically stacks and interconnects multiple materials, technologies, and functional devices to form highly integrated micro- and nanosystems. Such work in the third dimension will allow exten-

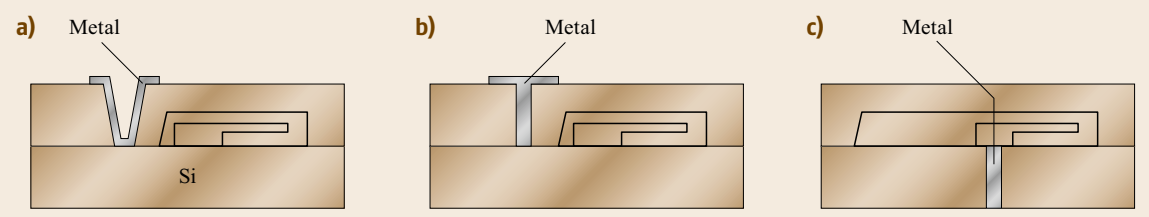

Fig. 43.22a–c Illustration of electrical feedthrough using a through-hole via in the wafer. **(a,b)** From top; **(c)** from bottom (after [43.103])

sion of Moore's law to higher density, functionality, and performance, as well as integration of more diverse materials and devices at lower cost. The potential benefits also include reduced power, small form factor, reduced packaging, and increased yield and reliability. It is recognized as an enabling technology for integration of MEMS, micro-opto-electro-mechanical systems (MOEMS), photonics, electronic ICs, and emerging NEMS.

Modern 3-D packaging technologies employ wafer-to-wafer joining, processing, and interconnection materials and components prepared using different processes. Typically they are classified into two categories: via-first approaches and via-last approaches. In via-first approaches, the vias establishing electrical (or alternatively optical) contacts between components on different substrates are defined during the bonding process. In contrast, in via-last approaches, the components are first bonded to each other, then vias to establish electrical (or alternatively optical) contacts between components on different substrates are defined. The advantages, limitations, and technological challenges of the via-first and via-last approaches are introduced in the following sections.

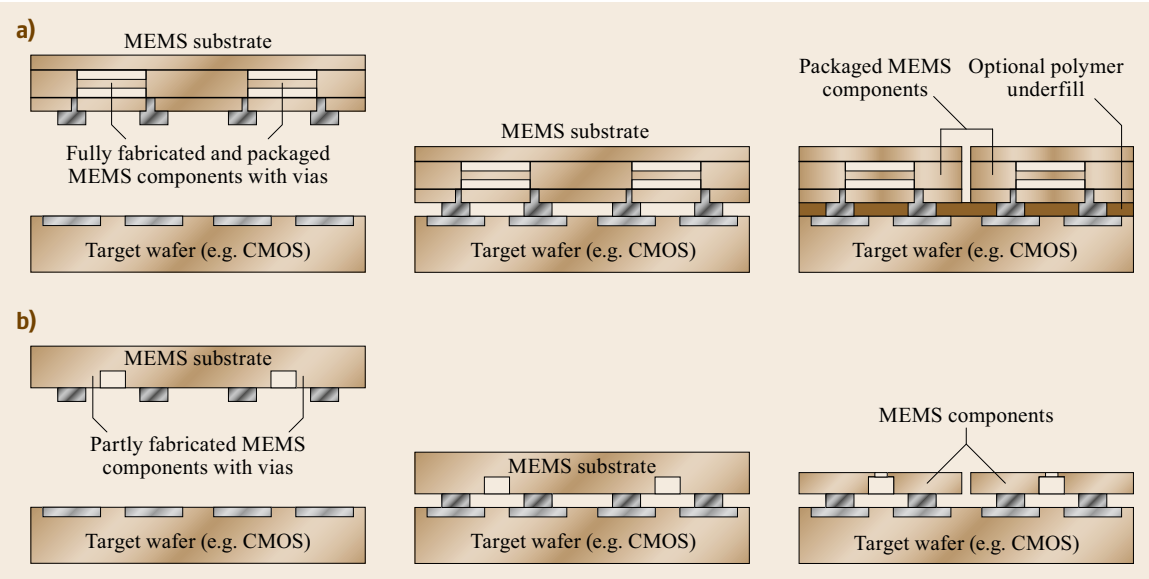
3-D Packaging by Via-First Approaches

Figure 43.23 shows the conceptual schemes of two major via-first 3-D packaging approaches. The bump bonding can be implemented by using, for example, solder bonding [43.120], eutectic bonding [43.121] or direct metal thermocompression bonding [43.122]. Typical dimensions of such bump-bonded metal vias are in the order of $100 \times 100\,\mu m^2$. At wafer level, it is challenging to obtain highly reliable processes for vias with dimensions below $20 \times 20\,\mu m^2$. In the technique shown in Fig. 43.23a, a completely processed and packaged MEMS device wafer containing metal bumps is bonded to a target wafer, typically a CMOS-based ASIC wafer. This technique is simply an extension of conventional chip-to-chip bump bonding to wafer-level bump bonding. Due to the minimum size of the metal bumps and the thickness of the wafer with the packaged MEMS devices, this technique allows only limited miniaturization and integration densities for the final system. In the technique shown in Fig. 43.23b, a partly processed MEMS wafer containing metal bumps is bonded to the target wafer. Thereafter, the components are further processed at wafer level to complete the MEMS devices using, e.g., etching and/or thinning processes. Although this technique allows only limited integration densities due to the minimum dimensions of the metal bumps, it has been proposed for a number of MEMS devices [43.123] and successfully implemented for commercial MEMS products [43.124].

The via-first 3-D packaging approach is being used for manufacture of gyroscopes [43.125], and combined three-axis accelerometers and three-axis gyroscopes integrated on a single chip. These devices are sold at very high volumes for consumer products such as motion controls in gaming. Taking the example of a gyroscope chip, the monocrystalline silicon capacitive gyroscope sensor and parts of the gyroscope package are prefabricated together, then bonded to the ASIC wafer that contains an etched cavity. Bonding and sealing is carried out directly to the top CMOS Al metal layer using an Al/Ge eutectic bonding process. Figure 43.24 shows a cross-sectional and top view of a gyroscope packaged using this approach [43.124].

3-D Packaging by Via-Last Approaches

In the technique shown in Fig. 43.25a, a completely processed and packaged MEMS device wafer is bonded to an ASIC wafer. Due to the thickness of the wafer containing the packaged MEMS devices, this technique allows only limited integration densities. In the techniques shown in Fig. 43.25b, a wafer containing the unpatterned MEMS device material(s) is bonded to the ASIC wafer. Thereafter, the handle wafer is released from the donor wafer. After the MEMS device material has been transferred to the ASIC wafer, it can be further processed and patterned. The vias between the devices and target wafer can then be formed. Finally, the sacrificial bond layer is removed by a selective etch. This technique has the advantage that accurate substrate-to-wafer alignment is not needed during the bonding process. The via and component positions on the target wafer are exclusively defined by the lithography and etching processes after bonding. Therefore, critical device dimensions and overlay accuracies in the nanometer range can be achieved, which is not possible with other techniques. The first MEMS device including fully functional CMOS ICs manufactured using very large-scale heterogeneous integration with a via-last approach was a 1-megapixel monocrystalline silicon micromirror array [43.126]. A polymer adhesive is used as the bonding layer, in combination with sputter-deposited aluminum vias [43.127], electroplated gold vias [43.128], or electroless-plated nickel vias [43.129]. Bonding with a polymer adhesive has the advantage that the MEMS device wafer and ASIC wafer can be bonded with very high yield and without any surface pretreatment or surface planarization. Planarized SiO_2 layers have also been proposed as an intermediate bonding layer for heterogeneous integration [43.130]. The tilting monocrystalline silicon mirrors are integrated on top of fully functional high-voltage CMOS drive electronics. The mirror array has resolution of 1 megapixel and pixel pitch of $16 \times 16\,\mu m^2$. The sil-



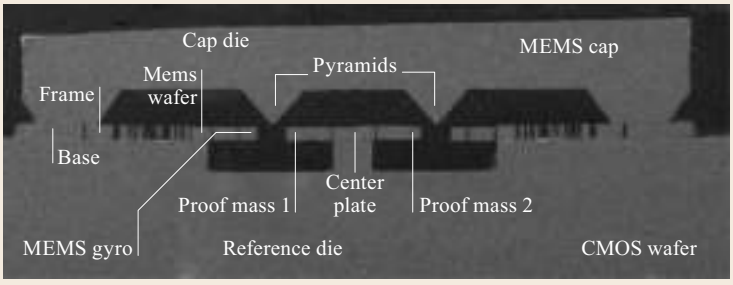


Fig. 43.23a,b Conceptual schemes of via-first 3-D packaging approaches. **(a)** Integration of fully processed MEMS components; **(b)** integration of partly processed and/or packaged MEMS components with subsequent wafer level processing (after [43.104])

icon mirror membranes are 340 nm thick and have an extremely well-defined distance of 700 nm to the addressing electrodes on the underlying CMOS ICs. The mirror vias have diameter of 2 μm, and the torsional mirror hinges are 600 nm wide.

43.3.3 Polymer–MEMS Packaging

By using microheaters to provide heat locally for the bonding process, the global temperature can be significantly reduced to satisfy the strict low-temperature processing requirement for a variety of biomaterials and polymers. Polymeric materials are extensively utilized in microfluidic systems for applications in life sciences [43.131–133]. The advantages of polymer-MEMS include a broad range of choices of material properties, low raw material cost, and feasibility of mass production. To facilitate fabrication and application of polymer-MEMS, effective assembly and packaging processes are highly desired. In this section, two localized bonding and assembly schemes are introduced, employing soft thermoplastic materials with low glass-transition temperature as intermediate layers to demonstrate packaging of various systems, including polymer to silicon, polymer to glass, and polymer to polymer. The two packaging schemes are illustrated

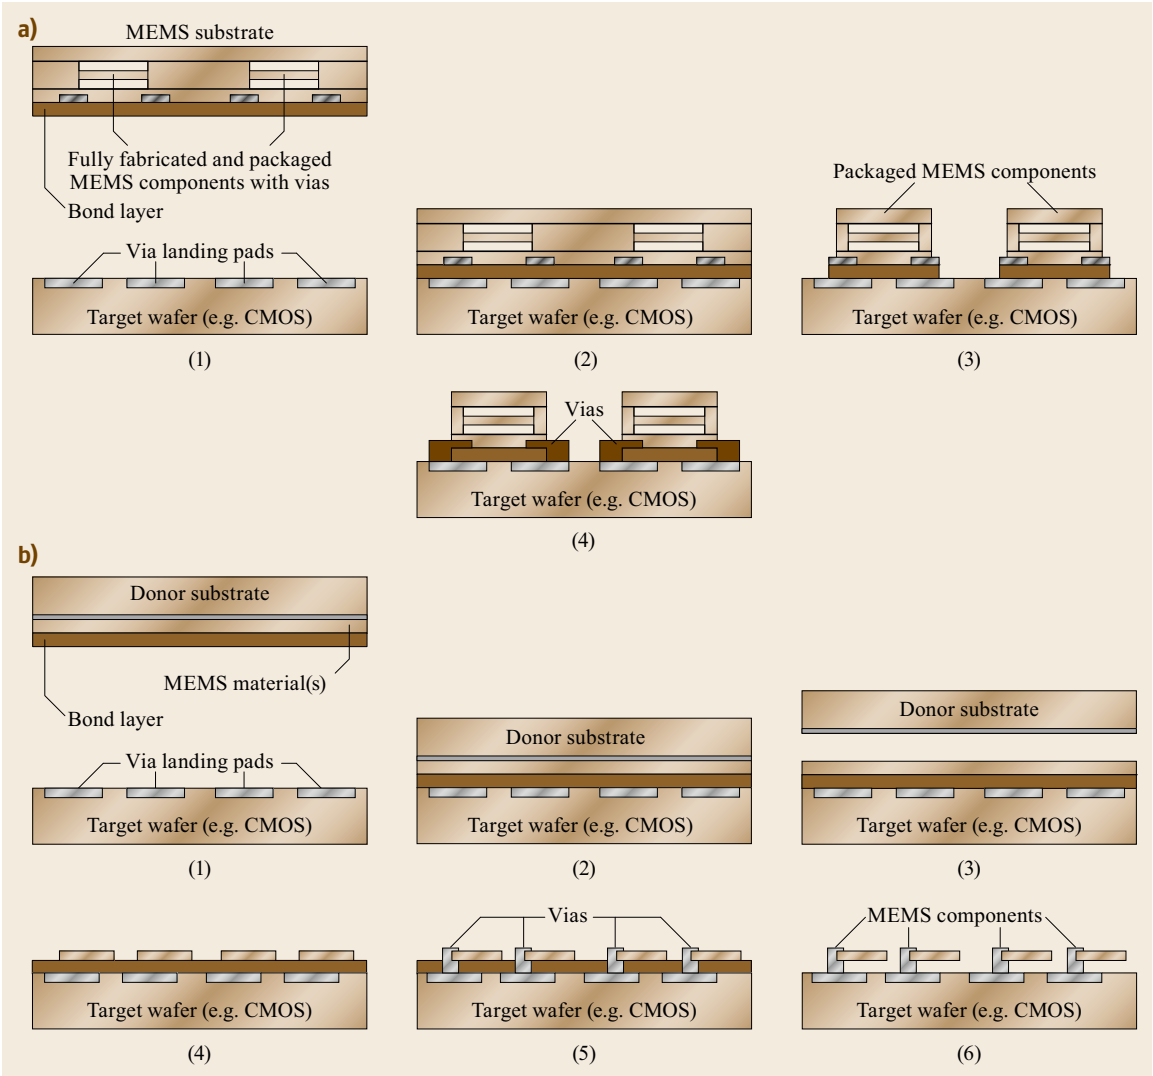

Fig. 43.25a,b Conceptual schemes of via-last 3-D packaging approaches. **(a)** Integration of fully processed and packaged MEMS components; **(b)** integration of MEMS material(s), release from donor wafer and subsequent processing of components (after [43.104])

in Fig. 43.26: (a) bonding by built-in-type heaters, and (b) bonding by external, reusable heaters.

A Mylar film (DuPont Teijin films) coated with a thermoplastic polyvinylidene chloride (PVDC) copolymer layer on one surface was bonded to either silicon, glass, or another polymeric substrate. The scheme with built-in microheaters is suitable for bonding thick polymeric materials with various types of substrate including silicon, glass, and polymer, because microheaters can easily provide the activation energy locally for bonding. Meanwhile, the scheme with external, reusable heaters is most suitable for bonding of thin polymer films to various substrates. Heat is transferred through the thin polymer film, and a heated zone is generated locally in the bonding interface where the bond is formed. In this case, it is preferable that the thin polymer film have two layers. The top layer should have high melting temperature to prevent bonding with the external reusable heaters, so that the heaters can be easily removed after completion of the bonding process and used repeatedly. Experimentally, aluminum wires of 30–70 μm width and 3 μm thickness were fabricated by a lift-off process and employed as the heating elements to form bonding loops of 1–2 mm in diameter on either silicon or glass substrates. Because of the small bonding area (less than $10^{-6}\,m^2$), about 0.4 N of force is sufficient to provide bonding pressure of 0.4 MPa. These aluminum heaters have resistance of approximately 0.8 Ω, and when voltages of 3.5 V are applied, about 15 W of power is generated locally to increase the temperature for bonding within about 0.25 s.

To test the quality of these bonding processes, several experiments were designed. In the first experiment, bonded systems were placed in a vacuum chamber and observed under an optical microscope. It was found that the top of the encapsulated chamber expanded to form a dome shape due to the 1 atm pressure difference across the membrane. The diameter of the bonding ring is 1.4 mm in this case, which corresponds to an effective area of $1.6\times10^{-6}\,m^2$, and the air permeability of Mylar is $8\,cc/m^2$ day atm. Based on a simplified approximation, it takes about 18 days for the air inside the cavity to diffuse out, and the membrane should return to flat. Figure 43.27 shows a SEM image of the result of Mylar bonded on PMMA. The dome shape can be observed as proof that a good seal was achieved. Afterwards, the polymer-to-polymer (Mylar-to-PMMA) bond was forcefully broken to examine the bonding interface under SEM (Fig. 43.28). It was observed that the bonding result was uniform, and part of the Mylar film was attached to the bonding substrate. Another experiment showed that direct encapsulation of water using localized heating can be achieved as a proof-of-concept demonstration of low-temperature processing. In this case, Mylar-to-PMMA bonding was performed with reusable heaters to encapsulate 0.18 μl of water in the cavity, as shown in Fig. 43.29. The close-up view at the top shows two small bubbles in the water-filled encapsulated chamber. These bubbles provide an easy way to verify the presence of water in the chamber. No leakage path can be identified, and water inside the package escapes mainly by evaporation and diffusion through the top Mylar membrane as well as the plastic substrate.

In summary, among the tested bonding systems using built-in aluminum heaters, it is found that plastic-to-plastic bonding shows the highest bonding strength. In the bonding systems using silicon or glass as the

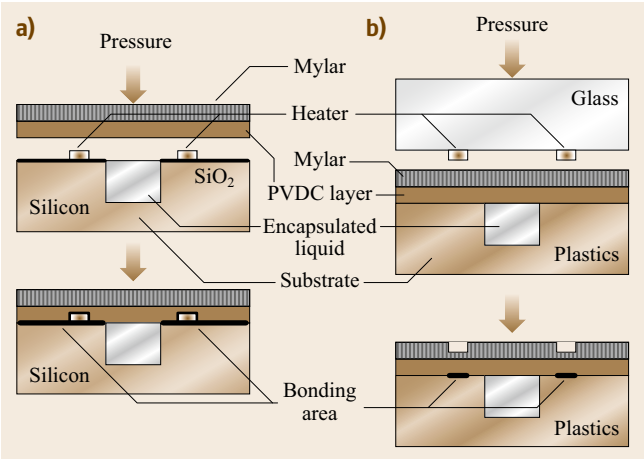

Fig. 43.26a,b Schematic illustration of polymer bonding processes in (a) built-in heater configuration and (b) reusable heater configuration

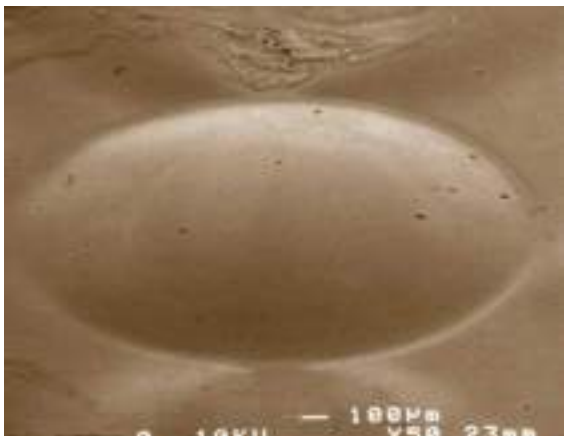

Fig. 43.27 SEM image of dome shape in Mylar membrane, demonstrating good sealing with poly(methyl methacrylate) (PMMA) (after [43.133])

bonding substrate, the bonding interface lies between the plastic and the aluminum heaters, and the bonding strength is lower than for plastic-to-plastic bonding but higher than that of plastic-to-silicon or plastic-to-glass bonds. Meanwhile, the plastic-to-plastic bonding process using reusable heaters shows the best bonding results as compared with plastic-to-silicon or plastic-to-glass systems. In the case of using external, reusable heaters for plastic-to-silicon and plastic-to-glass bonding systems, it is suggested that thin plastic films with (1) high adhesion chemistry with silicon and glass and (2) low melting temperature should be employed as the intermediate bonding layer to achieve high bonding quality.

43.4 Thermal Issues and Packaging Reliability

43.4.1 Thermal Issues in Packaging

The two key thermal issues related to MEMS packaging are:

- Heat dissipation from actuators and integrated circuitry components
- Thermal stress generated during the packaging process.

These two topics are discussed separately.

Heat Dissipation Issues

In an IC, heat dissipation becomes a serious problem as the size of transistors continues to shrink and their density on the chip keeps increase with advances in IC fabrication technology. The trend of packing increasing power into smaller packages has exacerbated thermal management challenges [43.134]. The electrical characteristics of transistors change with working temperature, so inefficient power dissipation that raises the working temperature can affect device performance. Present MEMS devices do not need high-power, high-performance microprocessors, so power dissipation is not a problem. Nevertheless, some functional components in packaged MEMS, such as biomaterials or laser diodes, are very sensitive to temperature variations. Several MEMS chemical sensors and other applications such as micro polymerase chain reaction (PCR) chambers for DNA replication actually require elevated temperature for operation, and microthermal platforms are built for these devices. Thermal management to maintain the working temperature of these chips for stable operation is still an essential packaging consideration. The geometrical complexity of MEMS resulting from packing various functional components into a tight space increases the difficulty of thermal

management. As the MEMS packaging integration process becomes more complex, fabrication constraints on the packaging process will have greater impact on the heterogeneous integration in front-end MEMS and IC processes; For example, a low temperature requirement for the packaging process generally limits the possible choice of materials in the back-end process. In general, conventional IC packaging employs a heat sink attached to the chip to remove heat. The heat sink is generally made of a copper or stainless-steel bar with an array of fin structures on one side for better natural or forced heat convection to dissipate heat to the environment. In addition to heat sinks, thermal vias, heat pipe cooling, immersion cooling, and thermoelectric cooling can also be used for effective heat removal. Because most MEMS packages still follow the typical IC packaging architecture, one promising thermal management method, viz. the heat pipe, is discussed for possible MEMS packaging applications.

A heat pipe is a sealed slender tube containing a wick structure and a working fluid, typically water for electronics cooling. It is composed of three sections: the evaporator section at one end, the condenser section at the other end, and an adiabatic section in the middle. In the evaporator section, heat is absorbed by the working fluid via phase transformation from liquid to vapor. In the condenser section, heat dissipates to the outside environment, and thus, the fluid returns to liquid phase. The vapor phase is in a high-pressure and high-temperature state, which forces the vapor to flow into the condenser section at a lower temperature. Once the vapor condenses and gives up its latent heat, the condensed fluid is then pumped back to the evaporator section by the capillary force developed in the wick structure. Therefore, the middle adiabatic section contains two phases: the vapor phase in the core region and the liquid phase in the wick, flowing in opposite directions and with no significant heat transfer between the fluid and the surrounding medium. Silicon has good thermal conductivity (1.41 W/(cm K)) and is easily micromachined to fabricate such heat pipes. Therefore, there is great potential for implementation of silicon micro heat pipes in IC and MEM packaging, and several approaches have been proposed on this topic [43.135–137].

Packaging-Induced Thermal Stresses

Thermal-based bonding processes have been used in MEMS packaging applications for many years, as described previously in this chapter. Thermal management is extremely important during the bonding process to avoid fracture of the substrate or MEMS devices themselves. Extremely high temperatures or rapid cooling conditions may result in damage and should be carefully evaluated both analytically and experimentally. There are many ways to provide heating energy, including electrical resistive heating, oven heating, or induction heating [43.100]. These bonding processes may be put into two categories: localized bonding, where heat is applied directly only to the adhesive material used to bond the package to the MEMS device, and global heating, where the entire system (MEMS device, adhesive, and packaging material) is heated to bond the materials, being the common approach for all MEMS packaging processes. Therefore, this section focuses on the thermal stress effects in MEMS packaging during heating and cooling procedures. The aluminum-to-glass bonding process using RTP is used as a specific example for the discussion of thermal stresses [43.92]. The bonding process heats up the packaging system to 750 °C for 10 s, then cools it back to room temperature. To simulate this process, an ANSYS program [43.138] was established to examine the shear stress due to coefficient of thermal expansion (CTE) variations in the bonding system as a result of temperature changes. The shear stress was recorded from the ANSYS analysis on the aluminum/Pyrex glass interface and the aluminum/silicon interface.

Two different models were analyzed. The first was for the quartz–aluminum–silicon bonding system, and the second was for the Pyrex glass–aluminum–silicon bonding system [43.139]. The results of the ANSYS analysis were then analyzed and compared with experimental observations. Figure 43.30 shows the ANSYS results for the Pyrex glass bonding system with aluminum solder width of 100 μm; the maximum residual stress is 60 MPa in the glass, slightly lower than the fracture strength of Pyrex glass of 70 MPa. It was discovered that increasing the aluminum width led to lower residual stresses. This likely occurred because the

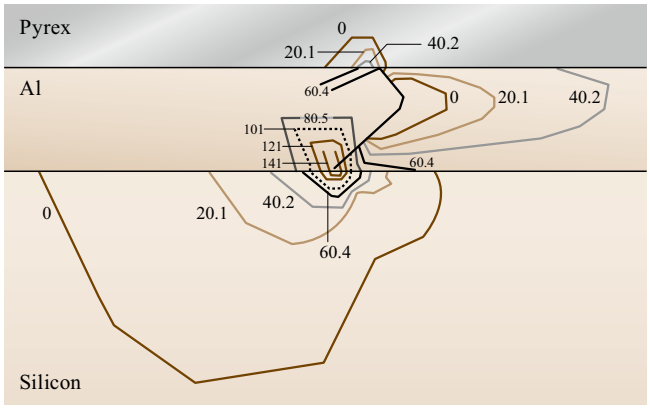

Fig. 43.30 Residual stress (GPa) for aluminum solder width of 100 μm in silicon–aluminum–glass bonding using RTP

length of the Pyrex glass, quartz, and silicon remained constant. As a result, it will always want to contract by the same amount for a constant temperature change, independent of the aluminum width. However, when increasing the aluminum width, the stress did not occur in such a concentrated area and therefore decreased; For example, the maximum residual stress analyzed from ANSYS in the Pyrex glass bonding system was 74.5, 58, and 60 GPa for aluminum width of 30, 50, and 100 μm, respectively [43.139]. Pyrex glass has documented strength of around 69 GPa [43.140]. Fracture should always occur for aluminum width of 30 μm or less, according to the ANSYS analysis. Fracture may occur sporadically at width of 50 or 100 μm, depending on the amount and magnitude of the flaws in the Pyrex glass. Experiments were carried out on the Pyrex glass bonding system with a width of 100 μm. The samples were heated up to 750 °C, then cooled down by taking them out of the oven. In all four experimental cases, small cracks were observed in the Pyrex glass, as shown in Fig. 43.31. These cracks may have occurred consistently for several reasons. First, they may be a result of handling the Pyrex glass before bonding. The Pyrex glass samples were kept in containers with each other, which may have resulted in abrasive contact and possibly caused flaws in the material. These flaws could result in reduced strength below the value of 69 GPa, so the predictions based on the ANSYS analysis could be correct. Second, it was observed that the cracks were small, only occurring tens of microns away from the aluminum and not propagating completely through the Pyrex glass. These cracks could be caused by the high stress applied, but the cracks did not reach a critical size and therefore did not propagate completely through the Pyrex glass. Therefore, the strength remained at the theoretical value of 69 GPa, and the Pyrex glass only partially cracked. Experimental analysis by *Chiao* and *Lin* [43.92] showed that fracture was not observed when using aluminum width greater than 150 μm. This is consistent with the results of the ANSYS analysis showing that, as the width of the aluminum is increased, the residual stress decreases.

ANSYS calculations were also carried out for the quartz bonding system, predicting maximum stress of 207, 117, and 100 GPa, for aluminum width of 30, 50, and 100 μm, respectively. All three of these stress values are much larger than the theoretical strength of quartz at 48 GPa, so fracture should always occur. Quartz has much higher coefficient of thermal expansion (CTE) than silicon, which explains this prediction. Experimentally, a quartz substrate was used to test silicon–aluminum–quartz bonding; the result is shown in Fig. 43.32. It was observed that cracks occurred all over the sample, causing serious damage to the quartz wafer. These cracks could be the failure mechanism of the hermetic package. Therefore, Pyrex glass was identified as a better bonding substrate than quartz.

The thermal stresses generated in the packaging process with quartz are much larger than for Pyrex glass, because of the different CTE mismatches in these two systems. Quartz has low CTE ($0.54\times10^{-6}\,\mathrm{K}^{-1}$) compared with aluminum ($23\times10^{-6}\,\mathrm{K}^{-1}$) or silicon ($3.5\times10^{-6}\,\mathrm{K}^{-1}$). On the other hand, Pyrex glass has a CTE ($3.2\times10^{-6}\,\mathrm{K}^{-1}$) much closer to those of silicon and aluminum, resulting in smaller stresses. The practical implications of the ANSYS results and the information presented above are that materials must be chosen carefully when carrying out bonding. To ensure that fracture will not occur, materials with CTE much higher or lower than that of silicon should not be used. This finding is a valuable feature of this particular packaging system and should benefit other packaging processes involving bonding of MEMS packaging, because it supports the prediction that Pyrex glass is an excellent material to bond with silicon in MEMS packaging, as long as sufficiently wide adhesive material is used.

43.4.2 Packaging Reliability

Packaging is one of the key issues to be addressed in evaluation of the reliability of MEMS products. Any

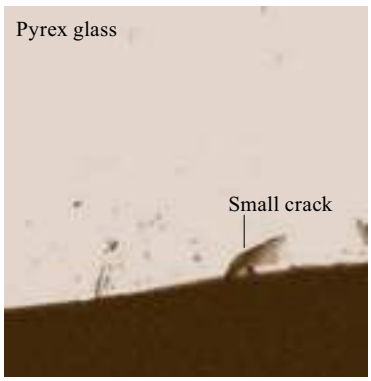

Fig. 43.31 Micrograph of experimental result for Pyrex glass–aluminum–silicon system. Small cracks can be observed

Fig. 43.32 Bonding result of the quartz–aluminum–silicon system; fracture can be observed

defects created during the sealing and packaging process may result in immediate device failure or may degrade device performance over time; For example, microaccelerometers that are used to deploy airbags in automobile safety applications require excellent reliability. If any leakage path is created during the sealing process at the two bonding interface, moisture may be able to enter the sealed microcavity and cause device failure over time. Thermal stress induced by the CTE mismatch is one of the main factors affecting packaging reliability. In fact, stress formation can occur not only during the packaging process but also during device operation. In particular, during device operation, the package will go through various temperature cycles because of environmental changes. Such temperature variation can cause expansion of packaging materials when constrained in the packaged assembly. As a result of such thermal mismatch, significant stresses are induced in the package and may finally cause device failure. In addition to thermal mismatch, corrosion, creep, fracture, fatigue crack initiation and propagation, and delamination of thin films are all possible factors that can cause failure of packaged devices [43.141]. These failure mechanisms can be prevented or deferred by using proper packaging designs; For instance, thermally induced strain inside the packaging material is generally below the tolerance of the material and cannot cause immediate catastrophic damage. However, cyclic loading can generate and accumulate stresses and eventually cause failure. Several common designs have been used in IC packaging to prolong device lifetime; For example, the strain in solder interconnects of BGA or flip-chip packaging can be effectively reduced by introducing a polymer underfill material between the chip and substrate for effective distribution of thermal stresses induced by CTE mismatch [43.142]. Such strain can be further reduced if excellent thermal paths are built around interconnects to diminish thermal stresses originated from the temperature gradient between the ambient and operation temperature. Delamination is another source of reliability problems, occurring at the interface between adjacent material layers. In MEMS, components made of dissimilar materials are commonly bonded together to provide specific functions. Delamination can result in electrical or mechanical failure of devices in the package, such as mechanically cracking through the electrical via wall to form an electrical open because of propagation of the delamination of the metal line from the dielectric layer or overheating of the die because of delamination of the die from the underlying layer to form a gap in the heat dissipation path. Because of the complex stress and thermal loading, geometry, and material properties of MEMS, development of packaging designs to increase reliability is very important and requires more extensive investigation.

Reliability testing is required before a new device can be delivered to the market. Test results can provide information for subsequent improvement of the packaging design and fabrication processes. Hence, the approach used to analyze failure data, known as *reliability metrology*, is very important in the packaging industry. This analysis method uses the mathematical tools of probability and statistical distributions to evaluate data, understand failure patterns, and identify sources of failure; For example, the failure density function is defined as the time derivative of the cumulative failure function

$$f(t) = \frac{\mathrm{d}F(t)}{\mathrm{d}t} \tag{43.1}$$

$$F(t) = \int_0^t f(s)\,\mathrm{d}s\,. \tag{43.2}$$

The cumulative failure function $F(t)$ is the fraction of a group of original devices that has failed at time t. The Weibull distribution function is one of the analytical mathematic models commonly used in packaging reliability evaluation to represent the failure density function [43.12].

$$f(t) = \frac{\beta}{\lambda}\left(\frac{t}{\lambda}\right)^{\beta-1} \exp\left[-\left(\frac{t}{\lambda}\right)^{\beta}\right], \tag{43.3}$$

where β and λ are the Weibull parameters. The parameter β is called the shape factor and measures how the failure frequency is distributed around the average lifetime. The parameter λ is called the lifetime parameter and indicates the time at which 63.2% of the devices have failed. By integrating both sides of the equation, $F(t)$ becomes

$$F(t) = 1 - \exp\left[-\left(\frac{t}{\lambda}\right)^{\beta}\right]. \tag{43.4}$$

Using the Weibull distribution function with the two parameters extrapolated from experimental data, one can estimate the number of failures at any time during a test. Moreover, knowing the meaning and values of these parameters, one can compare two sets of test data; For example, higher λ indicates that a set of samples has longer lifetime. Because all such mathematical models are statistical approximations based on real experimental data, use of more testing samples can provide more accurate estimations.

43.4.3 Long-Term and Accelerated MEMS Packaging Tests

The ability to estimate the reliability or lifetime of a device provides valuable information for the manufacturer to maximize the profit margin by balancing the cost and quality of the product. Moreover, the warranty period given by the manufacturer has to be determined based on product reliability information. The reliability of MEMS packages is best characterized using long-term tests with statistical data analyses. However, it is very difficult to measure the reliability or lifetime of a device in a real-time fashion, because testing during a prolonged time period may be required to prompt many devices to fail. To evaluate the reliability of a device in a timely fashion, accelerated testing is normally conducted to speed up the device aging process and thus shorten the total testing time required. Accelerated testing, from the packaging and sealing point of view, is a testing method that emphasizes failure of the seal when foreign elements leak inside the microcavity, which may affect device performance. For a hermetic package, the lifetime of a MEMS device is essentially an estimation of the time required for water to penetrate into the package. For vacuum-encapsulated MEMS devices, in addition to water penetration through the seal, gas penetration or outgassing from within packaging materials such as the substrate, cap, and seal over time can degrade the vacuum level and thus device performance. Therefore, the lifetime of a vacuum-encapsulated MEMS package can be evaluated using the time for gas to evolve into the package from either the seal or device materials, whichever occurs first. Unfortunately, there are not many research publications that deal with such long-term and accelerated testing to evaluate MEMS packaging reliability. In the conventional IC packaging industry, reliability estimation is carried out using accelerated testing and statistical predictions [43.12]. Accelerated tests often utilize high temperature and high humidity, e.g., autoclave tests [43.143], to speed up corrosion of the sealing boundary and thereby accelerate package failure. The MEMS industry could use very similar accelerated tests to estimate the lifetime of a MEMS package, because the basic assumptions regarding the failure mode and humidity issues are similar to those for conventional IC packages. Several research groups have reported reliability studies on MEMS packages formed using different bonding methods and materials [43.93, 94, 144]. In this section, two MEMS packaging examples that aim to address long-term and accelerated testing are discussed.

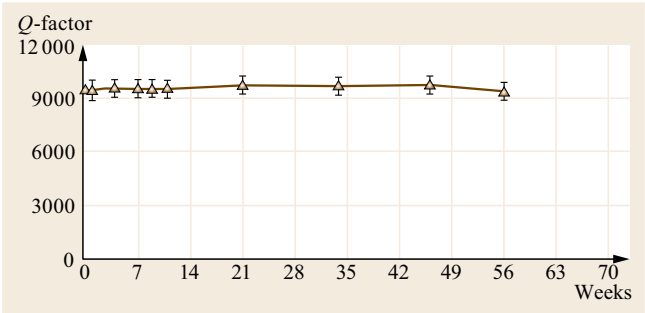

Fig. 43.33 Long-term measurement of encapsulated μ-resonators. No degradation of Q-factor is found after 56 weeks

Figure 43.33 shows long-term measurements of the Q factor of vacuum-packaged μ-resonators obtained using localized aluminum/silicon-to-glass bonding [43.93]. The vacuum encapsulation process is described in detail in Fig. 43.8. It was found that the vacuum package obtained by localized heating and bonding provided a stable vacuum environment for the μ-resonator with quality factor of 9600, showing no degradation over at least one year. Since the performance of high-Q μ-resonators is very sensitive to environmental pressure, as shown in Fig. 43.17, any leakage can be easily detected. The fact that this high Q value can be maintained for one year indicates that the packaging process was performed well and that both aluminum and Pyrex glass are suitable materials for use in vacuum packaging applications. According to a previous study of hermeticity in different materials, metal has lower permeability to moisture than other materials such as glass, epoxy, and silicon. With width of 1 μm, metal can effectively block moisture for more than 10 years [43.12]. In this vacuum packaging system, the bonding width is 30 μm, such that it can sufficiently block the diffusion process of moisture. On the other hand, the effects of diffusion of air molecules into these tiny cavities have not been studied extensively, and design guidelines for vacuum encapsulation are not clearly defined. Further investigations are needed in this area, and the example presented here serves as a good starting point.

On the other hand, accelerated testing involves placing a large number of samples in a harsh environment, such as elevated temperature, elevated pressure, and 100% humidity, to accelerate the corrosion process. Statistical failure data are then gathered and analyzed to predict the lifetime of packages under normal usage environment. As a result, the long-term reliability of the package can be predicted without going through true long-term tests. Unfortunately, accelerated testing is an area that has not been addressed in MEMS research papers. Although the MEMS industry must have done some extensive reliability tests, they do not publish the results, probably due to liability concerns. Among the

very limited publications, this section uses a specific MEMS packaging system that has gone through accelerated tests as an illustrative example [43.41].

The considered MEMS package was fabricated using RTP bonding, as described previously in this chapter. The goal of the accelerated testing was to examine the failure rate at the bonding interface. The accelerated test was started by placing the packaged samples into an autoclave chamber filled with high-temperature (130 °C) pressurized (2.7 atm) steam at 100% relative humidity for accelerated testing. Pressurized steam can penetrate small crevasses if any defect is present at the bonding interface [43.59]. The elevated temperature and humid environment speed up the corrosion process. A package was considered to have failed if water condensed or diffused into the package. The statistical data gathered from this accelerated test can be categorized as right-censored data [43.145]. Statistical failure data were gathered every 24 h by optical examination for a period of 864 h, during which new failures were seldom observed (therefore, right-censored on time axis). In practice, this method was easier and more economical to implement than other methods. Owing to the robustness of the samples, it was difficult to complete the tests to the point where all packages failed. The cumulative failure function $F(t)$ is defined as

$$F(t) = \frac{\text{Number of cumulative failures}}{\text{Number of samples, } N}\,, \qquad (43.5)$$

where N is the sample size at the beginning of the test. A package was considered to have failed if water condensed inside or diffused into the package; For example, water was found to diffuse into the cavity after 240 h of testing in Fig. 43.34. However, no leakage path could be identified under optical microscopy in this case. Figure 43.35 shows the function $F(t)$ (in %) plotted versus the logarithm of time. In general, most failures occurred in the first 96 h ($\ln(t) \approx 4.56$); this high number of early failures reflects a yield issue of the sealing process. Moreover, packages with smaller bonding width and larger bonding area showed higher failure percentages. Both statistical models, i. e., Weibull and lognormal [43.145], were used and compared to analyze the collected data to predict the lifetime of the packages, using the least-squares fit method to determine the best fitting model. It was found that the R^2, the coefficient of determination [43.145], values were generally in the range of 0.8 when using the lognormal model as compared with 0.5 when using the Weibull model. Therefore, the lognormal model was used to predict the lifetime of the packages.

Figure 43.36 shows the inverse standard normal distribution function versus ln(time). The maximum-likelihood estimator (MLE) was then used to predict the mean, standard deviation, and mean time to failure (MTTF). Table 43.2 presents the MLE calculation results for the MTTF. The wide confidence interval results from the fact that only a small number of samples had failed by the end of the test. It was also observed that packages with larger bonding width and smaller bonding area had longer MTTF values. The lower bound of the MTTF provides the worst-case scenario; For example, only 4 out of 31 samples had failed by the end of the test in the case of ring width of 200 µm and sealing area of $450 \times 450\,\mu m^2$. The MTTF predicts, in the worst-case scenario, a 90% chance that a package will fail in 0.57 years in the autoclave environment.

It is widely accepted that the acceleration factor (AF) for autoclave tests follows the Arrhenius equa-

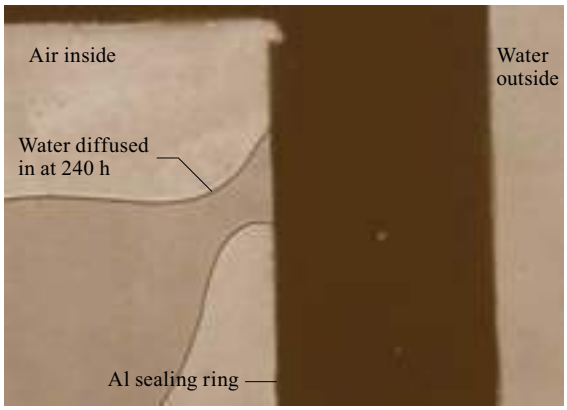

Fig. 43.34 A particular device that failed at 240 h of testing time

MLE calculation results for MTTF[a]				
Bonding width, W (µm)	**Area, A (µm²)**	**MTTF**		**Worst case in jungle condition (years)**
		UB (years)	**LB (years)**	
200	450 × 450	1.8×10^7	0.57	1700
100	450 × 450	5.3	0.10	300
200	1000 × 1000	6.5×10^3	0.09	270
150	1000 × 1000	0.50	0.017	50

[a] UB is the upper bound and LB is the lower bound of the 90% confidence interval, respectively. The MTTF LB times AF is the worst case MTTF used in jungle condition

tion [43.12] and can be modeled as

$$\mathrm{AF} = \frac{\left(\mathrm{RH}^{-n} \mathrm{e}^{\Delta E_\mathrm{a}/k_\mathrm{B}T}\right)_\mathrm{normal}}{\left(\mathrm{RH}^{-n} \mathrm{e}^{\Delta E_\mathrm{a}/k_\mathrm{B}T}\right)_\mathrm{accelerated}}, \tag{43.6}$$

where RH is the relative humidity (85%, RH = 85), k_B is the Boltzmann constant, and T is the absolute temperature. The recommended value for n, an empirical constant, is 3.0 [43.146], while that for ΔE_a, the activation energy, is 0.9 eV for a plastic dip package and 0.997 eV for an anodically bonded glass-to-silicon package [43.59]. Using $\Delta E_\mathrm{a} = 0.9$ eV, an AF of about 3000 is estimated for the accelerated testing condition as compared with the jungle condition (35 °C, 1 atm, and 95% RH); the corresponding worst-case lifetime values in jungle condition are also listed in Table 43.2. The high values of estimated MTTF in jungle condition could be a result of overestimation of the AF because the plastic dip package may have lower AF compared with glass packages. Nevertheless, these data and analyses provide important guidelines in the area of accelerated testing of MEMS packages.

For vacuum-packaged MEMS devices, the lifetime can be evaluated by monitoring the quality factor of microresonators inside sealed cavities. Again, vacuum-packaged MEMS resonators obtained by aluminum-to-nitride bonding using RTP are discussed in detail here to illustrate the various factors involved in reliability. It was found that, under normal condition of room-temperature storage, the quality factor of resonators remained constant after 37 weeks, as shown in Fig. 43.37. Furthermore, the vacuum quality in harsh environment was characterized by placing a vacuum-encapsulated comb resonator into an autoclave chamber

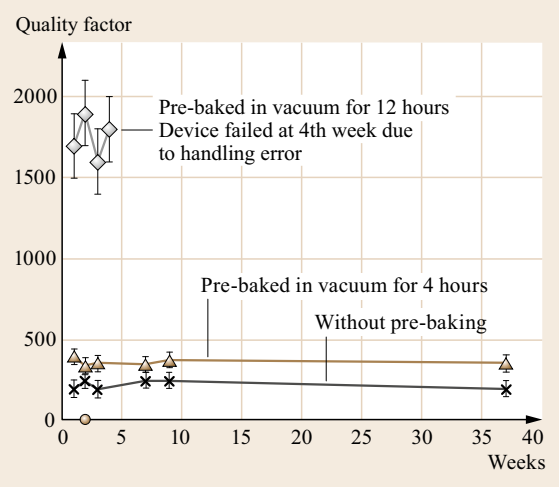

Fig. 43.37 Long-term stability tests to 37 weeks. The Q factor increased with prebaking time

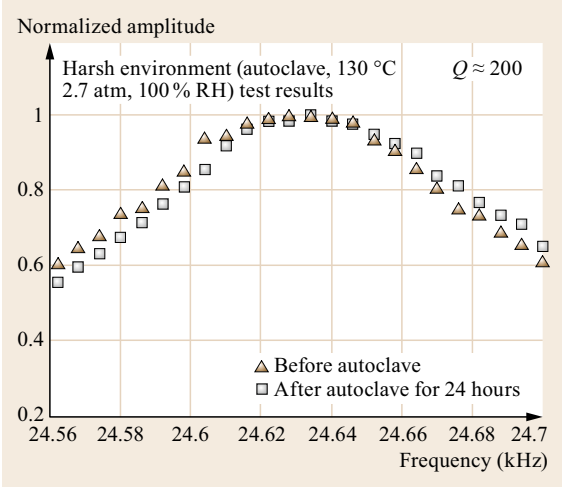

Fig. 43.38 Spectrum measured before and after accelerated testing for 24 h

(130 °C, 2.7 atm, and 100% RH) for accelerated testing. The result is shown in Fig. 43.38; the quality factor remained at 200 after 24 h in the autoclave testing chamber. Since the slight differences between the two spectra are within normal experimental errors, it can be concluded that the harsh environment in the test did not affect the vacuum seal.

To characterize the vacuum lifetime of the packages, two vacuum-packaged comb resonators were placed in the harsh environment for continuous testing for up to 1008 h; the results are summarized in Table 43.3. The quality factor of each package was measured in every 24 h interval, being found to remain at 400 and 200, respectively, before failure. The first packaged resonator with Q of 200 had aluminum sealing ring width of 75 μm and sealing area of $650 \times 650\,\mu m^2$. The second packaged micro resonator had Q value of 400 and aluminum sealing ring width of 200 μm and sealing area of $550 \times 550\,\mu m^2$. If the accelerated testing results on water penetration [43.94] are applied here for gas penetration as a measure of the vacuum sealing characteristics, the accelerated lifetime of the first and second packaged resonator would fall in the range of 0.017–0.1 years (149–876 h) and 0.09–0.57 years (769–4993 h), respectively. Experimentally, the first packaged resonator failed at 576 h into the test in the autoclave chamber. This corresponds well to the lifetime prediction from the previous work [43.94]. The second packaged resonator survived in the autoclave chamber for more than 1008 h (the device did not fail), and this result also verifies the prediction made from the previous work. However, note that these results are preliminary data, and more tests on more packaged devices should be conducted to enable meaningful statistical analyses.

Table 43.3 Summary of accelerated testing results on two vacuum-packaged resonators

	Package 1	Package 2
Q	400	200
Time under testing (h)	> 1008	576
MTTF, lower bound (h)	769	149

43.5 Future Trends and Summary

In the past, development of MEMS packaging mainly originated from IC packaging advancement, because existing packaging techniques could significantly reduce the development cost of MEMS. However, it is expected that this situation will change very soon such that MEMS packaging approaches will assist IC packaging development. Recent progress in IC packaging has aimed to provide high I/O density and greater chip integration capability to meet needs for higher speed and higher data communication rates. To satisfy these requirements, several packaging concepts and techniques have been developed, including 3-D packaging, wafer-level packaging, BGA, and flip-chip technique. Although all of these concepts and methods can provide packages with greater I/O density, flexibility in terms of chip integration, and lower manufacturing cost for IC fabrication, they are still insufficient to provide solutions for future applications,

because of the increasing complexity and requirements of MEMS packaging. In contract, with the progress of MEMS fabrication technologies, several key processes such as deep reactive-ion etching (DRIE), wafer bonding, and thick photoresist processes [43.147] have been utilized for IC packaging fabrication. Therefore, technologies developed for MEMS fabrication can also assist development of new IC packaging approaches.

To address future needs for process integration, adaptive multichip module (MCM) [43.31] or 3-D packaging combined with vertical through-substrate interconnects [43.10, 148] are promising approaches for development of future MEMS packaging processes. Based on low-temperature flip-chip solder bonding technique, these packaging methods can provide greater flexibility in terms of device fabrication and packaging. Devices can be fabricated before they are integrated together to form microsystems, thereby dramatically reducing packaging costs. Vertical through-substrate interconnects can achieve higher I/O density as well as lower resistance, parasitic capacitance, and mutual inductance. Although this approach offers many possible advantages, technical challenges remain; For instance, metal is commonly used as the filler material inside vertical vias to form electrical interconnects, which can introduce large thermal mismatch with respect to silicon substrate and generate huge thermal stresses that cause packaging reliability problems. Moreover, filling materials into these high-aspect-ratio vias will be an interesting engineering challenge.

The future development of MEMS packaging depends on successful implementation of various unique techniques:

1. Development of mechanical, thermal, and electrical models for packaging designs and fabrication processes
2. Wafer-level, chip-scale packaging with low packaging cost and high yield
3. Effective testing techniques at wafer level to reduce testing costs
4. Device integration by vertical through interconnects as an interposer [43.1] to avoid thermal mismatch problems.

In addition to these approaches and challenges, there are many other possibilities that have not been listed but that also require dedicated investigation; For example, several key nanotechnologies have been introduced in previous chapters, but packaging solutions for such NEMS devices have not been addressed. Because it is feasible to use MEMS as a platform for NEMS fabrication, all the packaging issues discussed in this chapter apply directly to NEMS devices as well. On the other hand, nanotechnology may introduce new opportunities for MEMS/NEMS packaging applications by providing superior electrical, mechanical, and thermal properties [43.149–152]; For example, carbon nanotubes have very high thermal conductivity [43.151] and may be applicable to enhance thermal cooling effects for improved IC/MEMS/NEMS packaging applications.

In summary, this chapter has introduced MEMS packaging issues in the areas of fabrication, application, reliability, and future development. Design and modeling, material selection, process integration, and cost are main issues to be considered when developing a new MEMS packaging process.

44. Nanotechnologies in Societal Context

Barbara Herr Harthorn

This chapter provides an overview of the past decade of research on the societal aspects and implications of nanotechnology in the USA. It starts by providing key terms and definitions and then outlines the contours of the social, ethical, governance, and participatory research in the USA, with key examples of nanoELSI work. The chapter argues that all these elements are different facets of responsible development and responsible innovation, and that the National Nanotechnology Initiative's investment in nanoELSI research, education and outreach has provided an unprecedented advance in scholarship and policy. The chapter proposes that nanoELSI has in some respects developed new forms of hybrid social science, ethics, historical, legal, sociological, psychological interdisciplinarity in addition to the interdisciplinary collaborations that form the basis of much nanoscale science and engineering innovation. Integration of the societal and the technical is an ongoing challenge, and the chapter cites some notable advances in this area as well.

44.1 **Assessing Technological Progress in Societal Terms** 1545
44.1.1 Approaches to nanoELSI/nanoELSA 1545
44.1.2 Responsible Development and Responsible Innovation 1547

This chapter provides an overview of research on the societal implications of nanotechnologies. It begins by defining key terms used by the societal research community and then discusses societal assessment of technological progress, nanotechnologies and *upstream* societal engagement, ethics, governance, law and regulation, public perceptions and participation in decision-making and the challenges and progress made in the past decade of work on integrating the societal with the technical. The US National Nanotechnology Initiative (NNI) has provided an unprecedented program in support of societal implications research, education and outreach and as such serves as the primary focus of this chapter, but comparative others from Europe, East Asia, and Latin America are included as appropriate.

This chapter takes up the critical issue of how to consider the crucial question of *what does the world need?* in terms of new technologies and innovation. Who decides, whose values matter? Determining that in a democratic society and responsible global innovation system requires systematic knowledge of that world, in all its social, economic, and political complexity – societal expertise, in addition to scientific/technical expertise – and it requires the ability to integrate the two. In this chapter I will address the current state of knowledge about these issues, using selective examples to illustrate.

The primary funding for societal research in the USA has been through cross-directorate support from the National Science Foundation (NSF), which received a small portion of the NNI budget from 2005–2015. In addition to dedicated funding of two societal implications Nanoscale Science and Engineering Centers (NSECs), the Centers for Nanotechnology in Society at the University of California at Santa Barbara (UCSB) and Arizona State University (ASU), and a number of other societal Nanoscale Interdisciplinary Research Team (NIRT) and Nanoscale Exploratory Research

(NER) awards, the NNI has also mandated Societal and Ethical Implications of Nanotechnology (SEIN) components in the other NSECs and the National Nanotechnology Infrastructure Network (NNIN). The NSECs and NNIN (now the National Nanotechnology Coordinated Infrastructure) societal programs are run under agency-directed cooperative agreements and can be seen as *program-initiated research*; the relevant NIRT and NER awards are *investigator-initiated*, but constitute a much smaller piece of the funding pie. Much of the work discussed herein derives from this critical support.

Many other chapters in this handbook address in detail the issues of definitions and standards for nanomaterials and nanoenabled technologies. US societal researchers have largely followed the NNI definitions of engineered materials at the nanoscale measuring between 1−100 nm [44.1]. For the purposes of societal research, there is a diversity of approaches with some researchers addressing *nanotechnology* in its generic form and a larger segment, especially in the second half of the *societal decade* from 2005–2015, that follows the UK Royal Society [44.2] which specifies the plural form as a necessary distinction due to the very large class of materials represented by the term and the variation in physical, chemical and optical properties within that class. In the societal research arena, these variations have also been critical dimensions across the material/product life cycle, and in the ethical, legal and societal issues they raise.

The *societal context* of new technologies is an idea that draws from the social sciences and science and technology studies (STS). In these fields, technologies are seen to be both produced by society (for example, by funding research, defining priorities, and training the scientific workforce) and in turn to have significant effects on and in society (for example, by changing whole systems of transportation, or construction materials, or how people communicate). Studying the societal context therefore means learning both how technologies are designed, innovated and produced, including historical, economic and political aspects of their creation, development and governance and their interactions with society, for example, the way new technologies might create new jobs or create technologies that replace jobs. The societal context is thus conceptualized as the encompassing framework for research and development (R&D) of new technologies and their consequences. It is a multiscalar idea – this context and its interactions can be studied at local (or community), regional (which in the USA might be state level or broader), national, and global levels. It operates across the life cycle of products from the upstream to the downstream, so it has temporal/spatial variance. And, it involves the individual and collective thoughts, values and behaviors of human beings, a notoriously tricky research subject. So technologies in society are also a highly dynamic system, changing over time in ways that are complex and difficult to track and model.

Given this understanding of the societal context, *societal implications* of nanotechnologies refers to all those potential interactions, near-, middle- and long-term, between the science and technology (S&T) enterprise and wider society, both in the innovation and production of new technologies and in their dissemination into society. In the NNI, this research has been implemented largely as a nanoELSI program, where ELSI refers to the ethical, legal and societal (or social) issues (or implications) of a new technology. This is modeled in concept after the main (and only) prior example in the USA, the ELSI program of the Human Genome Project implemented by the National Institutes of Health (NIH) in 1990 [44.3]. The NNI and NSF also refer to this program in parts of its documentation as societal and ethical implications of nanotechnology (SEIN), but it references the same focus on societal contexts. Until recently, the NNI has clearly differentiated nanoELSI from nanotechnology-related environmental health and safety (EHS) and nanoeducation programs in its guidelines and funding streams. A decade ago, the German philosopher, *Schummer* [44.4] explored the very diverse interpretations of the meaning of *societal and ethical implications of nanotechnology*, pointing to the *immature* state of nanoscience and the problems posed by its early stage of development for *ethical and sociological reflection* on its potential societal implications. This plurality of views is still evident today.

NanoELSI or SEIN is often differentiated from nanoELSA (ethical, legal and social aspects) as the latter term is used in Europe. Researchers there make a point of differentiating their ELSA focus on *aspects* versus the *implications* focus of US nanoELSI and human genome ELSI, because the US ELSI focus is argued to reflect an exclusive focus on *negative downstream* side-effects *at the expense of the broader set of upstream questions of the priorities and directions for research driven societal change* [44.5]. However, nanoELSI as implemented in the USA has arguably cast a very broad net in its scope and was also the earliest in the world to create a dedicated upstream societal program. The 10-year investment in the two NSECs, the Centers for Nanotechnology in Society at UCSB and ASU, represents the largest such investment in the world, and it has focused intently first on upstream and now midstream issues. However, the US societal research focus is now drawing to a close, just as societal issues related to nanotechnology reemerge as a concentrated focus in EU/EC programs [44.6].

As the scope of potential societal implications and effects of such a large class of new and emerging technologies, products, and systems is enormous, the expertise needed to address this research agenda is likewise very broad. The societal initiatives related to nanotechnology (ELSI and ELSA) in the USA and abroad have gathered together an unusually interdisciplinary group of scholars with a wide array of expertise in nanoenterprise/societal interface, including ethics/bioethics, cultural analysis, history of S&T, law and policy, regulation and governance of S&T, innovation systems and their global political economies, environmental studies, media and communication about new S&T, risk analysis and decision risk, public opinion, sustainability studies, social movements, public deliberation, democratic participation, to name only some of them. Nanoscale scientists and engineers, both practicing and in training, have also been key participants in the work. The two US societal centers, CNS-UCSB and CNS-ASU, as leaders of the NSF Network for Nanotechnology in Society, have also taken the lead, in conjunction with the NanoCenter at the University of South Carolina and its societal project, in founding in 2009 a new international professional society, the Society for the Study of Nanoscience and Emerging Technologies (the S.NET; recently renamed the Society for the Study of New and Emerging Technologies). The societal NSECs at UCSB and ASU have provided essential infrastructure and resources to this international network that NSF national Center funding has made possible. With broad international membership, the S.NET's participants reflect the diversity of approaches brought to this field; what follows can only provide a broad overview, with key examples.

44.1 Assessing Technological Progress in Societal Terms

The NNI was developed with four main goals:

1. To advance world-class nanotechnology R&D
2. To foster transfer of new technologies into products for commercial and public benefit
3. To develop and sustain educational resources, a skilled workforce and supporting infrastructure to advance nanotechnology
4. To support responsible development of nanotechnology [44.7].

The societal research within the NNI was designed to help meet these goals and has provided critical social, behavioral and economic analysis relevant to all four of them. This body of work uses a large and diverse methodological toolkit and focuses at scales from the local to the global and back again.

44.1.1 Approaches to nanoELSI/nanoELSA

Philosophical approaches. NanoELSI and SEIN have pursued a robust engagement with the philosophy of ethics and represents ... *the first major scientific endeavor that embodies a transformation in science with a major place for ethics* [44.8, p. 102]. Philosophers in collaboration with nanoscientists at the NanoCenter at University of South Carolina, for example, identified six main SEIN issues for nanotech development:

1. Environmental issues
2. Equity concerns
3. Legal, regulatory and insurance challenges
4. Privacy
5. Nanomedicine and medical ethics
6. *Hypertechnology*, their term for the rapid advance of these new technologies [44.8].

They also advocated for a full stakeholder engagement with *dialogue that is open, honest and attentive to interests and equity* [44.8, p. 101]. Other philosophers have added military applications, human enhancement and risk to the list of ethics concerns [44.9]. *Schummer* and *Baird* [44.10] explored the range of philosophical and ethical issues posed by nanotechnology, citing metaphysical issues with what *Nordmann* [44.11] called the *incredible tininess of nano*, and issues of truth and knowledge construction. *Lewenstein* [44.12] also explored the scope of nanoSEIN, as others in the volume reflected on issues of risk management, public discourse and anticipating unknown futures. Philosopher *Rosalyn Berne* also published that same year her book on *Nanotalk* [44.13], which reported on her conversations about ethics with Nanoscale Scientists and Engineers (NSE) that demonstrated both the unfamiliarity and importance of these issues. In addition, the NSEC at Northeastern University, for example, incorporated a societal implications component that included a partnership with an ethicist (*Sandler*) and integration of his work into the work of the center [44.14, 15].

Social Sciences Approaches

The core social sciences of anthropology, sociology and political science, along with communication, global studies and economics, have made signal contributions to nanoSEIN. The CNS at UCSB is built on such approaches that range from ethnographic studies of nanomaterials and toxicology labs [44.16], mul-

tilevel sociological and anthropological analysis of the global nanoenterprise [44.17, 18] and comparative global analysis of national investment programs in nanoR&D [44.19–21], to comparative nanoworkforce development analysis [44.22–24] and nanotech social movement analysis [44.25]. Political scientists and theorists have contributed essential theoretical and empirical understanding of collective action, democratic participation and governance [44.26–28]. For example, the team at the University of Wisconsin led by Scheufele and Brossard, along with ASU's Corley, has devoted itself to polling and political communication research about US public attitudes towards nanotechnology [44.29–31] that has culminated in two National Academy of Sciences (NAS) Sackler Colloquia on the Science of Science Communication (2012, 2013) [44.32] and an edited supplement in *Proceedings of the National Academy of Sciences* (PNAS) [44.33].

Science and Technology Studies

Science and technology studies (STS, also called Science, Technology and Society) is an interdisciplinary field focused on social, political and cultural analysis of scientific knowledge and technology in their societal contexts, both contemporary and historical. The CNS at UCSB has been notable in the SEIN for its focus on the *applied history* or *history in the making* of nanoscience and nanotechnology. For example, the work of these scholars has looked at how the history of the development of new instrumentation brought about changes in interdisciplinary collaboration among nanoscientists [44.34], at the sociological processes for developing and maintaining such new forms of interdisciplinarity at conferences and other meetings [44.35], and how more than 50 years of S&T development and citizen engagement have contributed to the current nanoenterprise [44.36]. STS also has a strong science policy focus as one of the critical points of connection between science and technology (S&T) and society. Science policy scholars at Georgia Tech have been particularly active contributors to nanoSEIN, notably *Shapira* and *Youtie* who, along with *Kay* (now at UCSB), have together mapped the global nanoinnovation system [44.37–40] for policy makers, and *Cozzens*, who has elevated developing world studies of equity issues [44.41]. ASU's combined CNS and Consortium for Science, Policy and Outcomes (CSPO) efforts have developed and staffed a science policy school in Washington, DC that is training a diverse rising generation of new technology policy scholars.

Risk Analysis and Perception

The NNI has demonstrated a keen interest in public risk perceptions about emerging nanotechnologies and particularly the potential for public backlash against nanotechnologies. Risk perception is an interdisciplinary field that combines approaches from social psychology, sociology and anthropology to systematically study the factors driving public perceptions and attitudes. Perceptions in this field are viewed as having both cognitive and affective components that vary based on knowledge, familiarity and other factors [44.42]. The processes that produce the social amplification of risk perception are of particular interest to policymakers and industry, as amplified risk perception can lead to stigmatization and backlash [44.43]. The CNS at UCSB has taken the lead on nanotech risk perception research, dedicating one of its three main streams of research (led by Harthorn, Pidgeon and Satterfield) to risk perception and social response in the USA and comparative UK publics. They organized an international specialist meeting on the topic in Santa Barbara in 2010, coedited a special issue of the journal *Risk Analysis* on nanotech risk perception in 2011 [44.44] and have also studied the risk views of scientists, toxicologists, regulators, and industry leaders in order to fully understand the current and projected future societal context for these emerging technologies [44.45–47].

Technology Assessment

Technology assessment (TA) is a Northern European-derived mode of studying and evaluating new technologies that serves as both an antecedent and parallel to many aspects of US SEIN research and projects. It has had well-developed programs across Northern Europe beginning in the 1960s. In particular, its form of Constructive Technology Assessment (CTA) developed in the Netherlands and Denmark in the mid-1980s [44.48] has served as the model for such US SEIN programs as CNS-ASU's real-time technology assessment (RTTA). One of CTA's key distinguishing elements from other European TA is the development of strategies and tools to contribute *feedback of TA activities into the actual construction of technology* [44.48, p. 252]. Indeed, Dutch chemist/philosopher and CTA author/promoter Arie Rip has played an active cross-national and intercontinental role in the development of US SEIN research, including at both CNSs and in the S.NET. Technological forecasting is a critical element of CTA, and this has been carried into the US SEIN through a number of pathways, most notably CNS-ASU's *anticipatory governance* framework [44.49] and the responsible innovation framework for governance [44.50].

Nanotech as Hybrid, new Path?

Just as NSE has necessitated and forged new Science and Engineering (S&E) interdisciplinarities [44.35], it

is arguable that SEIN has in some respects developed new forms of hybrid social science, ethics, historical, legal, sociological and psychological interdisciplinarity as well. The question of what is new about nanotechnologies is one researchers in this field direct at both our subjects of study and our methodological and reflexive practices in studying them [44.51].

44.1.2 Responsible Development and Responsible Innovation

As noted above, the fourth aim of the NNI is *to support responsible development of nanotechnology*. This may seem obvious – billions of dollars of public funds are being expended in the NNI, and new and potentially disruptive technologies have already or are predicted to result, and of course this would better be done responsibly than otherwise. However, in the nanoELSI research world, the specificities of this commitment are an important focus of both social and ethical inquiry; the mandate also means that the SEIN community shares in that responsibility and the problems of its implementation. Indeed, we are all engaged in a large societal experiment in advancing these goals – not surprisingly, the pathway forward here is not unified, nor even all proceeding in parallel. In simplest terms, responsible development involves a kind of cost-benefit analysis, where nanotech development has a normative/ethical obligation both to maximize the environmental, social, and economic benefits of the technologies developed, and to minimize their negative environmental, social and economic consequences. Societal research is essential to that assessment.

But of course different sectors of society often have very different values about what constitutes *benefit* and what risks or harms are acceptable to achieve those benefits. In the nanotech case, one of the readily agreed upon aspects of responsible development is the need for adequate EHS governance.

In the past half-decade, nanoELSI/ELSA researchers, primarily in Europe, have led the way to a focus on responsible innovation (RI). Although this approach shares many features with the responsible development aims of the NNI, its proponents have articulated a more integrated framework that both credits science and technological innovation with enormous transformative benefits, particularly in wealthy countries, but also lays responsibility with past S&T for unmet promises and unintended consequences. To create innovation that is good for society under conditions of uncertainty, unpredictability and ignorance, the RI framework stipulates 4 main features of innovation and development:

1. Responsive
2. Deliberative
3. Anticipatory
4. Reflective [44.50].

See below for more on this in relation to governance of nanotechnologies more specifically.

44.2 Nanotechnologies and Upstream Societal Engagement

Because the societal initiative within the NNI was implemented early in the technological development process, before many of the new materials and nanoenabled products and systems had been extensively scaled up in commercialization, this represented an unprecedented *upstream* societal effort. The mandate with upstream societal engagement is different from one in the midstream or downstream, when the R&D effort has matured, public awareness may be widespread, and effects on the ground may already be visible. Such engagement has been recurrently troubled by late-stage consultation, when the decisions have already been made and technologies are widely disseminated. If risk issues emerge at that stage, past efforts indicate that public dialogue is likely to prove frustrating at best, for example, in the GM Nation project in the UK [44.52]. The nanotechnology *upstream* conditions from over a decade ago created an opportunity, at least in theory, for a different kind of dialogue in society about technological development processes and decisions, one in which public views could in theory inform government, industry and S&E action [44.53].

Such public engagement and participation efforts are often seen differently among the different nanoR&D stakeholders. Government and industry often pursue public engagement in a potentially fraught effort to gain public acceptance. This is problematic in several ways:

1. Across studies of different technologies, public engagement has been shown to have highly variable effects on acceptability [44.54].
2. What constitutes acceptability is more complicated than it seems [44.55].
3. In order to be successful, public engagement and participation needs to include two-way communication, not just top-down S&E experts instructing the lay public in how to think [44.56].

There are three widely agreed upon reasons to pursue public participation and engagement in S&T decision making:

1. *Normative*: because it's the right or ethical thing to do, for example because the public have a right to know and to participate in decisions that may directly affect them
2. *Instrumental*: because it is often useful to do, for example to gain public buy-in on controversial decisions that affect them
3. *Substantive*: it can often provide important knowledge and perspectives that can produce better policy or decisions [44.56, 57].

However, most prior engagement has taken place further downstream in the S&T production life cycle, often after risk controversies have arisen. So, how to effectively engage diverse publics early in development, in an ethical and two-way mode, has occupied a great deal of the nanoELSI communities' thought and effort. First, in the upstream context, it is particularly important to see the results of engagement as provisional or contingent. Thus, for example, widespread benefit-centric public views on nanotechnology [44.46] should not be taken to mean publics share an unconditional approval of nanotechnologies. Rather, these upstream views in the nanotech case have been associated with very high levels of uncertainty and unwillingness to provide acceptance/rejection decisions, which scholars take to be a measure of potential malleability [44.47]. And both experimental survey and deliberative research have indeed shown that people's initial uncertainty about nanotechnologies can move toward either greater acceptance or greater risk concern or it can remain ambivalent following deliberative dialogue or experimental information provision in surveys [44.58, 59]. In order to fulfill the ethical, substantive and instrumental goals, *public engagement should be done early in the tech development process*, as we have seen in the nanotechnology case in the USA [44.45, 60], the UK [44.45, 61] and elsewhere in Europe and South America [44.61, 62], *and it should be done often*, which is far rarer [44.63, 64].

Who are the publics to be engaged? As indicated above, this is not a given. For democratic participation, *the public* is necessarily plural and obviously needs to be diverse enough to represent a range of social positions and locations. For a large multicultural nation like the USA, this is very difficult, although multisited efforts [44.60] and diversely drawn groups [44.45, 63] help. Cross-national comparisons have also contributed new understandings, particularly regarding the deeper social risks attributed to some new nanotechnologies, and shared by many people around the globe [44.45, 61]. In most of these efforts the publics invited to participate are selective – for research reasons they are not run as open community fora as self-selection may bring those more concerned or more knowledgeable than a representative sample of the full population [44.65]. Social science survey research, by contrast, often aims to reach truly representative samples of a total population. These people are recruited randomly or selectively by survey research firms for their demographic and locational attributes.

Have nanotech deliberative engagements been successful? A systematic review by *Corner* and *Pidgeon* [44.66] of 18 nanotech deliberation projects in North America and Europe found that a number of them were effective in producing deliberative, informed judgments, even among participants who walked in the door with little to no knowledge, and that benefit-centric views of nanotechnologies were widespread among participants, but there were also deep-seated reservations about government, corporations and responsibility [44.47].

Nongovernmental organizations (NGOs) or civil society organizations (CSOs) represent another kind of publics, sometimes referred to in STS scholarship as the *uninvited public* because their tactics and protest aims (needlessly) intimidate S&E, government and industry [44.67]. *Welsh* and *Wynne* have argued [44.68] that such policy maker anxiety about *unruly* publics is misplaced and that engagement is often constructive and beneficial to desired outcomes. In the nanotech case, NGOs have also often been reluctant to serve as token representatives of *the public* and fear becoming coopted by government and/or industry in multistakeholder meetings. In theory, NGOs are the main publics to be consulted downstream [44.69], but in the nanotech case, NGOs have also played significant roles, across nations, and studying them is an important part of the societal agenda [44.25]. They have a clear role to play in advocating for responsible development and innovation. One recent book-length study of the independent organization the Project on Emerging Nanotechnologies (PEN) provides a model demonstration of this argument [44.70].

Science museum audiences constitute a ready-made science-interested public for engagement. In 2005, along with the two societal NSECs at UCSB and ASU, the NNI SEIN generously funded the formation of a Nano Informal Science Education Network (NISEnet), a large national network of science museums, with the Boston Museum of Science as lead [44.71]. This multisited organization has engaged and educated a network of educators and the publics they serve. Although arguably designed in principle around a *deficit model* of public knowledge, the

NISEnet in practice has reached beyond one-way science education to engagement, incorporating societal aspects into their materials and programs directly and indirectly, demonstrating the synergies that can exist between nanoELSI and nanoISE.

Engagement and public participation have been integral to the organizations of both CNS-UCSB and CNS-ASU, in part in response to funder-driven criteria. Both centers have used large and creative toolkits to engage diverse publics via nanoscience cafes, series of deliberative workshops, Nano Days informal science education, citizen advisory boards, NGO conferences and meetings, multistakeholder workshops, web-based courses, blogs, Twitter, Facebook and myriad other activities. Other notable nanotech public engagement efforts have included the Citizens' School at University of South Carolina [44.72] and deliberative exercises at the University of Wisconsin [44.73]. Engagement assumes a relatively deep connection and two-way dialogue; public outreach activities, which often do not meet these engagement criteria, of course, are far more numerous throughout the NNI.

In spite of these many efforts and solid methodological advances, there have been impediments to fully realized public deliberation and engagement in the USA. The most serious of these is the lack of direct channels of communication to policymakers, an essential element of democratic participation, and a relatively common practice in EU citizen engagement. Center level funding for the societal work has enabled more information flow between engagement work and policy makers, but it is not institutionalized and hence very labor intensive over time and fragile as a process. In addition, scaling up S&T deliberative engagement to the national level would require substantial investment not yet in evidence for nanotechnologies, nor in the plans for converging technologies societal implications work.

44.3 Ethics

Like its predecessor ELSI program in the Human Genome Program [44.3], the nanoELSI or SEIN program in the USA has ethics and bioethics as a central part of its agenda. In addition to the domains of nanotechnology applications and effects of enduring interest to ethicists cited above, ethicists have had unusual opportunities in the context of nanoR&D in the USA and Europe to engage NSE but also social scientists, policy makers, and others about the ethical principles for technology assessment.

The German philosopher *Schummer* has argued compellingly that international reflections about nanoethics are necessarily complicated by the diversity of sociocultural issues (such as language, cultural heritage, economics, and politics) that affect the way people perceive the ethical issues in nanotechnology [44.74]. That is, he has raised the issue of ethical relativism in *the globalization of the ethical debate around nanotechnology* [44.74, p. 217]. In this, he is asking how individuals' or societies' moral order or intuition may be in conflict with given nanotechnologies. He clearly differentiates this from the idea of risks (although risk perceptions do incorporate moral judgments). Like many others in the nanoELSI arena, he uses *technology* to reference not just actual products but also the full range of R&D activities and their governing mechanisms.

Schummer points to the embedded normative (ethical) concepts built into goals, such as those articulated above as the goals of the NNI. Because such goals are prescriptive – they state what kind of technology should be developed – they encompass a *hidden normative debate about norms and values that are frequently expressed in the form of hopes and fears* [44.74, p. 220]. The fact that such normative debates should be explicit and deliberately in the public discourse is itself an ethical issue because [44.74, p. 220]

> *it smuggles in values in the disguise of definitions or forecasts of allegedly deterministic technological developments, which are kept apart from normative debates.*

Although these values can and do vary within societies at the level of individuals, they also reflect the patterns different countries tend to use. As one example of how cultural context may shape ethics and values in relation to nanotechnologies, Schummer points to German sensitivity to the idea of *human enhancement*, which in the USA has been a central goal for nanobiotechnology and also a vested interest of the military. In Germany, because of their Nazi legacy, there is strong abhorrence of any approach that could be used for eugenic purposes. Other concepts with strong cultural-specificity in normative ideas are those about human identity and integrity, privacy and ideas about the private sphere, national prestige objects, and underlying concepts of what constitutes *a good life*. Economic imperatives are also deeply implicated in ethical issues, but with significant differences across developing and developed countries because developing countries have a unique opportunity to catch up economically through entering new tech markets that may lead them to neglect ethi-

cal issues. However, patent policies in place since 1980 and changes in raw material dependency are likely to increase economic gaps more than previous technologies [44.74].

Thus, the list of potential ethical concerns that can or should be brought to bear on the case of nanotechnology development is lengthy [44.75]. The main ones that have been the focus of nanosocietal research and discussion in the past decade include the following:

- Distributive justice or fairness regarding the benefits and harms: Does/will the technology improve the lives of some but not others? Does/will the technology production harm some but not others? Are the ones who are harmed different from the ones who benefit [44.44, 45, 76]?
- Procedural justice: Are people informed about the technological effects? And who gets to make the decisions? Do people share in the decision making? Are there procedures in place to ensure a fair outcome [44.76, 77]?
- The precautionary principle(s) (PP): *Weckert* and *Moor* [44.78] have argued that in spite of its definitional issues (e.g., over the threshold of anticipated harm required to invoke it) the precautionary principle is valid and useful in the case of nanotechnologies. Ethicists have noted its particular applicability in environmental effects [44.79]. The EU has employed active precaution in its approach to nanomaterials regulation (e.g., through the REACH program (Regulation on Registration, Evaluation, Authorisation and Restriction of Chemicals), implemented by the European Union in 2007), putting the burden on industry to do safety testing before taking nanotechnologies to market; in the USA the National Institute of Occupational Safety and Health (NIOSH) adopted a *better safe than sorry* approach to nanomaterials industry guidance and precautionary information dissemination to proactively reduce potential worker exposures to nanomaterials like carbon nanotubes ahead of full hazard characterization [44.80]. And in the USA and Europe, NGOs have frequently been the stakeholders advocating most vocally for precautionary approaches, often including moratoria on development [44.81, 82].
- Involuntary exposure through lack of informed consent to risks and hazards, including such broader social and economic risks as invasion of privacy through use of nanosensors, accelerating inequality, loss of identity, loss of humanness, and loss of livelihood, in addition to exposures to toxins.
- Whether a technology is needed is also a concern in risk perception research and deliberations as well as larger responsible development/innovation contexts.

As can be seen from above, equity issues top the list and are the first-order concerns. These include access to beneficial technologies or economic gain as well as safety from potential harms. They also include issues of emerging technologies and global inequalities [44.83]. It is also clear that ethics issues are inextricably intertwined with both governance and risk, which will be discussed below. The ethical challenges in the past decade have in many cases been about anticipated rather than present issues and finding new methods to assess anticipated concerns has been on many researchers' minds [44.84].

44.4 Governance, Law and Regulation

Technological governance is a central ethical issue in all technological R&D, and nanoELSI researchers have been concerned with potentially ungovernable or unanticipated aspects of nanotech innovation through the past decade. The term *governance* refers to a much broader system of responsibility and political control of technologies than that of formal governmental regulation. Governance includes governmental R&D programs, subsidized industries, and restrictive or incentivized regulation. It also includes decisions on technology control made by corporations. Such decisions that are made without public information, or with secrecy, are likely to raise ethical issues, suspicion and mistrust [44.4]. Nanotechnology governance thus includes legal and regulatory aspects but refers as well to this wider scope of responsibility and power.

In his recent overview of nanotechnology governance since 2003, *Bosso* argues that

> *the incentives driving innovation and commercialization* [...] *always outpace incentives for more anticipatory and systematic oversight of a technology's potentially adverse environmental and health impacts.*

In addition, nanotechnology poses particular challenges for risk governance because of its framings as revolutionary and unfamiliar [44.69, p. 163].

One early (2006) anticipatory approach to governance issues of nanotechnology was undertaken by the International Risk Governance Council (IRGC) in Switzerland, in consultation with a number of lead-

ing international figures, and led by German sociologist *Renn* and US NNI leader *Roco* [44.85, 86]. In their IRGC report, they proposed a risk governance framework that divided two different risk governance concerns across present or near-term technologies, and longer-term technologies. They aimed to identify risk governance deficits (technical and organizational, institutional and risk communication) and make recommendations to address them. The Royal Society's Report on Nanotechnology in 2004 [44.2] similarly initiated a robust assessment project, including focused attention to societal context, and anticipated a range of potential problems.

Both of these approaches reflected strong upstream efforts to critically examine future directions. Both included the societal context for nanotechnologies as critical to governance, and both made a number of recommendations for successful governance and risk communication. However, in the intervening decade, neither has been carried forward in a cohesive or programmatic way by governments, industries or nanoELSI researchers. Instead, a more fragmented approach has emerged, without the critical coherence and power to effect needed change in the absence of crisis [44.69].

The following are the main examples of nanotechnology governance, regulation and legal change issues in the past decade.

44.4.1 Standards

Nanotechnology is not a technology but rather a very broad class of technologies defined through their scale, many with new and hitherto unknown characterization, and as such they have posed major challenges to classification and standardization. Although physical, technical classification is a technical rather than societal issue being addressed by the International Standards Organization (ISO), the Organization for Economic and Co-operation and Development (OECD) and the US National Institute of Standards and Technology (NIST), the lack of agreed upon standards, and the difficulty of deriving them, have produced many spillover effects on the societal side. For example, since with few exceptions in the USA engineered nanomaterials (ENMs) continue undifferentiated from their bulk forms from a regulatory standpoint, they are also untrackable from a governance standpoint. Efforts such as the California Department of Toxic Substance Control (DTSC) call-ins with legally required ENM reporting in 2010 (carbon nanotubes) and 2011 (quantum dots and nanometals/metal oxides) proved remarkably unsatisfactory for identifying or monitoring nanomanufacturers [44.87]. Thus firms that are producing or handling ENMs continue to fly largely under the radar, limiting governmental ability to ensure workplace, community or consumer safety. In a recent review, *Schulte* et al. at NIOSH outlined 15 years of occupational health and safety (OSH) of nanotechnology and noted that in spite of progress, *unified analytical standards and exposure characterization methods are still lacking* [44.88, p. 1] and that protection across the life cycle is still lacking.

44.4.2 EHS/OHS

Regulating and governing risks to EHS and OHS have been at the top of almost everyone's list as the leading regulatory concern for many aspects of the nanoenterprise. *Beaudrie* et al. [44.89] applied a gap analysis to regulatory oversight of nanomaterials across the life cycle and found many problematic areas where existing regulatory controls were simply not in place. They then went on to demonstrate in an expert survey that among diverse experts, nanoregulators had significantly lower confidence in the adequacy of the current regulatory apparatus to handle ENMs than did physical scientists or toxicologists [44.90].

Expert surveys have provided extensive understanding of how nanoscientists and nanotoxicologists view the hazards of ENMs, and how they handle such materials. Industry surveys have also provided insight into the ENM workplace and its safe handling and product stewardship practices, as well as the ENM industry's strong preference for autonomy from regulation [44.91, 92]. Thus, experts are a highly diverse group in their views on the risks of nanomaterials and on regulatory capacity.

44.4.3 Voluntary Approaches/Soft Law

Nanotechnology has witnessed several attempts at voluntary regulation, the first via the joint Environmental Defense Fund/DuPont NanoRisk Framework sponsored by Rice University's International Council on Nanotechnology (ICON) (2005) – it failed to generate sufficient active participation from the nanoindustry, as did the EPA's voluntary Nanomaterials Stewardship Program (NMSP). Even California's mandatory call in failed to generate significant response, and in the absence of regulation, DTSC personnel had few means to identify companies and businesses handling ENMs. *Bosso* [44.69] shows that as recognition of the shortfalls of current regulatory approaches has coalesced, there has been increasing advocacy for radical change to the current US risk management regime such as EPA's Toxic Substances Control Act (TSCA). Yet more recently most calls in the legal field are for address-

ing deficiencies in governance *by calls for more flexible combinations of* soft *and* hard *law approaches* [44.69, p. 163], including voluntary industry standards and codes of behavior, voluntary information sharing and other flexible and self-regulated approaches. However, such approaches have major acknowledged limitations. Bosso's analysis suggests that *where* in the upstream-midstream-downstream innovation stream technological governance occurs should have a major effect on what kind of approach is taken, with the upstream permitting public engagement and dialogue, and the midstream allowing soft law approaches with coordinating committees bridging industry and society, but that the downstream requires hard law and regulatory teeth, relatively less role for the public and elevated roles for NGOs and lawyers [44.69]. As one example of the uphill battle involved in formal regulatory change, he traces the ups and downs of attempts to reform and update TSCA, first in 2009–2010, then again in 2015 (finally signed into law on 22 June 2016).

There are numerous other legal and regulatory issues involved in nanotech R&D, too many to address in this brief overview. The innovation system has changed significantly and patent thickets and other problems abound. Privacy issues continue to mount in the USA and globally, in spite of legal protections in the USA under Health Insurance Portability and Accountability Act (HIPAA) and Federal Deposit Insurance Corporation (FDIC) that create national standards and regulate consumer financial information. Consumer safety and protection are regulated under the Consumer Product Safety Commission (CPSC) and agricultural uses are regulated by the US Department of Agriculture, while food and pharmacological products are regulated by the Food and Drug Administration. The complexity and division of duties and boundaries among all these US players creates a disjointed process for regulatory scrutiny of ENMs and their enabled products and inevitable gaps in coverage [44.89] as well as communication issues.

44.4.4 Responsible Development/ Responsible Innovation

As noted above, the responsible innovation framework defines responsibility in legal terms, but goes beyond legislated safety (e.g., general liability regimes and sector-specific regulation), which regimes are notably after-the-fact regulation of the products of innovation [44.93]. Such legal tools have been critical to safeguard health.

However, RI advocates for a prospective kind of responsibility, one that is *anticipatory* and can move alongside innovation's creative imagination and invention. It needs to be *reflective* about the purposes of innovation, the values underlying innovation. It also needs to be *deliberative* about engaging publics and others as a part of democratic participation, and *responsive* in being open to new information. *Owen* et al. define it as follows [44.93, p. 36]:

> *Responsible innovation is a collective commitment of care for the future through responsive stewardship of science and innovation in the present.*

The RI framework itself provides a normative statement of what innovation in society should be and do, and it has garnered interest and support. It has generated a growing literature that is a mix of theoretical treatises on the ethical and legal aspects of the framework and empirical case analyses of RI in action [44.94–96]. It has also spawned a new journal, *Responsible Innovation*, founded and edited until recently by ASU's Guston, and now by ASU's Fisher. The decade ahead will serve as a critical test of its ability to invoke the kind of care and responsibility for societal aspects of the global S&T innovation system.

44.5 Public Perceptions and Participation in Decision-Making

From the above, it should be clear that public attitudes, public risk perceptions and beliefs and values are of critical importance to the nanoELSI program. Both the nanoELSI centers and a substantial number of other leading societal researchers have contributed to a now substantial literature on this. These studies have used in-depth, qualitative research based on interviews and public deliberations; they have also conducted numerous public attitude, risk perception, and experimental surveys of US and other publics. Media studies based on both traditional print and new media have been important to understand emerging public attitude formation. NGOs have also been studied for their efforts to influence public views, journalists and policy makers. Risk has been a critical dimension of this work, but values, beliefs, and identities also play primary roles in public perceptions [44.44, 47].

As indicated above, there are strong ethical, instrumental and substantive principles for public participation in advanced democratic societies. The analytic-deliberative model for understanding risk explicitly invoked the need for both analytic assessments and

deliberative engagement in making risk decisions and became the normative model for understanding risk in the USA [44.97]. New forms of participation are also a part of the mix, exemplified by the United Kingdom Energy Research Centre (UKERC) project on energy technologies and public engagement [44.98].

Full democratic public participation in technological R&D in a large multicultural nation like the USA, not to mention the global community, is undoubtedly a significant challenge. The nanoELSI and responsible innovation work has created successful models that can now be deployed in the new and converging technology in society work ahead. However, public participation in the nanotechnology innovation system has just completed its upstream phase. Midstream engagement and participation should be of critical importance to scholars, scientists and engineers, industry and policy makers.

44.6 Integrating the Societal with the Technical

As indicated above, the generous funding of SEIN research in the NNI has resulted in a large body of scholarly research on ethical, legal, economic, environmental and social research on aspects of nanotechnology. We SEIN researchers have been challenged not to just research societal aspects of nanotechnologies but to get out of our familiar sandboxes to integrate those efforts within the NSE enterprise. The work has been shared widely, with major efforts to disseminate and publish in S&E publications, to disseminate to policy makers and to present to and engage in dialogue with industry (for a set of examples, see CNS-UCSB presentations 2005–2016 [44.99]). A number of collaborative research projects and programs have emerged in this context. Some of the main things we have learned in this process are discussed here.

The education of both society and the S&E enterprise is necessarily a mutual process and SEIN researchers need to reach out, forge partnerships, be willing to travel and to step outside the comfort zone of the social sciences to work in S&E contexts that may not start with a lot of space, intellectual or symbolic, for the societal aspects. This has also on occasion required a new kind of three-way communication between science–social science–society, where the societal researcher needs to serve as an essential broker and translator. The *trading zone* metaphor has been used to describe a creolized form of language and interaction to describe how scientists with different disciplinary backgrounds can meet and engage, particularly with the help of those with interactional expertise in more than one area [44.100], and this has been advocated within the NNI [44.101]. However, models based on scientists converging in the shared use of instrumentation, for example, may not be the most apt for societal science/nanoscience interface, where values may diverge more strongly and the impetus to *trade* may not be self-evident to all participants. More subtle and ethnographic approaches to traversing cultural divides, particularly where asymmetrical power relations apply, may well be called for. Below are several examples of successful approaches to this challenge of integration between nanoscience and society.

NanoELSI researchers with both societal and materials training and expertise have been important full partners in the SEIN context. For example, CNS-UCSB has had a political scientist and STS scholar who is also an electrical engineer (Bimber) on its leadership team from the start, and the history of science research group in the center is led by a materials-trained historian (McCray). The risk perception group includes a faculty member (Kandlikar) who is both a materials and science policy trained researcher, who has trained students into both approaches (e.g., Beaudrie). CNS-ASU is similarly diverse with a number of faculty and researchers in past or present leadership positions with S&E backgrounds and science policy training and interests (e.g., Sarewitz, Miller and Bennett)

Collaborations of societal researchers with S&E have proliferated in the USA under NSF SEIN funding. In CNS-UCSB, founding co-PI Hu was a vital part of proposal development and early center organization. The CNS-UCSB Executive Committee has always included one or more leading NSE researchers (Hawker, Hu, Holden). Research and education collaborations have abounded, the most notable between Harthorn and her group in the CNS, and the UC CEIN, where she has led a societal research group, served as an executive committee member, and coauthored publications. Collaborative research projects have also resulted from this.

Another important form of interaction has been expert workshops as a form of both research and engagement. This includes the structured decision making (SDM) work at the University of British Columbia on codeveloping expert decision risk tools in the case of EHS risk uncertainty [44.102], Delphi experiments with nanoscientists by nanoresearcher *Berube* et al. [44.103], expert meetings at the Project on Emerging Nanotechnologies [44.70], and others.

Both CNSs have leveraged center-level funding and infrastructure to implement highly successful programs to increase the societal understanding of the next generation of NSE-in-training and the NSE understanding of the next generation of societal researchers-in-training [44.104, 105]. At UCSB this has taken place primarily by the integration of NSE graduate fellows into the social science and science policy work of the CNS [44.104]; at ASU this has been primarily through the embedding of social scientists in the bench science lab settings [44.105]. Both approaches have used new modes to develop new capacities that can be models for programs elsewhere. With funder-driven incentives, NNI NSECs have also successfully integrated societal information into NSE courses and NSE content into social science courses over the past decade, as well as jointly providing public engagement activities.

44.7 Concluding Remarks

Because of its proactive, anticipatory societal work as well as its complexity as a class of technologies, nanotechnology is in many respects a new hybrid form of science in society, much though our history of science colleagues point to its deep historical antecedents. The NNI has led the world in funding a robust and diverse societal implications research, education, and engagement enterprise. The latter has been highly productive in terms of both scholarly merit and broader impacts of its work. Even more impressive are the many intersecting lines of connection forged between the societal research community and the nanoscience R&D community.

This science in society *testbed* has developed the intellectual infrastructure, broader partnerships, and deeper ties *across the aisle* with NSE for future societal work even as the institutional and programmatic funding for it is diminishing. The work of the two CNSs at UCSB and ASU has demonstrated again and again the importance of center-level funding for ramping up this new and important national nanoELSI project.

What the future holds is not clear for the next decade of societal work. We have learned a great deal about the upstream as a research site. We've created two national clearinghouses to share information, approaches, toolkits and data, and we have developed and specifically tailored a methodological toolkit for research in the upstream of new technology development and societal emergence. We have developed an international network of scholars that is already expanding its footprint around the globe, in the Global North and the Global South, and this community stands ready to tackle the rising issues ahead with converging technologies, and the unanticipated consequences that will doubtless accompany their development and deployment in society.

This is also the moment when we can see the path forward to socially sustainable technology development with unusual clarity. Responsible innovation frameworks provide a normative guideline, but practices on the ground will inevitably require new collaborative approaches and effort and inspiration from societal and technological experts. As we expand the scope of societal research and the responsible innovation framework to other emerging technologies, it is likely the relevance and impacts of our work on nanotechnologies in society will become more and more evident.

45. Environment, Health and Safety Issues in Nanotechnology

Rui Chen, Chunying Chen

With the rapid development of nanotechnology and its application, lots of nanomaterials or nanorelated products are now used in society. Nanotechnology offers substantial economic and societal benefits, but its impacts on environment, health, and safety (EHS) issues are not clearly understood or defined. Interactions between nanomaterials (sourced from nanotechnology development) and the human body and even with the ecological system have attracted much concern. In this chapter, the impacts of the development of nanotechnology on EHS issues has been surveyed focusing on present knowledge of the most important nanomaterials, dominant physicochemical characteristics which contribute to relevant toxicities, and state-of-the-art techniques and established biomarkers within this research field. This information may not be enough to fill the knowledge gap concerning the impacts of nanotechnology on EHS, but should help scientists and authorities to realize the risks involved and to take steps for sustainable development in the foreseeable future.

45.1 Impacts of the Development of Nanotechnology on Environment, Health, and Safety Issues

As illustrated in this handbook, nanotechnology has undergone broad development in terms of the techniques of characterization, fabrication, and manufacturing to keep pace with actual requirements from fields such as electronics, cosmetics, catalysis, gas sensing, energy storage, structural materials, environmental remediation, medical diagnostics, and drug delivery [45.1]. Nanomaterials (NMs) or nanoparticles (NPs) with novel physicochemical properties are the main products or research subjects in nanotechnology development. Among such properties, the most significant change in the properties of NPs is the increase in the surface-to-volume ratio compared to their large bulk counterparts. Importantly, the emergence of these products and research subjects, along with their applications and extinctions has led to great concern over adverse impacts on the environment, health, and safety (EHS). NPs may be released into the environment with the possibility of human or ecosystem exposure at various stages in their life cycles (Fig. 45.1). It is proposed that NPs may enter the body and accumulate in organs, such as lung, liver, spleen, kidneys, or brain, potentially causing harm or death to humans and animals, and the release of NPs into the environment might

harm the ecological system. Consequently, the field of nanotoxicology emerged around 2004 to 2005 in an attempt to answer critical questions related to these EHS issues [45.2, 3]. *Oberdörster* [45.4] defined nanotoxicology as the study of the adverse effects of engineered nanomaterials (ENMs) on living organisms and the ecosystem, including the prevention and amelioration of such adverse effects. According to a report [45.5] from the Committee to Develop a Research Strategy for Environmental, Health, and Safety Aspects of Engineered Nanomaterials (National Research Council, USA), there are many issues in relation to EHS of NMs:

1. Engineered nanomaterial sources and manufacturing
2. Modifications, fate, and transport
3. Bioavailability and dose
4. Effects on organisms and ecosystems.

As particularly important for EHS, topics related to nanotoxicology and ecotoxicology of NMs will be paid the most attention in this chapter.

NMs/NPs are also defined as nanosized materials/particles that have at least one dimension less than 100 nm. Man-made NMs are generally called engineered nanomaterials (ENMs). Ultrafine particles (UFPs) refers to airborne particulates of less than 100 nm in aerodynamic diameter, i. e., particles generated through the use of nanotechnology, diesel exhaust particles, products of cooking, heating, and wood burning in indoor environments [45.9]. Alongside the booming development of nanotechnology, life-cycle assessment of EHS impacts is important yet difficult to carry out because of the lack of enough detail on the ENMs [45.6]:

1. The manufacturing processes of newly developed NMs are usually evolutional, i. e., with constant changes before final standardization. Thus, EHS impacts could vary considerably among different production procedures.
2. The formula of NMs and related manufacturing processes are new and often subject to confidentiality constraints in the nanotechnology industry.
3. NM release and ecotoxicology impacts are ambiguous at both the nanoproduct use and application stage and at the final disposal and recycling process stage.

This means risk estimations for impacts of NMs on EHS vary from one scenario to another. However, we still need to deepen our understanding of such impacts from the whole life-cycle perspective in order to address uncertainties over possible future outcomes. This may help to bridge the knowledge gap and provide an opportunity to improve the health and safety of scientists, workers, and consumers who work with or use NMs/NM products or are exposed to nanoparticles in society.

The NM production process plays an important role in nanotechnology. This is because a high release potential correlates directly with the mass production process of NMs, generally involving pure and uncombined nanomaterials. Thus, workers in this environment are not only at the forefront of risk due to advancements in nanotechnology, but also their working environments have

high priority for the establishment and implementation of responsible practices [45.10]. The basis of evaluation of EHS impacts from nanotechnology is the structure of the ENM life cycle. The first step in NM release assessment is to obtain knowledge of the production process which determines the maximum amount of NMs that could potentially be released to the environment. This means that the most accurate estimation of NMs that could potentially be released to the environment may be the one that is based on the production volume of the raw nanomaterials. In 2012, *Piccinno* et al. [45.8] summarized the production quantities of ten engineered nanomaterials based on their own survey and other literature sources [45.6, 7]. NMs like silica, titania, alumina, iron oxides, and zinc oxides dominate the ENM market in terms of mass flow through the global economy (Table 45.1). Within this list, TiO_2 is by far the most significant ENM in terms of exposure based on modeling estimation [45.11, 12]. The modeling of the NM's flow should generally track its entire life cycle which is illustrated in Fig. 45.1: this includes ENM production, incorporation into products, ENM release from products during use, transport and disposal of ENM during and after recycling processes, transfer to air, soil, water and sediments (ecosphere), and transport within environmental compartments of the nature system. The amounts of ENM in said compartments provides the basis for calculating the overall environmental concentrations of ENM [45.13]. Recently, using dynamic probabilistic material flow modeling, *Sun* et al. [45.14] found that the concentrations of all ENMs in all compartments of the nature system are increasing with the increase of production and applications of ENMs, i. e., of nano-TiO_2, nano-ZnO, nano-Ag, and carbon nanotubes (CNTs) for example, in the world. ENMs generally enter the Earth's surface water first and end up in the sediment where the accumulated concentrations of CNTs and nano-TiO_2 were estimated to be 6.7 μg/kg (CNTs) and about 40 mg/kg (nano-TiO_2) in the worst-case scenario [45.14]. The concentration of NMs in the nature system is a crucial factor in the evaluation of EHS impacts. However, one report shows that Ag ENM contributed to a higher ecotoxicity to freshwater algae, daphnia, and fish compared to TiO_2 ENMs, even though a much lower concentration had accumulated in the ecosystem [45.15].

In nanotechnology there are two principle nanoscale manufacturing strategies: the top-down and the bottom-up approach [45.16]. The top-down approach begins at the bulk level and involves miniaturization to nanoscale dimensions via carving or grinding methods, i. e., lithography, etching, or milling. The bottom-up approaches begin at the atomic or molecular level with growth through nucleation and/or growth from liquid, solid, or gas precursors via chemical reactions or physical processes, i. e., through techniques like sol-gel or epitaxy [45.16, 17]. The top-down approach dominates compared to the bottom-up approach, but it is believed to produce more waste. It has been suggested that the bottom-up approach represents should be emphasized in order to minimizing the unwanted waste for sustainable development in nanotechnology [45.17].

The release of NMs during production and manufacturing not only constitute a possible release pathway to the environment, but also has high relevance in regard to occupational exposure. With no release and no exposure there will be no impact on EHS. Actually, from a life-cycle viewpoint there is significant impact from

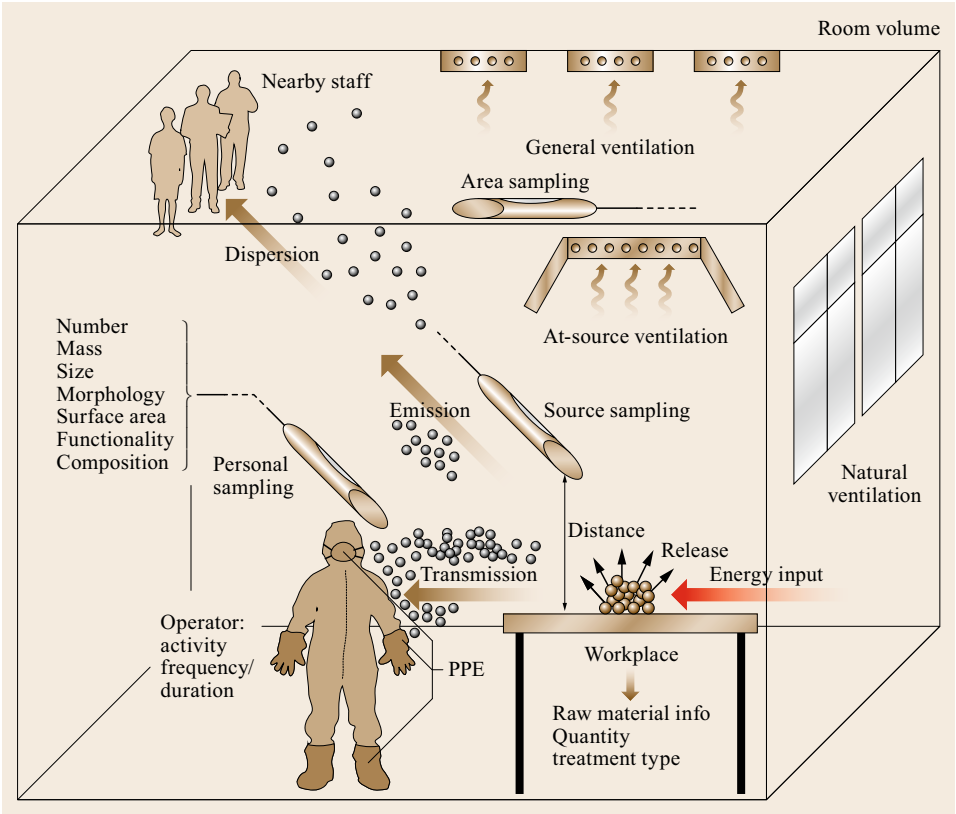

Fig. 45.2 Diagram representing various elements and processes in an occupational exposure scenario. Reproduced with permission from [45.18]

the process of NM production. Figure 45.2 shows a typical occupational NM-handling setting where ENMs could be released, emitted, and transported, resulting in actual exposure to workers [45.18]. Exposure assessment and management are critical in order to minimize impacts on the production environment, although there are too many variants in application situations. Detailed procedures and strategies for occupational exposure assessment and risk evaluation can be found in the literature [45.10, 18]. Further, appropriate risk management practices including engineering control systems in working environments or personal protective equipment (PPE) for individuals are important but beyond the scope of this chapter. In addition, it would be informative if more effort is paid in the future to evaluations of impacts during use and application processes, and the final disposal of nanorelated products.

45.2 Current Progress of the Most Important Nanomaterials

45.2.1 Carbon Nanotubes

Much of the concern associated with nanotechnology comes from the potential risks of CNTs [45.19, 20]. Typically a few nanometers in diameter, CNTs are long and thin cylinders of carbon with a single wall or multiple walls defined as single-walled carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWCNTs), respectively. They have a needle-like shape and are strong and tough in character, similar to asbestos. In vitro evidence showed that exposure to CNTs could reduce viability, induce apoptosis, and cause DNA (deoxyribonucleic acid) damage [45.23, 24]. These adverse effects may result from the interruption of cellular redox status after CNT exposure, e.g., increasing ROS (reactive oxygen species) and malondialdehyde (MDA) levels, as well as altering superoxide dismutase (SOD) activity and glutathione peroxidase (GSH-Px) levels as previously reported [45.25–27]. In vitro studies based on mammalian cell models often show inconsistent results because of the different cell lines, doses, and exposure times used. However, in vivo pulmonary tox-

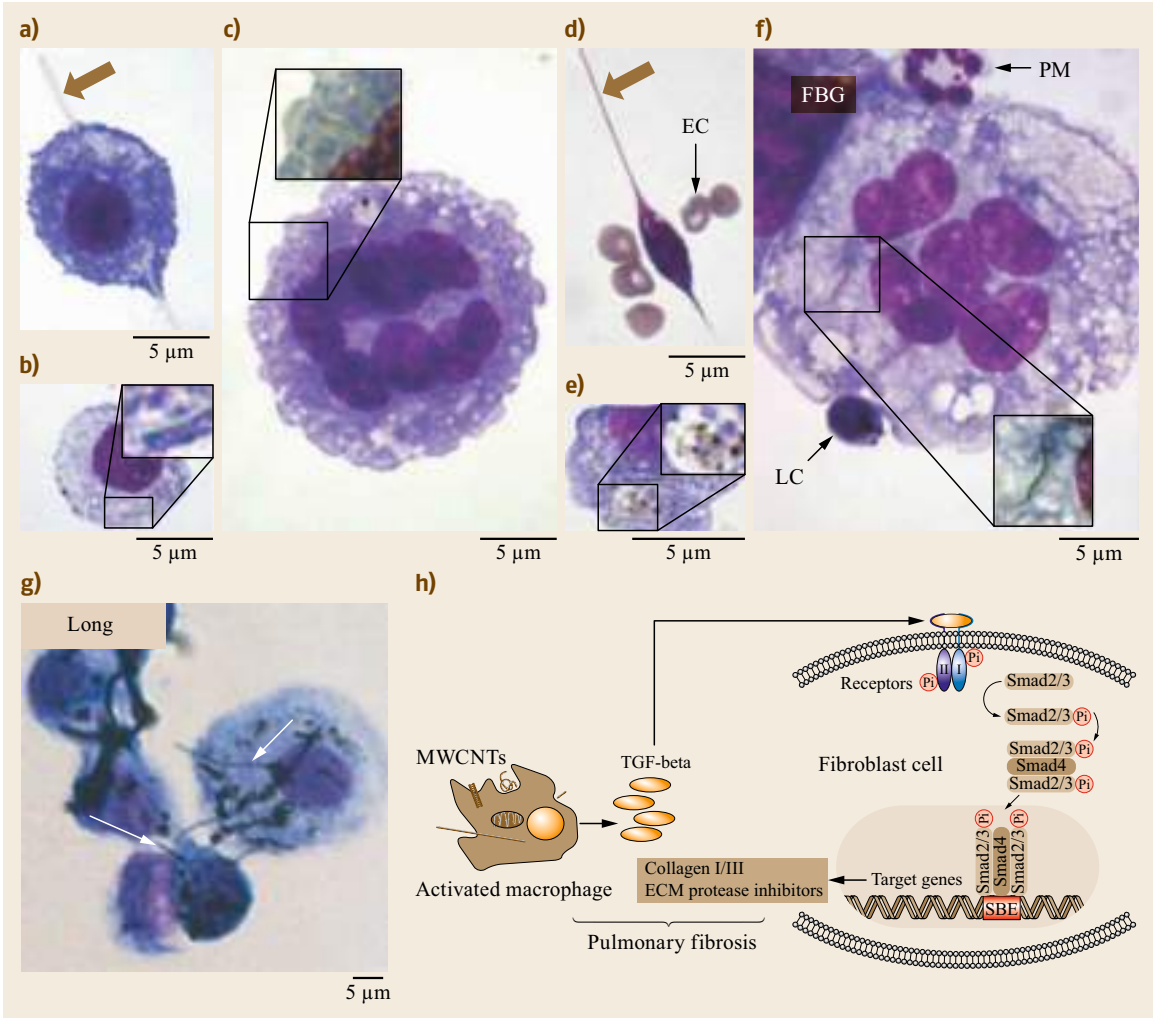

Fig. 45.3a–h The phagocytosis of asbestos and CNTs by macrophages. **(a,b)** Histological sections show incorporation of long-fiber amosite **(a)** (*arrow*) leading to *frustrated phagocytosis*, but short-fiber amosite **(b)** (see *inset*) is successfully phagocytosed by peritoneal macrophages. **(c)** Representative image of a foreign body giant cell after injection of long-fiber amosite containing short fiber fragments. **(d)** Like long-fiber amosite, long CNTs ($> 15\,\mu m$) also lead to frustrated phagocytosis in peritoneal macrophages (EC, erythrocytes). **(e)** In contrast, short CNTs ($< 5\,\mu m$) can be readily phagocytosed (see *inset*). **(f)** Foreign body giant cells (FBGC) are also present after injection of long CNTs in peritoneal macrophages (see *inset* for internalized fibers) (PMN, polymorphonuclear leukocyte; LC, lymphocyte). **(g)** Representative optical microscope image to show the in vivo cellular uptake of MWCNTs by alveolar macrophages. **(h)** MWCNTs promote pulmonary fibrosis through the TGF-β/small mothers against decapentaplegic (Smad) signaling pathway. All images are shown at $\times 1000$ magnification with a $5\,\mu m$ scale bar (after [45.21], **(g,h)** from [45.22] reprinted with permission)

icity studies usually show CNT causing clear adverse toxicity effects. It has been found in animal experiments that exposure to long CNTs (longer than $15\,\mu m$) at the mesothelial lining of the body cavity of mice will result in asbestos-like, length-dependent, pathogenic behaviors including inflammation and granulomas [45.21]. The macrophages at the mesothelial lining may resort to *frustrated phagocytosis* and giant cell formation caused by macrophage fusion in inflammatory conditions when attempting to phagocytose or engulf long CNTs (Fig. 45.3a–f). These results suggest a potential link between inhalation exposure to long CNTs and mesothelioma which is generally regarded as the specific type of cancer caused by inhalation exposure to

asbestos, although it remains unknown whether there will be sufficient exposure in the environment or workplace to actually cause it.

Granuloma formation and/or fibrotic responses in the lungs are the dominant injuries after inhalation exposure to CNTs. It is worth noting that long CNTs have much more significant effects [45.22, 28]. The underlying mechanisms were systematically investigated in our lab. The alveolar macrophages show the same *frustrated phagocytosis* phenomenon with peritoneal macrophages when phagocytosing long MWCNTs (Fig. 45.3g). It was found that TGF (transforming growth factor)-β1 could be induced in alveolar macrophages or released from the bronchiolar epithelium by MWCNT exposure, which plays an important role in MWCNT-caused pulmonary fibrosis (Fig. 45.3h). At the same time, the fibroblast-specific protein-1, α-smooth muscle actin, and collagen III were significantly upregulated by the induction of TGF-β1 [45.22]. Further research showed TGF-β1 secreted from macrophages serves as a critical paracrine stimuli to fibroblasts by directly activating TGF-β/small mothers against decapentaplegic homolog 2 (Smad2) signaling in fibroblasts or epithelial cells. This stimulation then induces the fibroblast-to-myofibroblast transition and epithelial–mesenchymal transition (EMT), respectively, both of which contribute to CNT-induced fibrotic responses [45.28].

The inhalation of carbon nanotubes has a high possibility to induce pulmonary fibrosis but also can directly cause acute and serious injuries to the pulmonary system [45.30, 31]. In our research, we tested the pulmonary toxicity of SWCNTs by intranasally instilling exposure using the spontaneously hypertensive rat model [45.32]. The inflammation, oxidative stress, and cell damage levels in the bronchoalveolar lavage fluid (BALF) were significantly increased at 24 h postexposure. The increased endothelin-1 in BALF and plasma and angiotensin I-converting enzyme in plasma suggested endothelial dysfunction in the pulmonary circulation and peripheral vascular thrombosis. Histological data on lung tissues showed that SWCNT-laden macrophages move to centrilobular locations and form multifocal pulmonary granuloma [45.32]. The formation of pulmonary granuloma lesions were the result of the lungs' immune response to the foreign substances that can not easily be eliminated [45.33, 34]. Further, the subchronic toxic effects and cardiovascular effects of CNTs were disclosed at 7 and 30 days postexposure to the inhalation system in rats [45.35]. These results suggest that respiratory exposure to CNTs not only induces acute pulmonary toxicity but also poses long-term adverse effects on the whole cardiovascular system. Humans with existing cardiovascular diseases are also susceptible to CNT exposure.

Knowledge of biodistribution and biopersistence in the body can help better understand the potential effects of their exposure to humans. Using the Raman spectroscopy mapping method it has been found that inhaled CNTs have the ability to penetrate deep into the lungs, cross the pulmonary epithelium, and enter the bloodstream [45.36]. Then, the extrapulmonary transport of CNTs was disclosed after inhalation exposure in C57BL/6 J mice by testing at 5 h/day for 12 days with a concentration of 5 mg/m^3 in a whole-body inhalation system [45.29]. It has been shown that inhaled MWCNTs, which were deposited in the lung, were transported to the parietal pleura, the respiratory musculature, liver, kidney, and heart in a singlet form and accumulated even until day 336 postexposure (Fig. 45.4). Similar biodistribution evidence for CNTs in liver, kidneys, and spleen has been reported after exposure to MWCNTs in rats using the inhalation system [45.35, 37]. After entering the blood circulation, CNTs will interact with blood proteins, i. e., fibrinogen (BFg), immunoglobulin, albumin, transferrin (Tf), and ferritin. Indications showed that there was a competitive binding of different blood proteins onto the surface of SWCNTs, which was governed by each protein's unique structure and the amount of hydrophobic residues of each kind of protein (Fig. 45.5). Atomic force microscopy (AFM) images indicated that the adsorption of transferrin and BSA (bovine serum albumin) quickly reached thermodynamic equilibrium at about 10 min, while fibrinogen and gamma-globulin (γ-Ig) gradually packed onto the SWCNT surface in a much longer period of about 5 h. Both fluorescence spectroscopy and SDS-PAGE have shown surprising competitive adsorptions among all the blood proteins examined, with the competitive order: BFg > γ-Ig > Tf > BSA. The far-UV circular dichroism (CD) spectra observation shows that the protein secondary structure has greatly changed for BFg and γ-Ig, with a decrease in the α-helical content and an increase in the β-sheet structure (Fig. 45.5g). In addition, our molecular dynamics simulations of SWCNTs binding with BFg, BSA, γ-Ig, and Tf complexes showed that both the contact residue numbers and binding surface areas exhibited the same sequence order: BFg > γ-Ig > Tf > BSA, in agreement with the experimental findings. Further analysis showed that the π–π stacking interactions between SWCNTs and aromatic residues (Trp, Phe, and Tyr) play a critical role in their binding capabilities. These different protein-coated SWCNTs may have different cytotoxicity by influencing the subsequent cellular responses [45.38].

The knowledge on the ADME (absorption, distribution, metabolism and excretion) of NMs could give help on the understanding of their adverse impacts to EHS. Much more research efforts should be taken

The tyrosine residues are rendered as Licorice representations and shown in *red*, with phenylalanine residues are in *green*. **(g)** The far-UV circular dichroism (CD) spectra of proteins after incubation with SWCNTs and the insets are near-UV CD spectra of proteins incubated with SWCNTs (after [45.38])

on this topic for CNTs. Other carbon NMs including fullerene and derivatives, graphene, and graphene oxide have a lower production quantity compared with CNTs (Table 45.1). Even so, a cautious attitude should be taken with all these carbon nanomaterials [45.40]. More information and data on the impact of these carbon NMs on EHS are urgently needed to support future effective assessment.

45.2.2 Silver Nanoparticles

With excellent antimicrobial activity, silver nanoparticles (AgNPs) are widely used as a major ingredient in industrial, consumer, and medical products [45.41, 42]. For example, AgNP-related products have been used in consumer products such as surface cleaners, room sprays, toys, antimicrobial paints, home appliances, food storage containers, textiles, and medical products including wound dressings, surgical instruments, urinary catheters, and bone prostheses. Several investigations have shown that silver-containing textiles could release significant amounts of Ag into the washing liquid when laundering fabrics [45.43–46]. It is inevitable that these discharged silver ions or silver nanoparticles are released into the ecosystem through sewer systems and constitute a high impact on EHS [45.47]. It has been discerned that Ag mostly transforms and precipitates to silver-containing particles like Ag_2S or AgCl during handling or disposal processes [45.46, 48]. Further, recent studies revealed that the reduction of Ag^+ in natural waters can form AgNPs naturally via the mediation of dissolved organic matter or sunlight [45.49–51]. This means that silver has complex transformation mechanisms in the environment [45.52].

As release from source products is inevitable, there is a high possibility that AgNPs will enter the human body and distribute within the circulation system or the organs after exposure. It has been shown that AgNPs are captured by the reticuloendothelial system and quickly distributed to other tissues after entering the blood [45.53–56]. In detail, AgNPs were mostly distributed to the liver, spleen, lung, and kidneys, and much less to the brain, heart, and testes after *i.v.* exposure [45.57, 58]. Interestingly, the concentrations of Ag in the blood remains steady with a slightly decreasing trend till at least 14 days for a single i.v. injection of AgNP, which means that AgNPs may be degraded and removed in a time-dependent manner [45.59]. The kinetic distributions of AgNPs in the body are important because they determine relevant toxicity. However, the mechanism of AgNP toxicity has not been clearly defined. Currently, there are three hypotheses to explain the toxicity of AgNPs after exposure. First, the ions released from NPs contribute to their toxicity. Second, the toxicity is caused through a silver ion-independent mechanism. Third, the Ag ions released from the endocytosed AgNPs in the cell dominate the toxicities, and this generally happens at endosome or lysosome locations. In reality, a combination of these may lead to the AgNP toxicity mechanism. *Jiang* et al. [45.39] showed that AgNPs were mostly localized in the endosome/lysosome in Chinese hamster ovary (CHO-K1) cells after exposure (Fig. 45.6a,b). Then, the cytotoxicity and genotoxicity of BSA-coated AgNPs on CHO-K1 were investigated. This showed that both BSA-AgNPs alone and Ag ions can up-regulate the cellular ROS level with the production of oxidative adducts, 8-hydroxydeoxyguanosine (8-OxodG), and induce the formation of micronuclei (Fig. 45.6c–f). The genotoxicity of AgNPs is prominent within the induced adverse outcomes, and merit special attention in future [45.60, 61]. Further research in our lab showed that there is a high possibility that AgNPs will cause adverse effects by the third mechanism listed above. Evidence concerning the intracellular fate of AgNPs is derived using x-ray absorption near-edge structure (XANES) spectroscopy, which is used to study the degradation and biointeraction of nanoparticles in biological systems [45.62, 63]. About 14.2% of the internalized silver was oxidized to Ag−O− after 12 h incubation of AgNPs in the CHO-K1 cell line. While 61.5% of the silver was present as Ag−S− after 24 h, suggesting that binding of Ag to sulfide groups of amino acids and proteins may be involved in the dissolution process of AgNPs. This intracellular binding of silver ions to proteins disrupts protein structure and function, thereby resulting in toxic effects [45.64].

The surface charge and various surface coatings of AgNPs play an important role in in vivo and in vitro toxicity, biodistribution, and pharmacokinetics [45.65]. Branched polyethyleneimine (BPEI)-coated AgNPs led to the highest toxicity in cells and mice, while the nearly neutral polyethylene glycol (PEG)-coated AgNPs showed low toxicity and long half-life in blood, indicating a high potential for application in medical products [45.65]. This means that the safety of silver NMs can be improved by adoption of particular surface coating strategies in their application [45.66–68]. Improving our understanding of the toxicity mechanisms of AgNPs could help with their safety evaluation and potential risks to EHS, and from different aspects such understanding may contribute to facilitating the design of safer and more effective antimicrobial products in the future.

45.2.3 Zinc Oxide Nanoparticles

Zinc oxide NPs have been used in personal care products including cosmetics and sunscreens as they efficiently absorb ultraviolet radiation and are also highly transparent to visible light. Attracting great concern are potential impacts through human exposure and health impacts at each stage of their manufacture and use [45.69, 70]. Dermal penetration is the first step in evaluating the toxic impacts of ZnO NPs on humans in regard to their long-term skin retention character.

Gulson et al. [45.71] tested the penetration efficiency of ZnO NPs by focusing on ^{68}Zn from enriched ^{68}Zn particles in sunscreens. Small amounts of ^{68}Zn tracer were tested in the blood of 20 human volunteers who received twice daily applications over 5 days. The highest ^{68}Zn concentrations were found in females after exposure to the ^{68}Zn nanoparticles [45.71]. This means that long-term retention of NMs on the skin may lead to dermal penetration by outer particles, although usually at the trace amounts level. For damaged skin, exposure of epidermal and dermal cells to high concentrations of ZnO NPs is sure to cause cytotoxicity and undesirable immune responses, which will instigate the penetration of even more particles to even deeper sites or even into the lymphatic or blood circulation [45.70, 72].

Inhalation exposure to ZnO fumes in the working environment can affect normal bodily functions, for example by causing metal fume fever, which is characterized in humans by short-term pulmonary and systemic alterations and is caused by inhalation of metal oxide aerosol [45.73]. It has been reported that humans exposed to ZnO particle fumes (MMD 300 nm) at 2.5 mg/m^3 for 2 h developed symptoms of metal fume fever with a significant increase of cytokine interleukin (IL)-6 in peripheral blood [45.74]. Human clinical experimental study showed that inhalation exposure of ZnO fumes for 10 to 30 min at a high concentration of 20–42 mg/m^3 increased the number of proinflammatory cytokines and neutrophils in BALF [45.75]. Animal experiments illustrated that inhalation of relatively lower concentrations of ZnO NPs, 1.1 to 4.9 mg/m^3 with occupationally relevancy for 2 week, can generate similar inflammation outcomes in the BALF in rats [45.76]. The National Institute for Occupational Safety and Health (NIOSH) recommended the permissible exposure limit of 5 mg/m^3 averaged over a work shift of up to 10 h/day, 40 h/week for zinc oxide fume inhalation exposure (NIOSH, publication number 0675). Whereas no exposure limit is available for nano-ZnO aerosol to date.

Both in vitro and in vivo systems illustrated that mechanisms underlying ZnO NP toxicity similarly include generation of ROS and subsequent DNA damage and apoptosis [45.77–79]. Oxidative stress produces *free radicals* and has been implicated in various adverse outcomes. For example, *Sharma* et al. [45.80] showed that significant DNA damage in a human epidermal cell line (A431) occurred upon ZnO NP exposure for 6 h at relatively higher concentrations (0.8 mg/ml to 5 mg/ml), while oxidative stress was induced at lower concentrations (0.008–0.8 mg/ml). Zinc ions released from the NPs serve as another key determinant for the toxicity of ZnO NPs [45.81]. Previous research showed that surface coating can considerably mitigate the cytotoxic potential of ZnO NPs by inhibiting ion release and/or minimizing ROS production, i. e., silica shell [45.82] and PEGylation [45.83]. In our own recent research, we found preincubation of ZnO NPs in a supplemented cell culture medium for 24 h could form a hard protein corona on the NP surface. These precoated stable protein layers on the NP surface facilitated further protein adsorption during the cell culture process. The amount of proteins adsorbed on precoated NPs could inhibit both ROS generation and ZnO dissolution and result in lower cytotoxicity [45.84]. This finding demonstrates an effective and convenient way to achieve safe biomedical and environmental applications of ZnO NPs. Besides surface coating, particle size, aspect ratio, doping type, and doping concentration all contribute to their toxicities [45.85]. Quantitative structure–activity relationships (QSAR) modeling is a powerful tool to predict how these physicochemical properties affect the toxicities of ZnO NPs [45.86]. Thus, there is a high chance of developing applicable models to guide the design and optimization of ZnO NPs with safe characteristics in terms of EHS issues.

45.3 Physicochemical Characteristics of Nanoparticles that Determine the Toxicity Impacts

Conventional toxicology places emphasis on chemical composition, dose, and exposure route as the primary variants in toxicity assessment of a chemical or a bulk material. However, many other factors, especially the physicochemical characteristics of nanoparticles, should be considered when we perform the same work in nanotoxicology (Fig. 45.7) [45.87]. This makes nanotoxicity evaluation much more complex and difficult than conventional toxicology [45.88]. There are two types of toxicity-related variants: intrinsic factors such as nanostructure, size, aggregation state etc. as listed in the right column of Table 45.2, and extrinsic factors, such as dose (presented by the metrics of mass/surface area/particle number), cell-/organ-specific responsiveness, exposure routes (e.g., pulmonary exposure, dermal exposure, oral gavage, ocular exposure, intravenous/intradermal/intramuscular/subcutaneous/intraperitoneal administrations), and biological species (e.g., rat, mouse, *Caenorhabditis elegans*, zebrafish, etc.) [45.87]. Understanding the func-

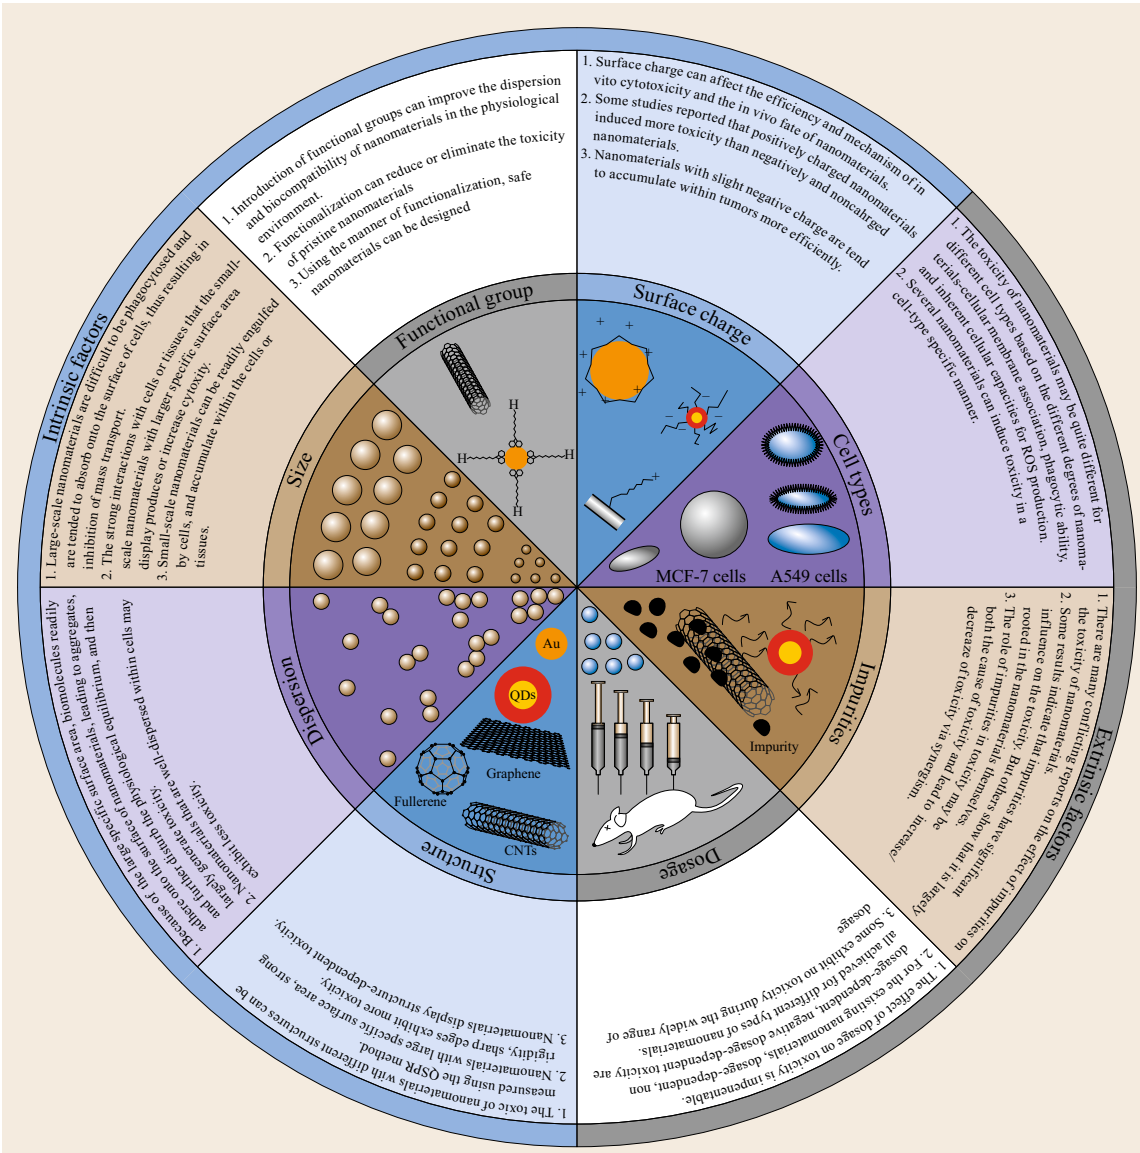

Fig. 45.7 Dominant factors influencing the toxicities of nanomaterials. They are classified into two categories: the intrinsic factors that mostly arise from the physicochemical properties of engineered nanoparticles (ENPs), and the extrinsic factors that include all other factors that can influence the toxic responses of NMs in experimental study or nanosafety assessment during real exposure scenarios (after [45.87])

tions of various physicochemical characteristics of NPs would facilitate the intended design of products with minimized EHS impacts in the future.

45.3.1 Particle Size and Surface Area

Particle size is a critical parameter in NM EHS impacts, which generally leads to the arising of other intrinsic factors. Particle size usually refers to the individual particle, not the agglomeration or aggregated ones which form during production, application, release, and disposal processes. As NM size decreases, the surface area/mass ratio exponentially increases and more atoms are displayed on the particle surface compared with the bulk material. The decreased particle size and increased surface areas make the NM surfaces more reactive to the surrounding biological components. Therefore, chemical reactions including catalytic

Table 45.2 Comparison of the physicochemical characteristics that dominate the toxic responses of nanomaterials with the bulk materials

	...

reactions and redox reactions may occur at the surface of NPs causing the formation of ROS (such as superoxide anions or hydrogen peroxide) and subsequently oxidizing other interacting biomolecules. Many studies have indicated that a small size can increase toxic effects compared to the bulk counterpart [45.89–92]. The particle size influences cellular uptake in vitro, i. e., large latex spheres (>200 nm) had a slower uptake and processing ability compared to smaller ones (50 and 100 nm) [45.93]. In a well-known in vivo study example, inhalation of ultrafine TiO_2 particles (20 nm diameter, 12 week) showed significantly prolonged retention and more inflammation in lung than the inhalation of fine TiO_2 particles (250 nm diameter, 12 week) [45.94]. This means that the physicochemical characteristics of size and surface area have dominant roles in determining toxic potential when NPs interact with organisms.

45.3.2 Nanostructure and Shape

Engineered nanoparticles (ENPs) may exhibit various shapes and structures, e.g., spheres, needles, tubes, rods, etc. For example, CNTs exist as either SWCNTs which are graphite sheets rolled to form a seamless cylinder, or MWCNTs that have many cylinders stacked one inside the other. Similar to CNTs, fullerenes are carbon allotropes composed entirely of carbon, but they are different in form, e.g., hollow sphere, ellipsoid. One representative fullerene is C_{60}. CNTs and fullerenes have various uses based on their novel physicochemical characteristics, e.g., in the biomedical field of bioimaging and therapy [45.95]. However, typically they have poor solubility and are difficult to manipulate in solvents or physiological solutions like serum, which influences their toxicity, metabolism kinetics, and biomedical functions [45.23]. One in vitro study showed that SWCNTs, MWCNTs, and C_{60} exhibit quite different cytotoxicity to alveolar macrophages, although they all represent carbon materials (Fig. 45.8). The comparative toxicities illustrated the following sequence on a mass basis: SWCNTs > MWCNT (with diameters ranging from 10 to 20 nm) > C_{60} [45.96]. CNTs with different lengths contribute to obviously different lung fibrosis potential after inhalation exposure [45.28]. Further evidence showed that short-length MWCNTs not only had lower toxicity but also higher cellular uptake and more obvious removal ability compared to longer versions, which can result in the higher promotion of PC12 cell differentiation [45.98]. This means that the cytotoxicity and even the bioeffects of different carbon nanomaterials in vitro are highly dependent on their nanostructures. In more research from our lab, it was shown that anatase TiO_2 particles had a much higher toxicity than rutile ones on the central nervous system [45.99]. The shape of nanoparticles is another important factor that directly affects cellular uptake. For example, it was shown that longer Au nanorods had much less cellular uptake when compared to shorter

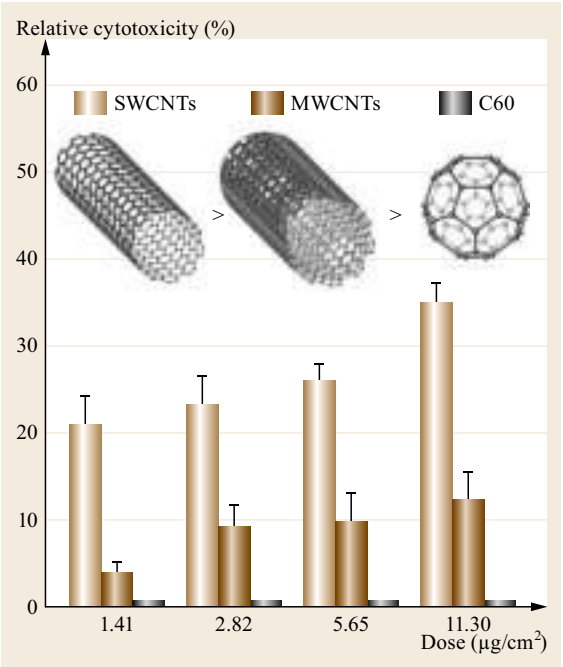

Fig. 45.8 The ranking of cytotoxicity of carbon NMs on a mass basis is: SWCNTs > MWCNTs > C_{60}. Reproduced with permission from reference [45.96]

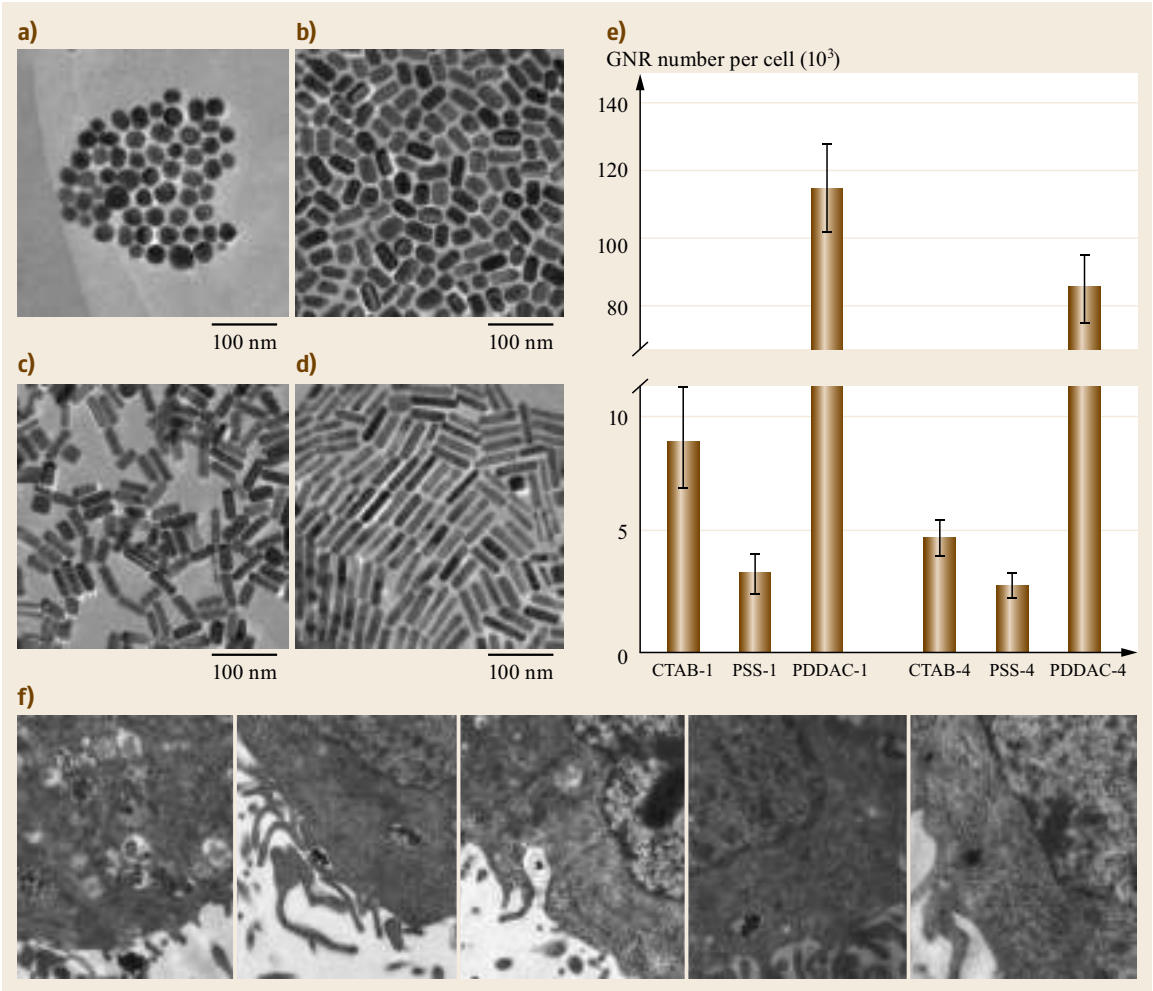

Fig. 45.9a–f Shape and surface-coating determine cellular uptake of Au nanoparticles in Michigan Cancer Foundation-7 (MCF-7) cells. ones, with similar particle surface charges used in the test (Fig. 45.9) [45.24, 97]. Spherical Au nanoparticles entered cells more easily than rod-shaped nanoparticles which may be because a longer membrane wrapping time is required for the rod-shaped particles [45.97].

45.3.3 Agglomeration and Aggregation

NPs have higher surface activity compared to larger sized versions of the same chemical composition. On this basis, the increased surface size also has a strong tendency for agglomeration/aggregation. An agglomeration is a collection of particles that are loosely bound together by relatively weak forces, including van der Waals forces, electrostatic forces, simple physical entanglement, and surface tension, with a resulting external surface area similar to the sum of the surface area of the individual components. Aggregated particles are a cohesive mass consisting of particulate subunits tightly bound by covalent or metallic bonds due to a surface reconstruction, often through melting or annealing of the surface, and often having an external surface area significantly smaller than the sum of the surface areas of the individual components. Agglomerates may be reversible under certain chemical/biological conditions whereas an aggregate

will not easily release primary particles under normal conditions [45.100]. Particulate matter in the air may come from release during the ENM production process. It usually represents a highly complex mixture of particles with different sizes. Field research showed that airborne NMs in occupational settings are mostly 200 to 400 and 2000 to 3000 nm in diameter [45.101, 102]. However, in some special environments such as metal processing, burning, photocopying or printing, and nanomaterial handling processes, the nanopeak of the aerosol is still extremely prominent [45.103–106]. The NMs in the air easily form agglomerates, which influences absorption in the organism after deposition in the inhalation system. The exact deposition dosages of differently sized particles could be estimated by the multiple path particle dosimetry (MPPD) model which was developed for estimating dose in the lower respiratory tract based on particle sizes [45.107, 108]. Toxic effects within the body are usually dominated by the NM agglomeration situation. It has been reported in mice that temporary organ injury occurs in lung and liver due to delayed clearance of agglomerated MWCNTs, while well-dispersed forms were easily eliminated from these organs [45.109]. Similarly, highly agglomerated SWCNTs cause more serious toxic effects on glial cells in both the peripheral nervous system and central nervous system compared with better dispersed SWCNTs [45.110]. In the estimation of the EHS impacts of NMs, the extent of agglomeration/aggregation should be taken into account and thoroughly investigated.

45.3.4 Chemical Composition, Purity, and Impurities

The chemical composition, also defined as elemental composition and chemical structure, is an intrinsic property of all materials. In the development of nanotechnology we see tremendously different NM chemical compositions. Roughly, there are four categories of NMs based on their chemical composition:

1. Carbon nanomaterials (e.g., carbon nanotubes, nanowires, nanocantilevers, graphene, and fullerenes)
2. Metallic and metallic oxide materials (e.g., gold or silver nanoparticles, magnetic nanoparticles, QDs, titanium dioxide, and iron oxide)
3. Silicon nanomaterials (silicon or silica nanoparticles)
4. Organic nanomaterials (e.g., DNA, polymers, polymeric micelles, liposomes, or nanoparticles prepared from polymers or lipids).

Some NMs are a hybrid of different compositions, with the various characteristics used to advantage in the final product. Recently, high content screening (HCS), a cell-based multiparametric image analysis technique, was adopted in the evaluation of eight different compositions of NMs [45.77]. It was found that Ag and ZnO NMs possessed much higher cytotoxicity to 16HBE cells than SiO_2, TiO_2, and CeO_2 based on the same mass level [45.77]. Impurities are inevitable in ENMs, and this needs to be considered when implementing the risk assessment. Raw nanotubes especially those in commercial products usually contain significant impurities, such as inert synthesis supports (silica, alumina) and metal catalysts (iron, cobalt, nickel), derived from the large-scale production procedures, postfabrication and postpurification treatments. Much evidence has shown that the impurities in NMs contribute greatly to increased toxicity through induction of oxidative stress [45.111–113].

45.3.5 Coating, Surface Modification, and Surface Charges

Coating and surface modifications of nanoparticles play an essential role in control of the physicochemical and surface properties of NMs. By employing these techniques, scientists can reduce material toxicity, increase solubility, enhance biocompatibility, and prevent aggregation of NMs in solution or in the air [45.114]. It was indicated that conventional hydrophobic fullerenes and the surface-modified hydrophilic ones have significant differences in terms of toxicity and biological functions [45.115, 116]. We investigated the influence of surface coatings on the cellular uptake and the cytotoxicity of gold nanorods, and found that the cellular uptake of Au NRs is highly dependent on the surface chemistry, as evidenced by poly (diallyldimethyl ammonium chloride) (PPDDAC)-coated Au nanorods exhibiting a much greater ability to be internalized by the cells compared to poly-sodium-*p*-styrenesulfate (PSS) and Cetyltrimethylammonium bromide (CTAB)-coated ones (Fig. 45.9e) [45.97, 117]. In nanotechnology, various nanosynthesis and nanofabrication methods have been applied to the NMs in order to obtain particular characteristics. However, the positive intention of NM modification may lead to unintended side effects, which in turn leads to alarm bells concerning possibly damaging health effects including poor biocompatibility, and acute and chronic toxicity. Surface charge, which can be manipulated by surface modification, is one of the most important factors in relation to the biological functions of nanoparticles. In contrast to neutral and negatively charged nanoparticles, positively charged particles can lead to the most efficient cell membrane penetration and cellular internalization because of their effective binding to negatively charged groups on the cell surface [45.118]. Fluorescent polystyrene (PS) particles

are good research objects to study the intercellular dynamics of allogenic materials in cell models. We investigated the effects of negatively charged carboxylated polystyrene (COOH-PS) and positively charged amino-modified polystyrene (NH_2-PS) nanoparticles with three different diameters (50, 100, and 500 nm) on cancer HeLa cells and normal NIH 3T3 cells during cell cycles. It was disclosed that the PS nanoparticles maintain a distance from the spindle and the chromosomes during the whole mitosis. They were never found to be associated with any components of the mitotic apparatus and no abnormal cell division was detected after their internalization. In addition, no abnormal daughter cells were detected. The data showed that the PS nanoparticles do not influence mitosis which is highly conserved in mammal cells in both normal and cancer cells [45.119].

Besides the aforementioned physicochemical characteristics, there are other factors, as listed in Table 45.2, that may have an influence on toxic impacts on EHS. Because of this situation the toxicity assessment of NMs is usually highly complex with sometimes even fragmentary and contradictory conclusions obtained from various sources [45.120]. Scientists have to face this difficulty and consider characterizing NMs in detail using state-of-the-art nanotechnologies.

45.4 Novel Techniques and Biomarker Development in Nanotoxicology

45.4.1 The Development of Biomarkers for Evaluation of EHS Impacts

The discovery of NM toxicity mechanisms could contribute a series of biomarkers for assessment of EHS impacts. Herein, biomarker is defined as key molecular or cellular events that have a direct link to health outcomes after exposure to NMs. It is highly feasible to fit developed biomarkers with in vitro cell model testing during risk assessment of EHP impacts due to the low costs, lack of an ethical animal abuse issue, and the high-efficiency of testing procedures [45.121]. This is in accordance with the strategy suggested by the US Environmental Protection Agency (EPA) and the National Research Council (NRC): cellular response or adverse outcome pathway (AOP)-based toxicity testing for adverse health effect evaluation should be the preferred toxicity testing strategy in the 21st century [45.122, 123]. Further, the in vitro testing techniques based on the biomakers of AOP generally provide more sensitive hazard identification than those detection methods using the endpoints of toxic effects when considering either the time or dose factors.

For the ENMs most investigated in nanotoxicology research, it is generally accepted that high NM surface area represents high ROS-generating capability which causes oxidative stress in biological systems after nano–bio interactions [45.124]. The high ROS level in the organism leads to the negative effects of the depletion of cellular antioxidants and accumulation of peroxidized lipids [45.25, 125]. In relation to these earlier inducing events, various markers at different tiers can be used in the assessment of EHS impacts of NMs along with the development of toxicity outcomes (Fig. 45.10).

Wang et al. [45.28] showed that MWCNTs could directly activate TGF-β/Smad2 signaling in fibroblasts or epithelial cells with the consequences of inducing the fibroblast-to-myofibroblast transition and EMT, both of which contribute to CNT-induced fibrotic responses. Therefore, it is suggested that TGF-β and the TGF-β receptor signaling system could be considered as potential biomarkers in the risk evaluation of CNTs. Attributed to the same carbon nanomaterial, graphene seems to induce toxicity through a similar mechanism. *Li* et al. [45.126] showed that the signaling pathways of both mitogen-activated protein kinase (MAPK) and TGF-β were activated and resulted in the downstream Bcl-2 protein family initiating mitochondrial-related apoptosis after incubation of the graphene in the RAW 264.7 macrophage cell line. Furthermore, p38 mitogen-activated protein kinase (p38 MAPK), extracellular signal-regulated kinase (ERK), and c-Jun N-terminal kinase (JNK) were significantly upregulated. Similar to the CNT exposure, the stimulated transcription activity of the Smad proteins verified that TGF-β was also found to be activated by graphene. As a result, Bim and Bax were significantly upregulated with the consequences of causing permeabilization of the mitochondrial outer membrane and the release of mitochondrial proapoptotic factors into the cytosol. These results indicate that graphene and CNTs could induce ROS production and trigger the mitochondrial apoptotic pathway, thus leading to apoptosis.

The endoplasmic reticulum (ER) stress and interruption of the aforementioned mitochondria metabolic signaling pathways has been fully investigated in the evaluation of EHS impacts [45.56, 81, 127–131]. ER stress, also known as unfolded protein response (UPR), is an important cellular self-protection mechanism that could be used as an early biomarker for evaluating the toxicity of NMs [45.81]. Toxicity initiates as the adaptation response and ends with toxicity formed after an

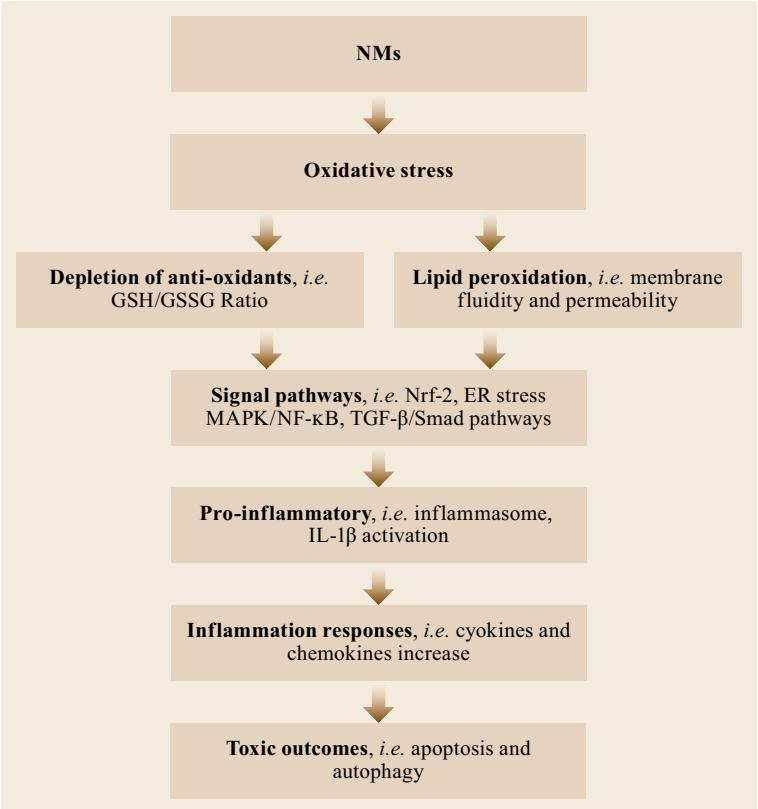

Fig. 45.10 Toxicity mechanisms of NMs and proposed biomarkers in assessment of EHS impacts

exposure dosage higher than the physiological threshold of the cellular self-protection capacity. The ER stress responses contain three dominant stress sensors that include inositol-requiring protein 1 (IRE1), PKR-like endoplasmic reticulum kinase (PERK), and activating transcription factor-6 (ATF-6). The ER-chaperone protein 78 kDa glucose-regulated protein (GRP78), or called binding immunoglobulin protein (BiP), binds these three stress sensors in the normal state, and in its active state releases them when stress occurs. IRE1, which functions as an endoribonuclease, initiates the splicing of x-box binding protein 1 (xbp-1) mRNA after activation. Then, the newly produced spliced form of *xbp-1* (*xbp-1s*) induces the transcription of chaperone protein-encoding genes for self-protection functions (Fig. 45.11). The *xbp-1* splicing and induction of BiP and C/EBP homologous protein (CHOP) have been identified as the specific biomarkers of ER stress responses [45.81, 132]. It is worth noting that ER stress, as a sensitive earlier biomarker, could be used to define the lowest observable effect concentrations (LOEC) in cell and animal models for predesigned safe applications of ENMs [45.77].

High-throughput screening (HTS) techniques and modeling based on QSAR should be developed for analysis of potential EHS hazards from NMs especially when handling NMs with exceedingly variable physicochemical characteristics [45.86, 133]. HTS techniques hold great potential, enabling faster and more reproducible toxicity testing for basic NMs as well as other nanorelated EHS samples. QSAR generally has a close relation to the application of various HTS methods. Therefore, researchers can predict a wide range of properties, including biological activities and toxicities, for new materials using QSAR models; this process depends entirely on the initial input data generated from HTS detection methods. Thus, this predictive toxicological approach will finally aid the design or optimization of NPs with commercially useful properties that are also safe to humans and the environment. Recently, *Le* et al. [45.86] developed QSAR models linking nanoparticle properties to cell viability, membrane integrity, and oxidative stress based on the testing data of 45 types of ZnO nanoparticles with varying particle sizes, aspect ratios, doping types, doping concentrations, and surface coatings. It was found that influencing factors such as the concentrations of NPs the cells are exposed to, the type of surface coating, the nature and extent of doping, and the aspect ratio of the particles provide significant contributions to the cellular toxicity of the NPs. These

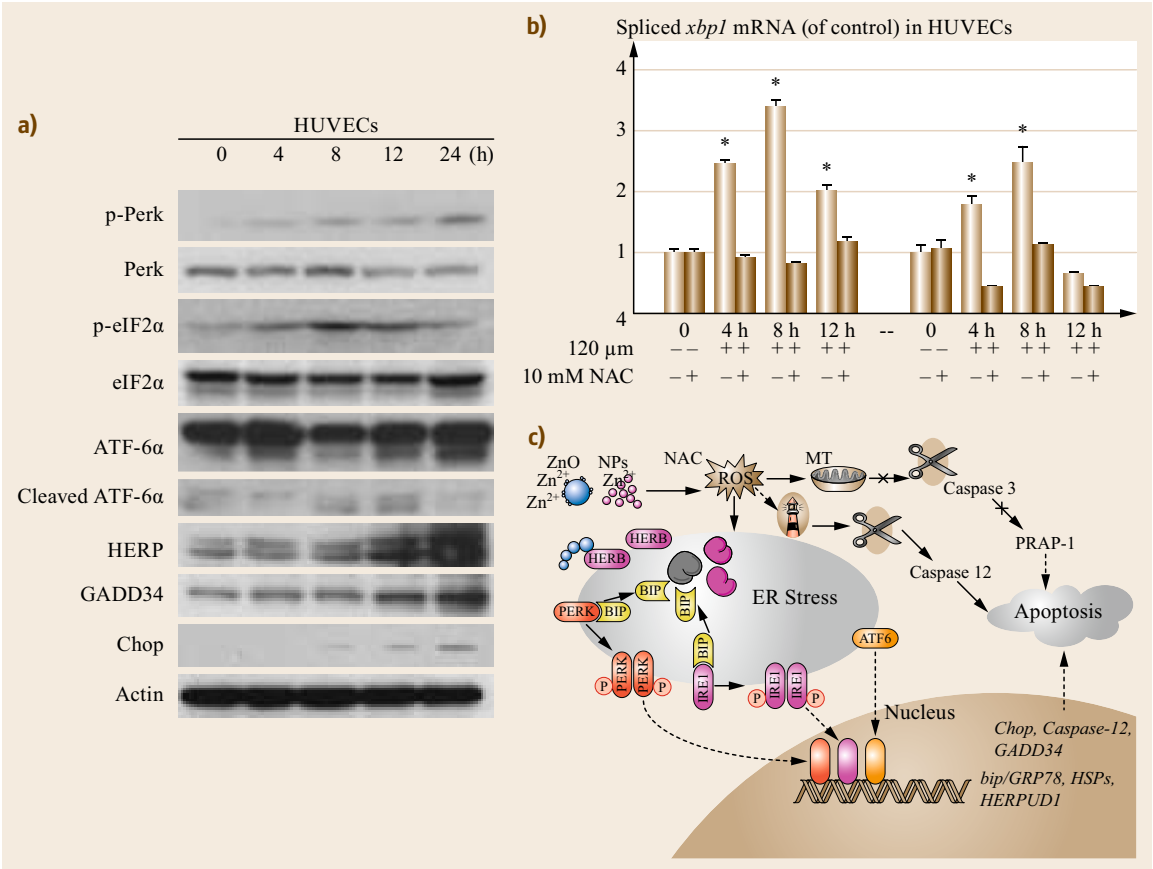

Fig. 45.11 Endoplasmic reticulum (ER) stress is an earlier biomarker for assessment of EHS impacts. **(a)** Western blotting analysis of ER stress-related proteins after exposure in human umbilical vein endothelial cells (HUVEC) at 240 μM. Reprinted with permission from [45.81] copyright 2014 American Chemical Society. **(b)** The PCR detection of spliced *xbp-1* was used for the detection of ER stress response in HUVECs after exposures to ZnO NP and zinc ions. The antioxidant (NAC, *N*-acetyl-cysteine) was used as antioxidant to abolish the ROS accumulation in cells. **(c)** The proposed mechanism for the activation of ER stress pathway after exposure to ZnO NPs

valuable strategies and techniques will promote the development of novel pathway mechanism-based in vitro approaches for assessment of EHS impact of NMs and risk assessment of influences on humans or contamination of ecosystems.

45.4.2 Novel Techniques Used for ADME Study in Nanotoxicology

After they are released and distributed, NMs generally appear as trace elements in biological and environmental science samples. The knowledge about ADME of NMs has high relations to the following evaluations of their EHS impacts. Nuclear analytical techniques (NATs) play important roles in facing the challenges in nanotoxicology [45.134–136]. NATs are a collection of techniques that deal with nuclear excitations, nuclear reactions, electron inner shell excitations, and/or radioactive decay. Typically, they have the advantages of absolute quantification, high sensitivity, excellent accuracy and precision, low matrix effects, and non-destructiveness in analytical applications [45.137, 138]. NATs mostly focus on the analysis of parameters in the samples e.g., nuclear mass, spin and magnetic moment, and excited states. Their application in nanotoxicology have been well summarized in the literature [45.134]. At the molecular level, synchrotron radiation circular dichroism spectroscopy (SRCD), x-ray absorption fine structure (XAFS), circular dichroism spectroscopy (CS), and AFM can be applied to characterize nanomaterials and analyze bio–nano interactions (Fig. 45.12). The cellular visualization of nanoparticles and the study of their transformation within the cell can be achieved through confocal laser scanning mi-

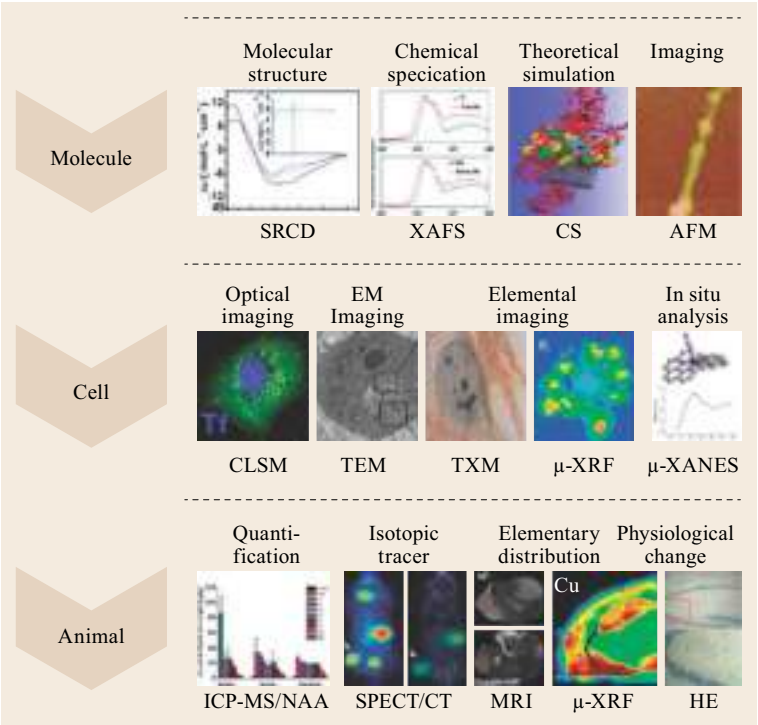

Fig. 45.12 Systematic platform using integrated advanced nuclear techniques for nanotoxicology. Adapted from [45.134] with permission from the Royal Society of Chemistry

croscopy (CLSM), TEM, scanning transmission x-ray microscopy (TXM), x-ray fluorescence (μ-XRF), and x-ray absorption near-edge structure (μ-XANES). Several approaches can execute in vivo ADME analysis: neutron activation analysis (NAA), ICP-MS (inductively coupled plasma mass spectrometry), inductively coupled plasma optical emission spectroscopy (ICP-OES), isotopic tracing (IT), single-photon emission computed tomography (SPECT), positron emission tomography (PET), x-ray computed tomography (CT), magnetic resonance imaging (MRI), fluorescence imaging, and photoacoustic imaging. The NAA, ICP-MS, ICP-OES, and IT techniques require the sacrificing of animals to obtain quantitative information on the NMs. SPECT, PET, x-ray CT, and MRI can show the whole body distribution of nanoparticles directly, while their quantification capabilities are limited. Fluorescence and photoacoustic-based methods have their own unique advantages in some scenarios of in vivo imaging, but the penetration depths are limited due to the limited penetration capability of light and sound compared to x-rays or γ-rays [45.139]. In recent research using the XANES technique, it was disclosed that disulfide bonds in BSA change into Au–S bonds quantitatively on the binding sites of BSA and Au nanorods. At the same time, a stable plane was found for gold–sulfur interaction supported by molecular dynamic simulation [45.140]. Further, the XANES technique has the ability to dissect the chemical transformation of metal NMs in biological systems. For example, it is known that silver NPs can be internalized by cells and degraded inside lysosomes, but how the cytotoxicity developed during the degradation process is unknown. Silver k-edge XANES clearly indicated that intracellular silver can be transformed from elemental Ag to a silver-sulfur (Ag−S−) form which played the dominant role in cytotoxicity [45.141]. XRF imaging is a powerful tool for elemental imaging in biological samples of cells and tissues. It is feasible to combine XRF imaging with XANES for analysis of the same sample. For example, this combined strategy has been used to study the distribution of Se when the worm *C. elegans* engulfs CdSe QDs. XRF imaging showed the locations of accumulation and distribution of Se, while Se k-edge XANES indicated the change in Se chemical forms in different body regions. This combined analysis can provide more accurate information on NMs than the more generally used fluorescence-based optical imaging [45.63]. There are two kinds of TXM, soft x-ray TXM and hard x-ray TXM (Nano-CT). The former can distinguish the NMs and organelles and is suitable for imaging a local region inside a cell due to the small x-ray penetration depth ($\approx 5\,\mu m$) [45.142]. While the latter, Nano-CT, can provide a much wider imaging field in a single cell ($\approx 2-50\,\mu m$) which could be used for three-dimensional (3-D) imaging of the con-

Table 45.3 Nuclear analytical and related techniques for physicochemical characterization, chemical element imaging, quantification, and speciation in nanotoxicological studies. Reproduced with permission from reference [45.134]

Techniques	Exciting radiation	Particle emission	Depth information	Spatial resolution	Detection limit	Chemical structure	Quantitative analysis	Imaging	Materials	Availability	Matrix effects
NAA	Thermal neutrons	Alpha, electrons, neutrons, and x-ray photons	None	None	0.001–0.1 ppm	No	Yes, 2–10%	No	Solids and liquids	Very rare	Less
ICP-MS	Plasma	Ions	None	None	0.00001–10 ppm	Little	Yes, high precision with isotope dilution	No, imaging by LA	Solution	Common	Yes, severe
SIMS	Ions, atoms for FABMS	Secondary ions	3–10 nm	0.02 μm best, 1–5 μm typical	0.1–10 ppm	Some chemical bonds	Yes, to 25% relative error	Yes	Any solid, some liquids	Relatively uncommon	Yes
XRD	x-ray tube or synchrotron x-rays	Diffracted x-rays	None	50 nm–10 μm synchrotron x-rays	1–5% mixtures	Yes, species identity and structure	Yes, to 5–10%	No	Crystalline solids and polymers	Common	Yes
XAS	Synchrotron and some rotating anode x-ray sources	Transmitted or characteristic x-rays	Yes	50 nm synchrotron x-rays	100 ppm	Yes	No	No	Solids and nonvolatile liquids	Rare, at synchrotron facilities	Yes

Table 45.3 (continued)

Techniques	Exciting radiation	Particle emission	Depth information	Spatial resolution	Detection limit	Chemical structure	Quantitative analysis	Imaging	Materials	Availability	Matrix effects
XRF	x-ray tube, synchrotron x-rays	Characteristic x-rays	None	50 nm–10 μm synchrotron x-rays	0.1—10 ppm (≈ synchrotron mg kg^{-1}) x-ray	No	Yes, high precision	Yes	Solids and nonvolatile liquids	XRF common, XRF Mapping only at synchrotron facilities	Yes
EDX	Electron	Characteristic x-ray photons	0.5—5 μm, depends on matrix	2 nm–5 μm, depends on matrix	100–1000 ppm	No	Yes, relative error	No	Any solid	Moderately common	Yes
EELS	Electron	Characteristic electron energy loss		1 nm	1000 ppm	Yes	Yes	No	Any solid	Moderately common	Yes
PIXE	Protons	Characteristic x-ray photons	None	2 μm–20 mm	0.1—10 ppm	No	Yes, 5%	Yes	Any solid	Rare	Yes
Isotopic tracing		Radioactive: α, β, γ-rays and stable isotopes	No		10^{-4}–10^{-8} g	No	Yes	Yes	Any solid	Common	No
PET	Positron	γ-ray	Yes	1 mm	100 ppt	No	Yes	Yes	Any solid	Common	No
SPECT	Single-photon	γ-ray	Yes	1 mm	100 ppt	No	Yes	Yes	Any solid	Common	No

struction of metal NMs [45.141]. Soft x-ray TXM also has its own powerful applications for the analysis of specific elements like Ce in CeO_2 NPs or Gd in Gd-metallofullerenol [45.143, 144]. The characteristics of the whole list of NATs and related techniques are provided in Table 45.3.

45.5 Conclusion and Perspectives

EHS impacts related to nanotechnology were investigated in this chapter. It is obvious that the presence and release of nanoparticles into the environment has important implications for human health and the environment. Scientists should not only focus on the beneficial effects of NPs, but also need to be careful in regard to possible adverse impacts on EHS. Particle attributes such as size, agglomeration or aggregation, composition, structure, coating, and purity are important for the determination of potential impacts on EHS, although they are generally quite complicated. State-of-the-art analysis methods and techniques should be used and developed for the gradually emerging challenges. Such techniques and biomarkers will have meaningful utilization in the protection of human populations, especially in the case of occupational exposure, and in regard to the total ecosystem. As the mechanisms of nanotoxicity and ecotoxicity are still poorly understood, the study of such EHS impacts through NMs definitely needs the input of greater resources. Both researchers and authorities should strive for a sound balance between the development of nanotechnology and the scientific evaluation of EHS impacts in order to achieve a sustainable and harmonious development of nanotechnology.

46. Nanoscience and Nanotechnology Convergence

William S. Bainbridge

A series of major conferences that emerged from the National Nanotechnology Initiative explored connections to other fields of science and engineering, resulting after 15 years in a comprehensive vision of how science, technology, and society could converge. One of two initial orientations focused on the human and ethical implications of nanotechnology, thus connecting nanoscience to the social sciences. The other considered the current partnership and possible future unification of four NBIC domains: Nanotechnology, Biotechnology, Information technology, and new technologies based in Cognitive science. Most recently, the extensive series of book-length conference reports has led to a comprehensive overview, *Handbook of Science and Technology Convergence*, that outlines concepts, research methods, and educational approaches across four *platforms* that comprehensively define the world in which humans live:

1. Foundational technologies
2. Human-scale phenomena
3. The Earth-scale system
4. Societal-scale implications.

46.1 Background

It should be obvious to anyone that nanoscience and nanotechnology can and should be integrated with several other fields of science and engineering, especially to develop new and better solutions for human problems. Atoms are smaller than the nanoscale, and living cells are larger, yet both physics and microbiology concern phenomenon that operate across the nanoscale. Several components of computer electronics are small enough to qualify as nanotechnology, and the flows of electrons inside semiconductors cover a range of distances. Nanoscale particles and layers on manufactured objects contribute to technologies on a wide variety of scales. More broadly, every human-significant application of nanotechnology requires some kind of collaboration with at least one other technical discipline. As obvious as these points are, it is not clear what general principles can guide collaboration across disciplinary boundaries, and what concerted efforts may be needed to maximize the contributions of nanoscience and nanotechnology to human society.

46.1.1 The Convergence Social Movement

At the beginning of the current century, a key leader of the nanotechnology movement, Mihail C. Roco, envisioned a vast intellectual and social transformation he called *convergence*. He was the first chairman of the Nanoscale Science, Engineering, and Technology (NSET) subcommittee of the National Science and Technology Council, and currently serves as senior

advisor for Science and Engineering at the National Science Foundation (NSF), two very influential positions in the United States government. With support from several specific NSF programs and other government agencies, he launched a pair of conference sequences that eventually merged together, to chart the goals and means for transformation of science, technology, and society through convergence, building outward from the nanoscale.

The first effort focused on *societal implications*, a theme that was built into the National Nanotechnology Initiative (NNI) from its very beginning [46.1, p. 2]:

> *The NNI is balanced across five broad activities: fundamental research; grand challenges; centers and networks of excellence; research infrastructure; and societal/workforce implications. Under this last activity, nanotechnology's effect on society – legal, ethical, social, economic, and workforce preparation – will be studied to help identify potential concerns and ways to address them. As the NNI is commencing, there is* a rare opportunity to integrate the societal studies and dialogues from the very beginning and to include societal studies as a core part of the NNI investment strategy.

Perhaps because of the substantive connections to biomedical research, or the naive and often sinister early representations of nanotechnology by science fiction writers, from the very beginning it was clear that researchers in this field needed to set high ethical standards. That could require consultations with philosophers of ethics, as well as intensive discussions within the field. But the NNI went further, concluding that the social sciences also needed to be involved. Every new technology has costs as well as benefits, both direct and indirect, so clearly economics has a role to play. As the goal is to achieve benefits for society as a whole, other social sciences also have their distinctive roles to play, most obviously sociology but also cultural anthropology and political science. This need not retard progress through excessive regulation, although on occasion government may need to draw upon social science to set priorities, favoring one technical approach over another. Hopefully, there will be many occasions when the social sciences document how nanotechnology can contribute to societal progress, in ways that encourage greater public investment.

The second effort concerned *converging technologies*, the mutually supportive integration of multiple technical fields. Since the starting point was nanotechnology, the obvious initial partners were biotechnology and information technology, but Roco was convinced that a fourth component was equally necessary, new technologies based on the discoveries of cognitive science. Given that nanoscientists are human beings, and their research instruments typically involve electronic data collection and analysis, all three of the other fields support nanoscale research. Put simply, their brains are biological versions of computers, and both their brains and their nonbiological instrumentation must follow sound cognitive principles. Thus, Roco's initial conception of converging technologies began with these four *NBIC* fields: Nanotechnology, Biotechnology, Information technology, and new technologies based on Cognitive science. But unification was really provided by a very fundamental conception of human discovery and invention [46.2, p. ix]:

> *Convergence of diverse technologies is based on material unity at the nanoscale and on technology integration from that scale. The building blocks of matter that are fundamental to all sciences originate at the nanoscale. Revolutionary advances at the interfaces between previously separate fields of science and technology are ready to create key transforming tools for NBIC technologies. Developments in systems approaches, mathematics, and computation in conjunction with NBIC allow us for the first time to understand the natural world, human society, and scientific research as closely coupled complex, hierarchical systems. At this moment in the evolution of technical achievement, improvement of human performance through integration of technologies becomes possible.*
>
> *Examples of payoffs may include improving work efficiency and learning, enhancing individual sensory and cognitive capabilities, revolutionary changes in healthcare, improving both individual and group creativity, highly effective communication techniques including brain-to-brain interaction, perfecting human–machine interfaces including neuromorphic engineering, sustainable and intelligent environments including neuroergonomics, enhancing human capabilities for defense purposes, reaching sustainable development using NBIC tools, and ameliorating the physical and cognitive decline that is common to the aging mind.*

46.1.2 The Convergence Conferences

For each of these two parallel efforts, a number of planning meetings were held at the National Science Foundation in Arlington, Virginia. The first societal implications conference was held there September 28–29, 2000, and the first converging technologies conference, December 3–4, 2001. Table 46.1 outlines the sequence of conferences, along with the numbers of scientists,

Table 46.1 Societal implications and converging technologies conferences

Conference	Location	Year	Contributors
Societal Implications of Nanoscience and Nanotechnology	Arlington, Virginia	2000	64
Converging Technologies for Improving Human Performance	Arlington, Virginia	2001	79
Nanotechnology: Societal Implications – Maximizing Benefits for Humanity	Arlington, Virginia	2003	130
The Coevolution of Human Potential and Converging Technologies	Los Angeles, California	2003	28
Managing Nano-Bio-Info-Cogno Innovations: Converging Technologies in Society	New York City	2004	34
Progress in Convergence: Technologies for Human Wellbeing	Kailua-Kona, Hawaii	2005	31
Convergence of Knowledge, Technology and Society: Beyond Nano-Bio-Info-Cognitive Technologies	São Paulo, Brazil; Arlington, Virginia; Leuven, Belgium; Seoul, Korea; Beijing, China; again Arlington, Virginia	2011–2012	312
Handbook of Science and Technology Convergence	online	2013–2015	76

engineers, and government leaders who contributed to each. These influential meetings occurred in two waves. The first ran from 2000–2005, with the last book-length reports being published in 2006, keeping the societal implications and converging technologies discussion largely separate from each other. The second wave ran 2011–2015 with the last book length report published in 2016, combining both major themes and providing a solid basis for considering the wider convergence of science, technology, and society.

The 2003 societal implications conference triggered an interesting debate, and is a good example of how the more complex conferences were designed. To what extent should a government agency give the impression that it agrees with especially visionary projections of future technologies and societal conditions? The obvious answer might be that government should always be cautious about associating itself in the public mind with any particular ideology, and some of the more stimulating products of futurology seem more like ideology than like objective science. Yet the future could be very different from the past, so unusual ideas should not be summarily dismissed, especially if they are proposed by brilliant and knowledgeable people. The government needs access to a wide range of perspectives, which it can then assess with care, and the general public deserves to be informed about these debates that may shape the future as well as imagine it.

At the same time, the individual contributors to all of the meetings not only represented a great diversity of intellectual traditions and forms of technical expertise, but also tended to have a diversity of personal styles. It is a mistake to imagine that rigorous science drains personality out of the equation. Thus, it was important to accord equal respect to all of the contributors, all of whom were remarkable people, even though the texts they wrote for the reports differed on every level, from vocabulary and grammar, up to optimism versus pessimism, and conservative versus radical. The practical solution to these challenges was to structure the published reports in different ways, most explicitly for the publications from the 2003 societal implications conference, but the others as well.

In 2005, the National Science Foundation and National Nanotechnology Coordination Office published a 106 page report, that summarized the deliberations of the conference, and served as a record of the events and group discussions. The first day of meetings began at noon, and served as an orientation, with three sets of presentations that followed a welcoming:

1. Considering nanotechnology as a national endeavor to achieve technological and economic goals, guided by a science and education vision
2. Identifying goals for the nanotechnology initiative, to benefit industry and society, and employing social science for assessing nanotechnology
3. Recognizing broader implications for the quality of life, aware of ethical issues, and intelligently navigating nanotechnology through society.

Prior to the gathering, each invited participant had selected or been assigned to two very different discussion groups, from a list of ten, for which they prepared brief contributions:

1. Productivity and equity
2. Future economic scenarios
3. The quality of life
4. Future social scenarios
5. Converging technologies

6. National security and space exploration
7. Ethics, governance, risk, and uncertainty
8. Public policy, legal, and international aspects
9. Interaction with the public
10. Education and human resource development.

On the morning of the second day, the participants divided into panels to discuss the first five topics from this list, and prepared outlines to share with all participants in a plenary session. In the afternoon, the same was done for the second five topics, with individuals working in very different combinations on the two halves of the day. The third and final day of the meeting was a combination of individual work and group sessions, to assemble a rough draft of a formal report. Thus, the very organization of this societal implications conference was an example of convergence.

After the meeting, on the basis of the collective report, individual participants and teams were invited to write up more detailed chapters, encouraged to be visionary as well as rigorous, and given considerable freedom to express their own perspectives. The final result was a two-volume publication, the group workshop report [46.3] and the collection of individual contributions [46.4]. This second volume assembled the chapters into a somewhat different set of seven aspects of societal implications of nanotechnology:

1. Socioeconomic impacts and commercialization of nanotechnology
2. Social scenarios
3. Converging technologies
4. Ethics and law
5. Governance
6. Public perceptions
7. Education.

While converging technologies was among the ten topics of the first report volume, and among the seven of the second, it really interwove across all the other topics. Thus, many analytical concepts relevant to convergence naturally were used extensively in the discussions, including these that were given formal definitions:

- *Converging technologies*: Unification of nanotechnology, biotechnology, information technology and cognitive technologies, based largely on the unity of nature at the nanoscale and on transforming tools for research and production.
- *Consilience*: Convergence of the natural sciences into one, unified body of knowledge.
- *Boundary work*: Effort invested in defining fields of activity, delineating the differences between concepts, and locating things in a socio-cultural context.
- *Diffusion*: The spread of a technical idea or other cultural element from one group, place, or application to another.
- *Interactional expertise*: The skill and experience required to pass information from one scientist to another, especially the ability to act as a cultural broker between significantly different fields.
- *Trading zone*: A metaphoric place, consisting of shared assumptions and terminology, where specialists from different fields can come together, communicate, and cooperate.
- *Co-evolution*: The simultaneous development of two different phenomena in interaction with each other, for example the emergence of nanotechnology coupled with the emergence of research on its societal implications.
- *Transilience*: In technology, a revolutionary leap that renders older technology obsolete, often involving convergence of technologies and a new relationship between producers and customers.
- *Disruptive technology*: New technologies that have the effect of changing the relations between existing organizations and institutions in society, often providing a net benefit even as some people may be harmed at least temporarily.
- *Cultural lag*: A maladjustment in the culture that comes about when rapid change in one area (such as technological innovation) is not immediately matched by concomitant change in other areas that are closely related to it.
- *Gap analysis*: A method of policy analysis that begins with a clear picture of a desired future state, compares it with the current state, and identifies actions that need to be taken to bridge the gap between them.

The three converging technologies conferences held in California, New York, and Hawaii were structured much more simply, as opportunities for leaders across the converging disciplines to present papers of great diversity but significant intellectual depth. After the wave of book publications in 2006, the NBIC community continued to be active, but chiefly through individual and informal efforts. Around the world, a number of scientific organizations and governments showed great interest, often conducting their own local conferences and research activities.

46.1.3 Parallel Activities in Europe

Already in 2004 a report for the European Commission applied this definition: *Converging technologies are enabling technologies and knowledge systems that enable each other in the pursuit of a common goal* and observed [46.5, p. 14]:

> *Conceptually, nanotechnology enables other technologies by providing a common framework for all hardware-level engineering problems. Everything that consists of molecules can, in principle, be integrated with each other. An understanding of properties at the nanoscale allows for the realization of desirable architectures at the micro- and macroscale. Instrumentally, nanotechnology enables biotechnology by developing new imaging techniques, probes and sensors. It contributes to the miniaturization demands of information technology. Also, nanochips and nanosensors are set to enable advances in the new world of bioinformatics.*

Over a period of years, European academic and government agencies developed a perspective complementary to, but somewhat different from the NBIC conceptualization, which seemed distinctively American to them, as expressed in a 2008 report [46.6, pp. II–IV]:

> *... the European concept of Converging Technologies for the European Knowledge Society (CTEKS) adopts a demand-driven approach in which CT respond to societal needs and demands. A major theme in both the US and European approaches is cooperation between the disciplines: the European approach makes a special issue of interdisciplinary cooperation and its specific conditions and problems, whereas the US approach argues for a new unity of science underpinned by reductionism enabled by the possibility of tracking virtually everything down to the nano-level.*
>
> *... both the NBIC and the CTEKS concepts devote much attention to issues of cooperation between scientific disciplines to realize applications of CT. While the NBIC initiative argues for underpinning cooperation through a base of common knowledge at the nano-level, the CTEKS concept argues for strong interdisciplinary cooperation including both hard sciences and social sciences.*

For a time there seemed to be a real difference of emphasis between the American and European approaches, with the Europeans raising a greater variety of ethical concerns, while at the same time suggesting that governments should set priorities to invest heavily in those areas of converging technologies that might be most beneficial for human beings. However, there may not have really been much trans-Atlantic difference of opinion among the scientists and engineers who were involved, rather in the political cultures of their different nations. While the Europeans suggested that converging technologies needed more collaboration with social scientists, in fact social science had been centrally involved in both the societal implications and converging technologies strands of the American effort. For decades, socialist parties had been influential in European politics, with a natural inclination to encourage social science as a tool of government policy, while over the decades a powerful trend in American politics had attempted to end government funding of social science research altogether [46.7]. Near the beginning of its second decade, the converging technologies movement sought to achieve greater convergence within itself and with society.

46.2 Convergence with Society

Even within the American wing of the Converging Technologies movement, social science had played an important role from the very beginning, although not officially becoming one of the government priorities [46.8]. When it came time for an assessment of progress after the first decade, however, it was clear not only that the social sciences should be central to many future efforts, but that convergence should expand to encompass a union of science, technology, and society. Indeed, when Mihail Roco launched a new series of international conferences, he called it *Convergence of Knowledge, Technology, and Society*, including science within the definition of *knowledge* but recognizing that humanities such as history and many less formal fields of human knowledge must also be included. The subtitle of the rather large resulting report was explicitly *Beyond Convergence of Nano-Bio-Info-Cognitive Technologies*, and the introductory paragraph set out an ambitious agenda [46.9, p. xiii]:

> *Convergence of Knowledge and Technology for the Benefit of Society (CKTS) is the core opportunity for progress in the 21st century. It is defined in this study as the escalating and transformative*

interaction among seemingly distinct scientific disciplines, technologies, communities, and domains of human activity to achieve mutual compatibility, synergism, and integration, and through this process to create added value and branch out into emerging areas to meet shared goals. Convergence is as essential to our future knowledge society as engines were to the industrial revolution. CKTS allows society to answer questions and resolve problems that isolated capabilities cannot, as well as to create new competencies, technologies, and knowledge on this basis. This concept is centered on the principles presented in this report: of interdependence in nature and society with application to the essential platforms of the human activity system; the enhancement of creativity and innovation within knowledge and technology through convergence–divergence (spin-off) evolutionary processes; a holistic system deduction approach being applied in decision analysis; the value of higher-level cross-domain languages to generate new solutions and support transfer of new knowledge; and the value of vision-inspired basic research endeavors.

The report was structured in ten substantive sections, each of which was developed through communications among a group of participants, both physically present at one or more of the conferences, and communicating afterward online. The expression *essential platforms of the human activity system* referred to a conceptual classification of domains in which human action has consequences on various scales, usually described in four categories:

1. Foundational science and technology tools
2. The individual human scale
3. The scale of planet Earth
4. The societal scale.

46.2.1 Convergence Platforms

The first platform, appropriately enough, is the original NBIC concept based on nanotechnology and its connections to the three other fields of technology. The contributors to discussion of the NBIC platform began by noting that the costs of research had been reduced considerably over the previous decade in such nano-related areas as gene sequencing, measurement and manipulation of nonbiological objects at the nanoscale, and the capacity of information systems to store and search ever greater and more complex sets of data. In considering the likely developments in the near-term future, the contributors considered the likelihood that the distinction between nanotechnology and the other technologies might fade, as the fields of science and engineering merged, yet what we currently call *nanotechnology* would remain significant if less distinct for many future technologies. They identified two illustrative goals for the coming decade:

1. Developing new tools and science for advanced electronic manufacturing
2. Greatly improve tools for studying the human brain
3. Cybersecurity risk management in development of innovative open source software systems, including those used to manipulate matter at the nanoscale.

The second platform concerns human-scale convergence and the quality of life, the realm in which human beings interact directly with technology, gain the benefits of innovation, and in some cases suffer indirect and unintended negative consequences. The team that considered this set of issues concluded that the really significant developments of the previous decade had occurred in public use of information technology: (1) democratization of Internet, and (2) reconceptualization of computing as a service, rather than the sale of hardware and software products. The challenge for the near future was viewed chiefly as the need for convergence to combat disorganization, notably through collaboratories and virtual organizations, thus emphasizing information technology and giving supportive roles to the three other NBIC fields. In a sense, this analysis treated as problematic the distinction between the human-scale and societal-scale platforms, because the end result of unlimited social disorganization would be a collection of isolated individual human beings, while total organization would unite the entire world. Disorganization would seem to alienate nanotechnology from the other fields, because only a very few individuals would possess a professional understanding of its technical details, yet organization might also wall off nanotechnology from other fields, unless it was inspired by the values of convergence.

The third platform covers the broadly defined natural environment of planet Earth, in the context of the solar system. Biodiversity and climate change were among the central topics, along with resource distribution including energy consumption by human civilization. This platform was not limited to the often rather contentious debates about sustainability, but sought to develop a context for evaluating such issues dispassionately and objectively, while also supporting the general advance of human knowledge about the world in which

we live. The Earth-scale platform was considered from five viewpoints:

1. Knowledge systems
2. Monitoring systems
3. Communication systems
4. Management systems
5. Earth-scale technologies and other contributing technologies.

Summarizing development over the previous decade, the working group considered that the capabilities of science and technology had increased significantly, but the problems had become worse, and the world's political systems were struggling to achieve anything like a consensus as these two trends were going in opposite directions. Seeking a solution to this difficult conflict, four government-supported initiatives were proposed, all requiring world-wide cooperation:

1. Global data and information infrastructure: This entails not merely the development of a unified, searchable, comprehensive database of all valid information about conditions on Earth, but also deployment of vast numbers of sensors for environmental monitoring, including many that would be worn by volunteers among the general publics of all nations.
2. Global catastrophic and existential risk assessment: This requires both significant advances in assessment methodologies, such as computer simulations based on *Big Data* archives, but also establishment of a new organization to conduct the assessments in the most reliable and authoritative manner, similar to the Intergovernmental Panel on Climate Change.
3. Global megacities initiative: To improve the living conditions of residents of large metropolitan areas, several types of systems must be integrated intelligently, including transportation, energy grids, smart homes, and decentralized manufacturing that may in many cases integrate nanotechnology with computer-controlled tools such as 3-D printers.
4. Global materials initiative: The components of megacity and industrial ecosystems must be maximally recyclable, reusable, and renewable, when feasible also serving other environmentally friendly purposes, such as sequestering carbon from the atmosphere in construction materials.

The societal-scale platform was considered primarily in integration with the other three, and in five implication areas that were reported separately:

1. Human health and physical potential
2. Human cognition and communication and the emergence of the cognitive society
3. Societal collective outcomes including manufacturing
4. People and physical infrastructure
5. Convergence of knowledge and technology for a sustainable society.

The concluding chapter of the book-length multiconference report identified six governance goals for the next decade, each of which would require convergence of multiple fields of science and technology for human and societal progress:

1. Advance innovation for economic productivity: New models for innovation must be developed, as well as common technical languages to facilitate collaboration across fields, sophisticated methods for assessing ethical and legal implications, and most probably a shift in emphasis from investment in traditional fields to emerging areas such as nanotechnology and genetics.
2. Support converging technologies to advance human potential and quality of life: Many prominent visionaries of technological progress have advocated development of methods not merely to give humans new tools, but to enhance human minds and bodies directly, for example reducing the effects of aging or improving the ability of children to learn; new methods and structures of socio-technical assessment are required to advise us which of these ideas are both practical and ethical.
3. Set grand challenges in the vision-inspired quadrant: This refers to a four-fold analysis of research that highlight projects that are between pure and applied, called *use-inspired basic research* [46.10], and addressed difficult challenges such as the future of space exploration, global sustainability, rigorous incorporation of imagination in the processes of discovery and invention, and reconceptualizing healthcare in terms of emerging approaches like nano-bio sensing for diagnosis.
4. Design integrated socio-technical systems: One organizational approach would be to found methodology and policy centers at universities and perhaps with industry connections, while others are to support a diversity of research projects developing knowledge and technology platforms, and establish major societal convergence databases to support development of new logical, mathematical, engineering, informatic, and philosophical paradigms.

5. Address deficits in risk governance for next-generation CKTS products: Risk governance can require balanced consideration at several levels of complexity, from simple statistical risk analysis done by the staff of the agency panning the action up to a combination of approaches, adding probabilistic risk modeling, assessment of risk balancing, and risk trade-off and deliberation including external experts and stakeholders in industry, directly affected groups in society, and the general public [46.11].
6. Improve the cultural balance between collaboration/harmony and confrontation, as informed by the global context and by CKTS: This sets idealistic goals for human cooperation, including conflict resolution between people from different nations or groups, maintaining existing international and intergroup harmonies, facilitating convergence between the real and virtual worlds such as Internet-based communities, and enabling better work and personal satisfaction for individuals.

46.2.2 Handbook Overview of Convergence

The 2016 *Handbook of Science and Technology Convergence* had some of the qualities of the collections of individual essays written after the conferences by participants, but was much larger, included additional authors, and was organized much more rigorously. It serves as a capstone to the series of conferences, and is a reference work establishing the conceptual basis of convergence as a mature orientation toward science, technology, and society. Each of the four convergence platforms was examined comprehensively, and will be summarized here. Two other sections of the handbook concerned concepts and methods, and convergence in education, which will be the next two sections of this chapter.

In summarizing the contributions about the Foundational Technologies Platform, Mihail Roco identified similarities across the four NBIC fields, and the ways that each could be central to some forms of convergence with the others. He argued that each of the four fields concerns a domain of nature that has its own fundamental building block: atom, gene, information bit, and neuronal synapse. He also saw four stages in the historical development of the movement:

1. The preliminary interdisciplinary phase of convergence that involved coincidental confluence of fields
2. The nanotechnology stage of convergence, in which concerted research and engineering efforts at the nanoscale called attention to affinities with adjacent fields
3. Convergence of Nanotechnology, Biotechnology, Information technology, and new technologies based on Cognitive science through the organization of NBIC conferences and other collective activities
4. Convergence of Knowledge, Technology, and Society (CKTS) beyond NBIC.

In discussing nano-centered convergence, Roco predicted that nanotechnology is currently transitioning from primarily an area of pure research to increasingly valuable applications, most obvious to the general public perhaps in medicine, but contributing to growth in many sectors of the world economy [46.12, p. 213]:

> *Using the same physical, chemical, and biological properties of nanoscale elements has proven valuable in application areas ranging from advanced materials such as metamaterials and nanophotonic structures, nanoelectronics such as* 10 nm *CMOS, and spintronic memory devices to nanobiotechnology and neurotechnology. Ability to probe single atom, single electron, single photon, single phonon, single charge, single spin, single-molecule vibration, and other parameters at the nanoscale has opened new capabilities for measuring, simulating, and changing continuum properties at the macroscale in all S&T areas.*

The Handbook's section on the Human-Scale Platform emphasized the many ways in which information technology is taking on ever more roles mediating between people and their environment, and between individuals and social groups. Specific topics included online collaboratories, virtual meetings, transformative communication media, robots serving as partners with humans, personalized and interactive arts and literature, open source technology development, and distributed manufacturing in which nanotechnology pays significant roles. An overview of this complex and rapidly changing convergence between human beings and information technologies identifies many fundamental principles, each of which is a domain of research that can progress best if combined with others [46.13, p. 363]:

> *The defining feature of the human species has always been that we employ technology to interact with nature. The modern case of human–computer interaction provides five distinct research and development approaches that could apply to any field of engineering: (1) ergonomics, (2) cognitive modeling, (3) user-centered design, (4) value-sensitive design, (5) technical culture. The felicitous symphony orchestra metaphor for social-technical sys-*

tems also identifies widely applicable principles: (1) division of labor, (2) a harmony of scientific concepts, (3) the need for significant human expertise, (4) social cohesion of teams, (5) human guidance, (6) properly defined general principles for decision making. Humanity may have reached a technological watershed at which the basis of much of the economy shifts from physical objects to information, but in any case innovation will require new collaborations between fields of expertise, in service of human wellbeing.

While the Earth-scale platform is the domain for much research and policy development concerning preservation of the environment, it also includes economic globalization, linguistic convergence, worldwide demographic trends, a sustainable food supply, and the potential human significance of the exploration of outer space. Many current trends seem quite negative, notably environmental degradation and social problems associated with globalization. However, there is also good reason for optimism, if enlightened science-based policies can be implemented [46.14, pp. 534–535]:

It also must be understood that anthropogenic change can also help protect our planetary life-support systems. The emergence and convergence of nanotechnology, biotechnology, information technology, cognitive (NBIC) science promise enormous societal and earth-scale sustainability benefits. Optimists can point to advanced technologies that reduce energy demand, emissions of greenhouse gases, air and water pollution, and industrial wastes. Water supplies and quality are being improved, food is being grown in more environmentally friendly manners, and applications of synthetic biology to reduce species extinction are gaining adherents. Humanity and our life support system can benefit from having these types of technologies sooner than later.

The societal-scale platform combines the institutions of society that have very wide-ranging impacts, including some that seem unscientific, notably government, culture, religion, and ethics. Even as we struggle with many narrow but important policy issues concerning the impacts of new technologies, a huge question lurks in the background: Has science reached its natural limits [46.15]? Well over a century ago, the frontier of the *Wild West* officially closed, and *Frederick Jackson Turner* raised concerns that a frontier is a necessary condition for democracy and cultural progress [46.16]. Without some dynamic, progressive domain for creative human action, society may decline into the equivalent of a global penitentiary, filled with poverty, suffering, and the consequences of injustice. Famously, *Vannevar Bush* called science *the endless frontier*, and *Star Trek* called outer space *the final frontier* [46.17, 18]:

Yet the final frontier *could actually be the nanoscale, and nanotechnology could overcome many economic and technical limitations by permitting efficient human design of structures across all size ranges. Or the* final frontier *could be the human mind, pioneered either by cognitive neuroscience or by cultural sciences, or by a convergence of both in the realization that mentality proceeds both at the individual and the social levels.*

46.3 Concepts and Methods

In the Handbook and the earlier conference books, a vast collection of analytic concepts and research methods was identified that could contribute to convergence of at least some areas of science and technology. Many of them are either already employed or worth considering for nanoscience and nanotechnology. In addition, several conference participants contributed case studies in which nanotechnology collaborated with an adjacent field, from which lessons could be learned.

Fairly often, when two fields interact very intensively, they may create a new field that is a hybrid of both, and an example considered seriously was *nanobiotechnology* [46.19]. As is the case with any new field, a formal definition has not fully congealed as yet, but nanobiotechnology is not merely the application of knowledge from nanoscience to biotechnology. It can also be development of biomimetic but nonbiological processes of use for specialized nanotechnology applications. From biology, we may learn much about separable chemical processes and structures of complex molecules, for example. They function within biology as features of complex evolutionary systems embedded in the biosphere, but can be applied and combined in different ways outside living organisms. This is not to say that success will be easy, even after a fundamental understanding has been achieved. After pilot studies have indicated how a valuable application could be de-

signed, perfecting and deploying it can still require very great investments.

A related example is convergence of *nanotechnology with neuroscience*, which not only gives each field new possibilities derived from the other, but also allows their partnership to contribute to computer and information science [46.20]. A major goal would be neuromorphic or neuromimetic computing, the creation of successors to computer chips in which the elements were structured and function like the neurons and synapses of the human brain. While research on the human brain is advancing rapidly, it is exceedingly difficult to study phenomena in living brains on the level of local nets of neurons, let alone individual neurons, in part because functional magnetic resonance imaging cannot operate at the fine resolution required. It may, however, be possible to deduce the structures and functions of small-scale neuron networks, with the assistance of insights from nanoscience. The results might require development of new programming methods in computer science, and many other innovations that cannot yet be specified.

Convergence, however, is not inexorable, unidirectional, or even the only creative process in a dynamic socio-technical system. Indeed, at times divergence becomes dominant, and a field effectively splits in two, each half develops somewhat independently, and then the pair become ready for a new phase of progress to be achieved by re-converging. An example of almost constant fission and recombination is social psychology, which is itself a convergence between psychology and sociology [46.21]. Under ideal but fairly common circumstances, a general convergence–divergence cycle can become established, in four phases [46.22, p. 79]:

1. Creative assembling of contributions from multiple fields leading to new concepts or ideas
2. System integration leading to a new assembly or invention for known uses
3. Technological innovation outputs leading to new products and applications
4. Spin-off outcomes that lead to solutions not possible before and that produce new competencies, tools, and applications.

46.3.1 Five General Principles

Both in the conference contributions, and in the wider social science literature on science and technology, a number of relatively obvious general principles have coalesced, even as research and visionary theorizing are identifying others. Five principles in particular have frequently been cited [46.23]:

1. *Exploiting interdependence among domains*: As in the example of nanotechnology-neuroscience convergence, the fields begin with very different vocabularies so shared terminology must be developed; databases must be structured and annotated so that both fields may effectively use them, and the scientists and engineers must be both assisted and rewarded in developing an encompassing social network including some interdisciplinary formal organizations. The motivation may begin with a preexisting awareness of how practitioners of each field need help from the other, to accomplish goals they have already defined. But then there must be sufficient vision, perhaps provided by leaders from both specialties, to recognize new opportunities of benefit to both, that can efficiently be exploited at reasonable cost. Thus, connections will begin in some of the most obvious areas, but lead to promising discoveries in other areas, hopefully triggering a cascade of creative cooperation.
2. *Improving the convergence–divergence evolutionary cycle*: A starting point would be to search through the literature on the history and social science of science and technology innovation, both to harvest relevant theories and findings that have already been articulated, but not yet combined, and to look for new questions and empirical relationships. For example, in general does the convergence–divergence cycle work best when it is visible to all major participants and occurring in isolation from potentially disruptive external forces? It is conceivable that sometimes the cycle is more productive when it is not fully understood by participants, because a diversity of opinion may facilitate innovative ideas, or lack of full comprehension may be the result of working at the cutting edge of discovery. Or, it may be that the collision of two initially separate convergence–divergence cycles could either magnify their productivity, or interfere with it. The cycle is itself a new theory, potentially generating new hypotheses, so quite reasonably it should be the focus of many kinds of research, including experiments as well as rigorous observation of naturally occurring cycles, to develop the knowledge required to improve today's rate of scientific discovery and engineering invention.
3. *System-logic deductive decision making and problem solving*: A common error is conceptualizing a complex system exclusively in terms of one of its components, and thus from only one perspective, thereby missing out on opportunities for more successful management of the system. Using system logic can mean integrating multiple analysis, for example considering multiple pathways through

the system before attempting to unify them through formal logic, statistical analysis, or computer simulation. Essentially always, human beings are components of the system, even if only as researchers studying it or the beneficiaries of its successful operation. Many choices exist concerning the tools with which to understand a complex dynamic system, from fractal analysis to network visualizations to knowledge mapping and beyond. At some point in the process it may be worth distinguishing two parallel systems: (1) a portion of the natural world, such as the complex interaction of structures and chemicals inside a living cell, and (2) a portion of the human world, such as the biochemists and nanoscientists studying the cell, and even a human medical patient to whom the cell belongs. Then new insights may come from combining the two systems into one, within a flexible, hierarchical logic system for making decisions.

4. *Creating and applying high-level cross-domain languages to facilitate transfer of knowledge and new solutions* In some cases, as has happened often in medicine, two different fields may have different names for the same phenomenon, so they can abandon one term in favor of the other, as they coordinate their technical dictionaries. In other cases, one field may have a concept of value to the other, which could give the term a more significant but no less precise meaning; an example is the transfer of *vacancy chain* from semiconductor physics, describing a nano-scale path along which electrons may travel, to sociology where it came to describe an almost identical structure in which the movement of employment opportunities or durable goods in economic exchanges may be described by essentially the same mathematics [46.24]. Once two or more fields have combined and harmonized their terminologies, not only can experts in one area function as near-experts in another area, but it becomes easier for highly motivated and intelligent volunteers to join the team in the capacity of citizen scientists [46.25]. Associated with the development of a high-level language, many of the crucial but smaller factual details can move from human minds to computer-based information systems, just as people no longer do long division by hand, thus redefining expertise less as total command of a particular area of science, to fluency with the high-level cross-domain language and skill operating the information system that manages the details.
5. *Using vision-inspired basic research to address long-term challenges*: How to be visionary and rigorous at the same time is very difficult, especially if great investments are required to develop a solution for problems that are still emerging, or for opportunities that we can only hope will become available in the distant future. Yet some significant fraction of our effort today should be invested in preparing for a positive long-term future, and some methods of forecasting, scenario development, and prototype research may have value for the particular domains in question. The dramatic phrase *grand challenge* has been traditionally applied to vast issues like protection of the environment or economic development of impoverished societies. Another term that must be taken seriously despite its grandiose connotation is *anticipatory governance*, which can refer to constant reassessment of the means to an important goal that does not merely respond to changes in the contexts of innovation and application, but also vigorously seeks new routes to the goal even when the current path seems satisfactory. Among the potentially innovative approaches is *reverse mapping*. Rather than starting one's analysis from the current situation and planning a route from here to the distant goal, one can analytically reverse the direction of time, and begin analysis at the goal and work backward from there to the current situation. Many aspects of vision-inspired basic research are risky, and people generally avoid taking risks with big investments. Yet it can be especially risky to follow a supposedly tried-and-true path to a revolutionary goal, without thinking critically about alternatives and exploring them in creative ways.

46.3.2 The Information Technology Infrastructure

Many participants at each of the conferences evaluated the kinds of information and communication technologies that would best facilitate convergence. Several examples were considered that superficially looked like conventional systems, but really were quite revolutionary when described in any depth. For example, it is obvious that researchers can benefit from shared databases, especially if they can be accessed online so that researchers need not be physically on site. Slightly more innovative is the plan to design each one with metadata descriptives and statistical analysis tools that are conducive both for communication across fields and for exploratory analyses incorporating new ideas. But those are somewhat antique ideas, while what is really needed is a *collective intelligence system* [46.26]. It would be the emergent result of synergy among three components:

1. A constantly evolving archive that goes beyond data to information and knowledge
2. Software and hardware tools that are not merely sophisticated but capable of rapid enhancement such as through user-created open source software and perhaps in some cases by nanotechnology-based quick-response 3-D printing of new instrumentation
3. A community composed of both subject-matter experts and diverse nonexpert contributors organized in a dynamic social network of vigorous personal commitment as well as in a computer-supported communication network.

Clearly, creation of a global collective intelligence system, or even a much more modest system for supporting convergence across many fields of science and engineering, will require innovations and investments of many kinds. The traditional methods for managing libraries and curating their contents are obsolete, for example the notion that each publication can be assigned to a single topic area category, when much more sophisticated and multidimensional information search methods are needed [46.27]. Indeed, simply accessing sources of information is of little value if we do not have multiple appropriate means for analyzing it and connecting it with other data, not merely through web links or statistical analysis but also through theory-based computer simulations [46.28]. Assembling the information, even using the most modern methods, is also insufficient, because we also need advanced means for assembling the team of people who will use and give human meaning to the information, for example through online collaboratories [46.29].

At the opposite scale extreme from nanoscience, but connected to it via global convergence, is the need for intensive whole earth monitoring [46.30]. Conceptualizing the Earth as a unified but complex natural system, increasingly affected by the artificial systems humanity builds upon it, the immense challenge is not merely tracking gross trends, but also constantly measuring and understanding local events and processes that may be cyclical, chaotic, or linear but heading in an unfavorable direction for human well-being. The data must be comprehensive but available to scientists, leaders of industry and other institutions important for the economy, and government policy-makers. Availability to journalists, social scientists, and leaders of nonprofit organizations is also important, yet proper concern must be addressed to issues of privacy and intellectual property rights. Not only must the data chart such long-term trends as climate change, but they also must be quickly available in sudden episodes of natural or man-made disasters, when the public response must be both quick and correct. Clearly, the challenges go far beyond the technical issues of sensing, storing, and analyzing the necessarily huge datasets required, but also require advancement of global civilization to a much more mature state than it has currently achieved.

46.4 Convergence in Education

To a significant degree, science and technology convergence requires overcoming the fragmentation of formal education into separate subject areas, without of course *dumbing down* the form or content of teaching. However, much more than this curricular transformation is required, because the convergence of science and technology with society will create a situation in which much education does not happen in schools, and may not even require educational institutions. While we can be optimistic, there is some reason to be concerned that the highly technical nature of nanoscience, and the fact that it often concerns phenomena that cannot directly be observed by human beings without the use of costly and complex instrumentation, may render educational convergence more difficult for this field.

46.4.1 Innovations in Formal Education

Nanoscience and nanotechnology have become so significant in the modern world that education about them is needed at many levels and in many subject areas, even in the social sciences. One contribution to the 2003 Los Angeles report showed how college students, and even high-school students, might do their own educational exercise in a social science or general science class by using the keyword *nanotechnology* while looking up books in Amazon.com, which was still in its early stages of development then [46.31]. For example, the *nanotechnology* category contained 246 books in November 2002. A student could check each one, instantly learn something about the subject merely by reading the description, and then discover convergence by looking at which additional categories the given book was assigned to. For example, 5.5% of these books were also in the *general business and investing* category, 3.7% in *electrical and optical engineering*, and 3.2% in *industrial engineering*. As of July 2016, merely entering *nanotechnology* into the Amazon.com search field for books reveals 9,861 books, 3,240 of which were also in *physics*, 2,599 in *ma-*

Table 46.2 Use of nano-related words in National Science Foundation grants

2005 Grants	BIO 1364	CISE 1382	ENG 1700	GEO 1672	MPS 2256	SBE 1163
Nanotechnology	0.6%	1.0%	10.1%	0.1%	4.0%	0.8%
Nanometer	0.1%	1.0%	3.8%	0.6%	2.9%	0.0%
Nanosecond	0.1%	0.0%	0.3%	0.0%	0.1%	0.0%
Nanoscience	0.1%	0.4%	2.6%	0.2%	1.9%	0.4%
Molecule	9.0%	1.7%	5.9%	0.7%	13.5%	0.2%
2015 Grants	**1331**	**2145**	**2673**	**1451**	**2669**	**1069**
Nanotechnology	1.1%	0.5%	4.1%	0.1%	2.8%	0.5%
Nanometer	0.3%	0.5%	2.2%	0.3%	2.7%	0.0%
Nanosecond	0.0%	0.0%	0.1%	0.0%	0.3%	0.0%
Nanoscience	0.0%	0.2%	1.0%	0.0%	1.5%	0.4%
Molecule	10.2%	0.8%	6.1%	1.8%	14.3%	0.1%

terials and material science, and 1,404 in *medical books*.

A contribution to the 2005 Hawaii conference showed how the public database of grants made by the National Science Foundation could be used for similar student assignments, since the database's search engine is versatile but easy to use, and students could read the abstracts describing the research grants, gaining some sense of satisfaction because they had found the abstracts themselves rather than merely reading the paragraphs from a teacher-assigned book [46.32]. The example given then tabulated the use of a long list of convergence-related terms across the six directorates of NSF: BIO (biology), CISE (computer science), ENG (engineering), GEO (earth sciences), MPS (math and physical sciences), and SBE (social and behavioral sciences). Table 46.2 reports the published data from fiscal year 2005 for the most nano-related keywords, followed by data from a decade later easily collated for this chapter, just as a student could do. In 2005, a student would discover, fully 10.1% of the 1700 grants made by the Engineering Directorate of NSF had the word *nanotechnology* in their online abstract.

A classroom discussion of results like those in Table 46.2 might go in any of several directions. The teacher would probably want to point out that the NSF directorates with the largest fraction of grant abstracts containing *nanotechnology*, ENG and MPS, had seen big increases in the number of grants, and new emphases in emerging areas might be partly responsible for the decline in the nanotechnology percentages. Also, the use of the term *nanometer* had not declined so much, and the word *nanotechnology* may have been used especially often when the field was new, being replaced by a variety of more specific terms in recent years. In any case the table does show connections to many fields, thus indicating the potential for nano fields to participate in convergence. Depending upon the scope of the course, and the instructor's expertise, a subsequent lecture might focus on future opportunities, such as greater involvement of nanoscience and nanotechnology in the geosciences [46.33].

Once a college or other suitable educational institution had sufficient expert staff, and material related to nanotechnology had been integrated into several different classes, then those resources could become part of a general plan to institutionalize convergence as a new paradigm for higher education more generally [46.34].

A common metaphor for science and technology convergence education is that it should produce professionals with T-*shaped expertise*, that is, possessing deep knowledge of one field, as represented by the vertical line of the T, but decent knowledge of adjacent fields, as represented by the horizontal line of the T. A more ambitious view argues that convergent professionals would need special abilities to integrate information from new fields as needed through life, and the social skills required to help other people achieve their own valuable degrees of convergence [46.35]. This perspective was widely shared at the New York convergence conference.

46.4.2 Integration of Learning with Life

The notion that learning takes place primarily in school may be one of the illusions of the 20th century that needs to be unlearned. A possibly sad fact about the field of computer science is that many of the best people in that diffuse field had already taught themselves to program computers long before they ever took a formal programming course, so people who enter the field only in college may be at a severe disadvantage. While much can be learned in school science and technology classes, students can also learn much about nature, machinery, and social relations outside educational institutions, simply by exploring their immediate environment with inquiring minds assisted by self-selected readings. Among the possibilities for transformation of

education in the 21st century are massive open online courses (MOOCs) that some innovative universities and colleges now offer to anyone anywhere [46.36]. This might be especially useful for early-level education in nanoscience and other disciplines in which the subject matter is not directly visible to the human eye. Yet it also could serve life-long learning, notably in refresher courses for people working in adjacent fields, who thus need to be brought up-to-date periodically, if they are to participate actively in convergence throughout their lives [46.37].

Much evidence indicates that passive learning is not effective, and students must be actively engaged with the aspects of reality they are currently seeking to learn about. Information technology can often provide a simulated environment to achieve greater student immersion in the more abstract fields of knowledge, a methodology currently called *cyberlearning* [46.38, p. 1008]:

> *Learning that is mediated or guided by interactions with the computer and done in an environment where both the computer and human agents can provide the help, or scaffolding needed, to foster deep understanding and masterful capabilities.*

Nanotechnology is a maturing field, in which some organizations and standards of learning have been established, but there is still much room for development of the best methods for education [46.39].

46.5 Conclusions

The 15 years of conferences and intensive written communications led to a firm consensus that science and technology convergence would involve essentially all aspects of society, potentially with revolutionary effects, and perhaps serving to protect society from some of the growing chaos in many nations and sectors of society. While information and communications technologies seem to be the most significant factor, in the context of convergence they might be reconceptualized as *cognitive technologies* [46.40]. Indeed, several contributors to the conferences suggested that our world could become a *cognitive society*, in which ordinary people were enhanced through their creative use of ubiquitous information, both individually and through their social interactions [46.41].

When the National Science Foundation surveyed the major research frontiers in 2016, from shaping the human–technology relationship, to predicting phenotypes from genotypes, and to the next quantum revolution at the nanoscale, it proclaimed that all required more convergent research [46.42, 43]:

> *The grand challenges of today – protecting human health; understanding the food, energy, water nexus; exploring the universe at all scales – will not be solved by one discipline alone. They require convergence: the merging of ideas, approaches and technologies from widely diverse fields of knowledge to stimulate innovation and discovery … Convergence blends scientific disciplines in a coordinated, reciprocal way and fosters the robust collaborations needed for successful inquiry. Convergence builds and supports creative partnerships and the creative thinking needed to address complex problems.*

It is reasonable to expect great diversity in the orientations toward convergence of scientists and engineers, and impossible to predict what consensus will emerge in the coming years. Given the uncomfortable social chaos that exists outside our universities and industrial laboratories, we could be forgiven for specializing in the narrow area that interests us most personally. Yet even from that modest perspective, the grand ideas of the convergence movement offer innumerable useful insights about the dynamic system that is science, technology, and society.

47. Global Perspectives of Nanotechnology Education

Kurt Winkelmann, Bharat Bhushan

The continued advancement of research and applications described in this book depends on the quality of the next generation of scientists and engineers who will lead the nanoetchnology revolution. This chapter first reviews the growth of nanotechnology education then describes the successful efforts of educators on six continents in developing the nanotechnology talents of their students. Examples of educational programs at the primary, secondary, undergraduate, and graduate levels, for teacher training, vocational education training, and for informal education of the general public are each presented.

Education and training are essential to produce a new generation of scientists, engineers, and skilled workers necessary for rapid progress in nanotechnology around the world. (For the sake of brevity in this chapter, the term *nanotechnology* encompasses all aspects of nanoscale science, engineering, and technology. Other terms are used only in cases when more specificity is necessary.) Nanotechnology education should be available to all people, not just future experts in this field. Politicians, policy makers, and voters need foundational knowledge in science, technology, engineering, and math (STEM) subjects because they make decisions that affect the growth of science and engineering, even though they do not study these technical fields. A trained nanotechnology workforce and a nanoliterate citizenry can be developed through both formal and informal education efforts, starting with the foundations in children and increasing in technical and specialized education through the university levels. Achieving these results requires teachers and education researchers to design curricula and programs that demonstrate the interdisciplinary nature of nanotechnology, including disciplines outside of the usual STEM fields. To achieve the best possible outcomes, activities should appeal to

and promote students' excitement and creativity at all educational levels: primary through graduate school, and continuing education programs, educator training, and informal science education.

With the decreasing number of people in western countries choosing to study science and engineering and with the rapid progress being made in nanotechnology, the problem of a trained workforce is expected to be acute. The question is being asked – is the traditional separation of academic disciplines into physics, chemistry, biology, and various engineering disciplines meaningful at the nanoscale? Arguably, nanotechnology education should begin by covering the broad science topics in order to facilitate new approaches to problems and new solutions based on a broader understanding of foundational science. However, business and entrepreneurial skills also are needed to transfer scientific knowledge into products, which increases the economic impact, importance, and continued support for scientific education. Therefore, it is essential that scientists and engineers no longer confine themselves strictly to the laboratory; broad and fundamental understanding of business, society, politics, and health and safety are required. To that end, it is also imperative that scientists and engineers prepare to work in a global environment, solve global problems, and address the implications of their work on a global scale. They must therefore collaborate with relevant experts to address the societal, ethical, political, and health and safety implications of their work for global humanity. Nanotechnology education should have as one focus a broad, interdisciplinary approach to science and engineering at the nanoscale. More on this subject can be found in the recently published book *Global Perspectives of Nanoscale Science and Engineering Education* [47.1].

To increase the pool of students interested in advanced education in science and technology, educators should convey STEM subjects as an exciting and creative endeavor from their first introduction. Innovative foundational education in schools and informal instruction opportunities can help to accomplish this goal. Since the mid-1990s, there has been a global push for better STEM education, particularly in the K-12 arena. The goal is to increase the number of people interested in pursuing advanced education in STEM fields, and to ensure sufficiently educated workers for STEM jobs. This has resulted in a generation of workers with content knowledge and enthusiasm, but many with limited ability to apply that knowledge to real-world scenarios and problems, and limited experience with thinking critically and creatively.

To address this challenge, there has been a drive to make technical fields more attractive to students by making STEM topics more relevant to students' interests. One approach, begun around 2010, includes the arts in STEM education, an initiative called STEAM, in order to encourage not only science content, but creativity and critical thinking skills derived from arts-based education as well. This approach is especially popular in the Republic of Korea (South Korea) [47.2, 3]. These arts-based skills are essential for translating discrete content knowledge into broad applications. If this STEAM education approach can be applied to nanotechnology, as well as more macroscale science and engineering fields, the beginnings of an interdisciplinary, broad education can be found [47.4]. However, interdisciplinary curricula relevant for nanotechnology need to be developed. This requires revamping the STEAM education model for nanotechnology, the development of new courses, and course material including textbooks and instruction manuals, and training of new instructors.

One might ask why a global perspective is needed for nanotechnology education. After all, scientific results should be reproducible around the world. Nanoscale phenomena in Brazil are the same as in Israel or Taiwan. A nanomaterial synthesis experiment conducted by scientists of either European or African heritage will have the same result. This is obvious to scientists; on the other hand, educators recognize that learning is a human endeavor so perspectives of students can differ due to their culture and environment. Students learn more when they care about the subject. Educators can motivate students to learn by designing activities that interest students [47.5]. For example, a student will be more interested in nanotechnology if the student identifies with aspects of people (gender, ethnicity, country of origin, etc.) associated with it. The many uses of nanotechnology that predate the scientific investigation of nanoscale features in the 20th century provide educators with culturally relevant examples that can increase student interest. Connections exist between a nanotechnology topic and many cultures since different cultures interacted and influenced each other throughout history. In addition, adding elements of history has the benefit of making future scientists more well-rounded in their education. History provides a cultural framework, making science more regionally relevant. By linking a cultural past with a cultural present, history makes science more enticing and relatable, perhaps sparking an interest in science among those students who are initially wary of studying it. A brief history of Damascus steel illustrates this point.

Damascus steel is commonly cited as an early use of nanomaterials [47.6]. Swords were made of this steel in Damascus, the current capital of Syria, until the 18th century [47.7]. The quality of the swords was unmatched during that time, and the particular iron ingots

used to forge the steel, known as wootz, were imported from India. In the 19th century, Michael Faraday studied Damascus steel. As the son of a blacksmith, the scientific study of what made Damascus steel superior in quality was relevant to Faraday's cultural framework. Later in 1857, as part of an unrelated study, he reported that metal colloids could have different colors depending on their particle size [47.8]. This is among the earliest observations that invoked nanostructures as an explanation. This foundational study in nanotechnology sparked further study, and we now know that carbon nanotubes and other nanostructures enhance the strength and sharpness of Damascus steel.

Development of nanotechnology curricula for primary, secondary, two-year vocational, traditional four-year university, and graduate education programs, continuing education for practicing teachers, and informal education, must continue to keep pace with research. It is hoped that this chapter provides a useful introduction to nanotechnology education for researchers with an interest in this subject and a survey of nanotechnology education as practiced in countries around the world. Educators and researchers can learn from the efforts of their peers and colleagues around the world who are pursuing the same goal of improving nanotechnology education.

Following Sect. 47.1, the remaining sections of this chapter provide summaries of nanotechnology education activities from around the world, with an emphasis on those occurring outside the United States. This approach was chosen because US-based programs are the most widely known, so there is less of a need to present them here. Chapter space limitations allow for only a somewhat random sampling, rather than a comprehensive review, of the many outstanding nanotechnology education activities. Long-standing programs are given preference for inclusion over short-term research studies of nanotechnology education. Information about the programs and curriculum materials is drawn primarily from articles published in the peer-reviewed academic literature and all referenced articles are written in English. Each chapter section addresses nanotechnology activities appropriate for a certain educational environment.

Not all of the programs described herein are still in existence. Nanotechnology courses may be absorbed into existing, traditional STEM courses. National priorities for STEM education can change, drawing funding from nanotechnology education to other subjects. Individual instructors may not sustain an activity that they created. This does not diminish the value of the successful programs, courses, and activities described here.

47.1 Growth and Trends of Nanotechnology Education

At the beginning of the 21st century, educators and policy makers assessed the need for including nanotechnology among the topics taught in schools [47.9, 10] as well as the funding mechanism to address that need [47.11, 12]. Due to the investment in the National Nanotechnology Initiative by President William J. Clinton in 2001, the United States led many of the early efforts to establish centers for nanotechnology research and education. Other countries soon established their own nanotechnology programs. The appearance of nanotechnology in school curricula is increasing around the world, as the examples cited in this chapter will show. In addition, readers may consult several reviews [47.13–15], books about this subject [47.1, 16–18], and ongoing published articles in the Journal of Nano Education.

47.1.1 History of Nanotechnology Education

Development of classroom nanotechnology activities preceded the establishment of these national programs. For example, Fig. 47.1 shows the number of publications related to nanotechnology appearing in the Journal of Chemical Education between the years of 1991 and 2015. Educators were already disseminating nanotechnology experiments such as the synthesis of ferrofluids [47.19] and demonstrating the use of scanning probe microscopy in the classroom [47.20]. Data was gathered by searching the website of the Journal of Chemical Education for the term *nano* in the titles and abstracts of articles. The resulting list of articles was reviewed to distinguish articles related to nanotechnology (shown in Fig. 47.1) from those that included other uses of *nano*, such as nanosecond spectroscopy or $NaNO_3$ (sodium nitrate).

A search for *nanotechnology education* within the SciFinder database provided by the Chemical Abstracts Service finds similar trends in other publications (excluding patents and including conference proceedings). SciFinder indexes not just chemistry journals but also those in materials science, physics, biology, and medicine. Figure 47.2 shows a similar trend for publication of nanotechnology education articles during the past twenty years. In fact, the data shown in

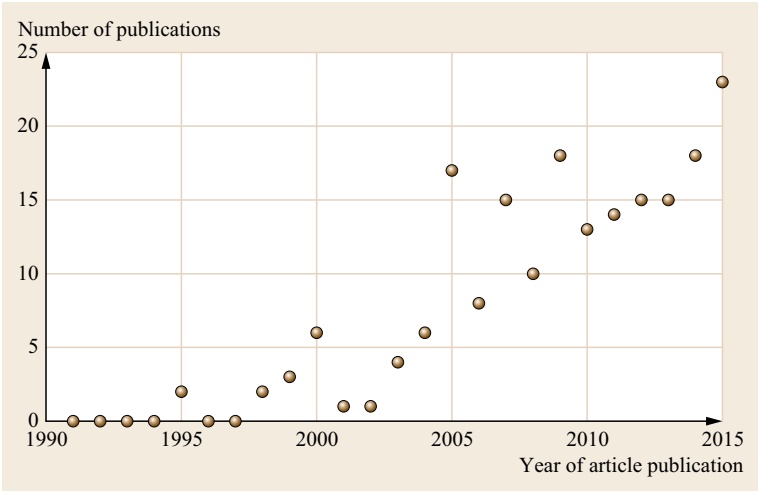

Fig. 47.1 Yearly number of nanotechnology-related publications in the Journal of Chemical Education

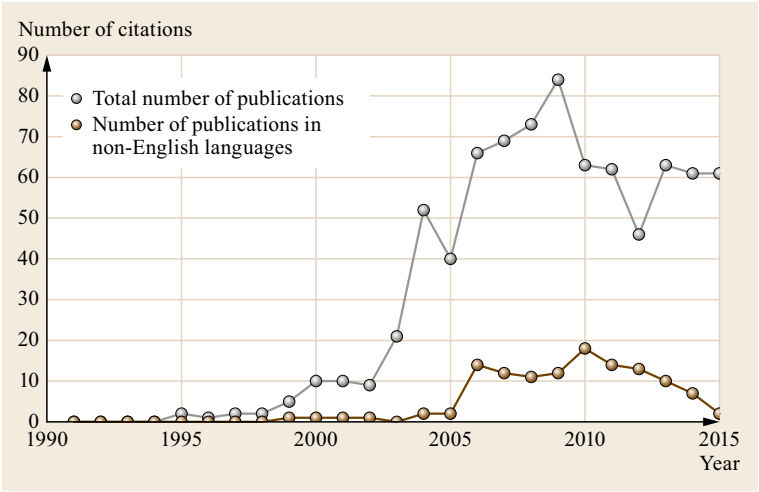

Fig. 47.2 Yearly number of nanotechnology education publications as indexed by the Chemical Abstract Service

Fig. 47.2 is certainly an undercounting of the number of publications because SciFinder does not list consistently relevant articles from smaller journals, such as the Journal of Nano Education. This may account for the apparent plateau in the number of published articles within the past six years. SciFinder does not index thoroughly journals of non-STEM-related subjects either, so articles about teaching nanotechnology history or ethics may not be included. Fig. 47.2 also shows that authors from around the world contribute to the academic literature of nanotechnology education research and practice. While most journals require authors to publish in English regardless of their native language, many nanotechnology education articles are published in other languages. The most common non-English languages are German (54 articles total) and Chinese (40 articles); articles written in a total of eight other languages constitute just 33 articles since 1995. Since 1999, 14% of the nanotechnology education articles accessible through SciFinder were written in a non-English language. It is clear that nanotechnology education publications are becoming more common and include contributions from many countries.

Implementation of a new topic requires a modification of the existing school curriculum, which raises questions. What is the goal of introducing nanotechnology to students? Which nanotechnology topics should be taught? Reviews of nanotechnology education activities published in the literature find two reasons that justify the inclusion of nanotechnology [47.14, 21]. First, from the US perspective, there is a looming shortage of nanotechnology workers so educators should prepare more students to fill these jobs of the future [47.9]. Fewer students are pursuing STEM degrees. Nanotechnology has applications in diverse fields, from electronics to pharmaceuticals to consumer goods, so learning

about nanotechnology could be a new way to get students interested in STEM subjects. To achieve the goal of a more nano-educated workforce, schools can add nanotechnology topics to existing STEM courses, such as a nanoparticle synthesis experiment to a chemistry lab course. Scientific literacy and more specifically nanoliteracy, is the second major reason cited for teaching nanotechnology in secondary schools. Due to its increasing number of applications, the general public should learn about nanotechnology so that they can have informed opinions about policies that involve the use of nanomaterials and related technologies. In order to introduce nanotechnology to as broad a student audience as possible, educators could add nanotechnology topics to both STEM and non-STEM classes. For instance, a discussion about the ethics of using nanotechnology could occur in a high school civics class.

47.1.2 Essential Nanotechnology Topics

Several research teams have addressed the question of which nanotechnology topics should be taught [47.22]. These are listed in Table 47.1. *The Big Ideas of Nanoscale Science and Engineering* by *Stevens* et al. [47.23] describes the following as the nine most important nanotechnology topics to be taught in US grades 7–12 (middle and high school):

- Size and scale
- Structure of matter
- Forces and interactions
- Quantum effects
- Size-dependent properties
- Self-assembly
- Tools and instrumentation
- Models and simulations
- Science, technology, and society.

A separate list for university-level students was also prepared. The authors gathered suggestions for list items from educators in US middle and high schools and higher education. Both groups gave similar feedback. The Big Ideas was the first and most well-known guide for educators in their development of new activities. A second survey of experts was conducted by *Huang* et al. [47.24] to determine the nanotechnology topics appropriate for Taiwanese primary school children. That list includes:

- Nanotechnology definitions
- Nanoscale features
- Nanophenomena in the natural world
- Nanomaterials
- The development of nanotechnology.

Most recently, *Sakhnini* and *Blonder* [47.25] reported a study of essential nanotechnology concepts to be taught to high school students, as chosen by Israeli nanotechnology researchers and high school science teachers. Topics are:

- Size-dependent properties
- Innovations and applications of nanotechnology
- Size and scale
- Characterization methods
- Functionality
- Classification of nanomaterials

Table 47.1 Important ideas about nanotechnology from four surveys of different groups of subject matter experts, organized by common features on each list

Primary School (Taiwan, 2011)	Middle and High School (US, 2009)	High School (Israel, 2015)	Undergraduate (US, 2009)
Nanotechnology definitions	Size and scale	Size and scale	Size and scale
Nanoscale features	Structure of matter Size-dependent properties Quantum effects	Size-dependent properties	Size-dependent properties Surface to volume ratio Quantum mechanics
	Forces and interactions	Functionality	Surface-dominated behavior
	Self-assembly		Self-assembly
Nanophenomena in the natural world		Innovations and applications of nanotechnology	
The development of nanotechnology	Tools and instrumentation	Characterization methods Fabrication approaches of nanomaterials	Tools and instrumentation/ characterization
	Science, technology, and society	The making of nanotechnology	Societal impact/ public education
Nanomaterials		Classification of nanomaterials	
	Models and simulations		Models and simulations

- Fabrication approaches of nanomaterials
- The making of nanotechnology.

Differences among these lists are likely due to the various ages of the target audiences (primary, middle, secondary, and undergraduate students). Cultural differences play a role and, given the rapid development of nanotechnology, the fact that the surveys were conducted in different years (2009, 2011, and 2015) may also contribute.

Still, similarities are obvious among the three studies. Entries in Table 47.1 are presented so that each row contains similar or related topics. Definitions of size and scale appear in all four lists. Different studies grouped nanoscale phenomena in different ways, either under a single category (e.g., nanoscale features or size-dependent properties) or separated into more specific items. It was assumed that undergraduates already understood the structure of matter so it was not included in their list. Ideas such as the impact of nanotechnology on society, the tools used to observe and measure nanoscale features, and applications of nanomaterials all appear in each list but these ideas overlap in a nonsimple way.

Of course, knowing the goal of introducing nanotechnology into a school curriculum and the general topics to teach are only the beginning of the process. Additional questions naturally follow, such as identifying the learning objectives, prerequisite knowledge required, and the appropriate pedagogy to use [47.14]. While critically important, these questions cannot be easily addressed in the present book chapter. Readers are urged to consult the STEM education research literature for a thorough presentation.

47.2 Primary and Secondary Education

Policies for funding primary and secondary education vary greatly around the world. Local, regional, and national governments can fund programs and individual educators can develop activities for their own students. Since the education of children is a high priority for every country, there is much interest in evaluating the effectiveness of nanotechnology education programs. The following examples of programs taking place around the world describe both top-down and bottom-up organizing approaches to secondary school education in nanotechnology and its overall evaluation. In preparing this chapter, little information was found regarding nanotechnology education in primary schools. Although many educators stated the need for this, there are few published accounts of nanotechnology classroom activities for young children. However, many educators describe outreach and informal learning programs for this audience. Readers will find informal learning discussed in Sect. 47.7 of this chapter.

47.2.1 Nanotechnology Field Trip for Primary School Children in Taiwan

Despite teaching nanotechnology in its primary schools, students in Taiwan lack an awareness of the subject [47.24]. To address this, educators at the Center for Nanotechnology of Ilan University collaborated with a local cable TV station and the county government to create a nanotechnology field trip to the university for primary school students [47.26]. Lesson plans allowed undergraduate students volunteering for a service learning program at Ilan University to help promote nanotechnology to sixth grade students attending four local schools. The half-day event focused on nanotechnology definitions, size-dependent effects, occurrences in nature, and applications.

Activities were designed to be interactive and entertaining, similar to activities used in informal education. This is especially appropriate since the children were attending the event away from their normal classroom. Although it was part of their day of formal schooling, it was also supposed to be a fun field trip. Students listened to a multimedia lecture that gave an overview of nanotechnology. They performed an experiment that allowed them to observe the effect of a hydrophobic surface on a water droplet. This was presented in the context of the nanoscale features that give a lotus leaf similar properties. Students played nanotechnology-themed games, visited a nanotechnology exhibition, and participated in other group activities.

Students completed a pre- and post-event quiz to measure changes in content knowledge. A comparison of these quiz scores showed that students gained approximately five points out of 15 questions (one point per question) on the quiz after participating in the activity. Among the four schools, average improvement ranged from gains of 3.4 points to 5.4 points.

47.2.2 Secondary School Nanotechnology Education in Italy

A project conducted at the Scientific-Technological Lyceum in northern Italy involved both secondary and primary school children [47.27]. Goals of the project

were to improve students' content knowledge about chemistry and nanotechnology, and enhance their communication and teamwork skills. After attending a seminar to learn about nanotechnology, a class of secondary school students developed a slide show presentation to show primary school students an application of chemical nanotechnology. Students chose to investigate a chemiluminescent sensor for detecting calcium ions in drinking water. Due to the cutting-edge nature of nanotechnology, no description of the subject appeared in the textbooks of either group of students. Therefore, the secondary school students had to research the topic using other sources. Students also performed laboratory exercises in which they prepared standards of calcium ion solutions and observed the chemiluminescence. Each student assumed a specific role within the team as they performed their research, created their own slide format, prepared the slides, and presented the research to the primary school children.

Students first chose a topic (chemical sensing of Ca^{2+} in drinking water), developed questions about nanotechnology to investigate, then answered the questions. In the second stage, students created a plan for teams to perform their research. Using online resources, students worked together to conduct their research, including the selection of images and information to include. Following this, they prepared their presentations and developed their own rubric to be used for assessing their work. Groups then gave their presentations to the primary school audience. The last stage was evaluating the groups' presentations by their peers. Students also reflected upon their own contributions to the project by answering a series of open-ended questions. They viewed the experience of researching, organizing, and presenting the information as worthwhile. Students answered questions about nanotechnology before the initial seminars, immediately after the project, and several months later. Students showed significant gains in content knowledge after completing the activity and they retained most of their knowledge over time.

47.2.3 Nanotechnology School Programs in Germany

Germany provides examples of support for nanotechnology education through various means. One common strategy for introducing students to nanotechnology is to bring the laboratory to them. This is the idea behind nanoTruck and Nanoshuttle [47.28]. For ten years, the nanoTruck program provided a mobile exhibit and teacher support within a two-story tractor trailer. Exhibits within the nanoTruck included examples of nanomaterials and their applications in consumer goods, transportation, electronics, building materials, and medicine. Visitors experienced multimedia presentations, hands-on experiments, and dozens of exhibits that helped them understand the basic science and how future careers will involve nanotechnology. Teachers could attend workshops where they learn about nanotechnology prior to a scheduled nanoTruck visit to their school. One million visitors participated in this program. Nanoshuttle is a current mobile exhibit touring the state of Bavaria. Like nanoTruck, students can perform experiments, learn about nanotechnology applications, and visualize nanostructures using advanced microscopes. The German Chemical Industry Association funds the dissemination of NanoSchoolBox, a kit containing materials for over a dozen experiments designed for high school chemistry and physics students. Online videos provide instructions and background information to students as they perform experiments individually or in groups. Other organizations, such as the Association of German Engineers and the Fund for the Chemical Industry, provide other electronic resources for students.

47.2.4 Evaluation of Secondary School Nanotechnology Education in Europe

The European Union's Nanotechnology Education for Industry and Society (NanoEIS) program recently published a report of the twelve most widely implemented and successful secondary school nanotechnology programs in EU countries as part of its 7th Framework Programme [47.29]. It indicates that compulsory activities were more common among successful programs compared to voluntary activities. Many programs lack hands-on activities for students and there is low community involvement outside of the school. There also existed a great variability in the involvement of industry and higher education as well as the degree to which the nanotechnology subject was integrated within existing science courses (or taught separately). The lack of hands-on experimentation, virtual environments, and involvement of other stakeholders were cited as deficiencies to be addressed.

Another NanoEIS report examined the extent that local secondary school nanotechnology programs and other tools encourage students to study science and technology at the university level [47.30]. As with the 2014 report [47.29], this report noted the general absence of university involvement in the secondary school nanotechnology programs. This leads to teachers not knowing what students should learn in high school if they want to study nanotechnology as undergraduates. In fact, the study found that in general, schools did not provide enough assistance helping students transition from secondary school to university. It found that the

exposure to nanotechnology among secondary school students was low, with a maximum of 20% of students in Ireland. Nanotechnology programs were rare and short-lived in all the EU countries studied. Once the program was initiated, it was expected that teachers should continue it on their own. This is likely a common problem in many regions of the world, as teachers are saddled with conflicting responsibilities to teach more information in different ways to more students. Despite these shortcomings, the report notes that most local nanotechnology programs were less than five years old. Some growing pains are common for young initiatives. It is hoped, even expected, that the dissemination of best practices of nanotechnology (and, in general, STEM) education along with the increasing need for nanotechnology workers will promote higher quality programs for secondary school students.

47.3 Vocational Education Training

Developing a skilled nanotechnology workforce requires more than talented K-12 teachers, new graduate and undergraduate university programs, and a knowledgeable public. Vocational education is needed to train technicians who need specific skills for industry. The audience for vocational education includes young people who do not attend a traditional four-year college or older workers who desire retraining so that they can advance in their current job or find a new job in the nanotechnology field. Specific skill needs of industry can change quickly as new products are developed or become obsolete and as new government regulations affect manufacturing processes. Universities are usually not nimble enough to keep up with these changes. Vocational education training (VET) can fill this gap. It should also be noted that industry and government seek nontechnical workers with an understanding of nanotechnology in order to devise policies governing waste, toxicology, risk assessment, and legal aspects of nanomaterials [47.31].

47.3.1 Potential Areas of Growth for Vocational Education Training

The approach to overseeing a nation's education program varies by country. In the US, the state and local governments play a larger role over the education priorities than the federal government, although higher education institutions often rely on indirect federal funding. In other countries, such as Germany, the national government takes a more active role. In order to develop an effective, single VET curriculum, the German Federal Ministry of Education and Research (BMBF) assessed the current and anticipated skills needed by nanotechnology workers. Following this, the BMBF began to modernize the existing curriculum for trades related to nanotechnology and set up new interdisciplinary degree programs and continuing education programs. They also work to promote a strong relationship between VET schools and the businesses that employ those graduates. Government plays a role in promoting relevant employment opportunities that VET can provide to secondary school students and current workers [47.32].

Other countries should follow this example. An assessment of relevant skills needed for industrial nanotechnology workers would provide guidance to schools seeking to create and maintain effective VET programs. Without ongoing assessment of these needs, educators will only react, often slowly, rather than be proactive in designing curricula to better suit their students.

Attendees at a 2014 National Science Foundation (NSF)-sponsored workshop, Nanoscale Science and Engineering Education: The Next Steps, identified several areas of improvement for vocational training [47.33]. Academic researchers and educators from many countries, policy makers, and representatives from other US funding organizations noted that a best practices manual that builds on existing VET programs could contribute to the effort to create nationwide programs that are sufficiently rigid to ensure a consistent quality of education and training in all areas, but sufficiently flexible to account for local and regional technical needs. General recommendations from the NSF workshop recognized the need to promote the societal impacts and interdisciplinary nature of nanotechnology education as a way to increase diversity in the student population.

A third area of growth is the dissemination of research studies and descriptions of successful VET programs. There are very few reports of nanotechnology programs for vocational training in the literature. This could be due to a lack of attention paid to vocational education by education researchers or the relatively low numbers of nanotechnology vocational programs compared to bachelor's and graduate degree programs. Whatever the cause, this should become less of a problem as the need for technicians of nanotechnology-related instrumentation and infrastructure increases.

47.3.2 Vocational Education Training in North America

There are two strong examples of vocational-level programs developed by postsecondary education institutions in the United States. The first example is the one-semester, 18 credit-hour capstone style program pioneered by Pennsylvania State University (Penn State). This program is intended to complete a student's vocational or bachelor's degree at a home institution by drawing traditional, foundational education disciplines together and integrating nanotechnology into them. In addition to this capstone program, Penn State developed the Nanotechnology Applications and Career Knowledge (NACK) network to develop a standardized curriculum to assist vocational institutions in those foundations, as well as to train practitioners.

The second example is the program developed by the Dakota County Technical College (DCTC) in Rosemount, Minnesota [47.34]. Inspired by information at a National Career Path Network conference, DCTC administrators began asking local industry (including such businesses as 3M, Honeywell, Synovis, Hysitron, General Mills, Seagate, Medtronic, among other, smaller companies) what they needed in vocational-level training for students. As a result of their inquiries, DCTC developed their Associate of Applied Science (AAS) degree Nanoscience Technician program in 2004, the first such two-year program in the US. This program takes a multidisciplinary approach to teaching not only tool usage and practical applications, but critical thinking capabilities as well. Developed from this program, and with funding from the NSF, DCTC created Nano-Link in 2008 to guide and mentor schools in the evaluation and validation of nanotechnology content.

The Northern Alberta Institute of Technology (NAIT) offers the first Nanotechnology Systems degree program in Canada [47.35]. Many of the 24 courses students complete are traditional subjects (e.g., chemistry, physics, biology, math, and materials science), some of which have an emphasis on nanotechnology. They also complete courses in manufacturing, project management, cleanroom practices, and a capstone project. Nanotechnology courses cover synthesis, characterization, and lithography. Students gain experience working in a cleanroom and in instrumentation such as a scanning electron microscope. They also visit industrial nanotechnology facilities in the area. The program advertises that students will have skills needed in the pharmaceuticals, electronics, manufacturing, and energy industries.

47.4 Undergraduate Education

Advancing nanotechnology skills and understanding requires comprehensive inclusion in four-year undergraduate programs. Existing nanotechnology courses and curricula can be incorporated into traditional science and engineering majors. Additionally, interdisciplinary nanotechnology majors may provide more focused education for interested students. Research opportunities may enhance the experiences of students both in terms of content and cultural awareness, and may provide impetus to continue to graduate school.

47.4.1 Different Models of Undergraduate Education in Australia

Two Australian schools are among the first in the world to offer Bachelor of Science degrees specializing in nanotechnology. Flinders University began offering its degree program in 2000 and the University of New South Wales started its degree program in 2002 [47.36]. Both degrees were developed by faculty in multiple disciplines to teach the relevant nanotechnology course material, important business skills, and soft skills such as communication and teamwork. Enrollment by Australian college students in science was not growing as fast as expected and nanotechnology was viewed as a potential way to attract more students to this cutting-edge field.

Although the goals and development of the two degrees have similarities, they are based on different models. Flinders University created a nanotechnology degree program housed entirely within a single school, the School of Chemistry, Physics, and Earth Science, with no others involved. This is the traditional and most common scenario for introducing new degrees. It allows more tight control over the curriculum by a single group of faculty and administrators. There are fewer stakeholders involved, which simplifies the decision making process. All students and faculty involved in the single-school program share a common set of scientific vocabulary and share a common academic culture. However, the topics covered within the degree program are limited by the expertise, space, and equipment of the faculty and infrastructure of that particular school. It also diminishes the scope of what is truly a widely interdisciplinary field.

The University of New South Wales (UNSW) offers its nanotechnology degree through four schools: Chemistry, Physics, Materials Science, and Biotech-

nology and Biomolecular Science. This gives students a broader perspective of what the subject nanotechnology includes, especially biology (Flinders University does require students to enroll in a biology course but biology faculty are not involved in administering the program). More resources are available and more input from different disciplines can lead to better decisions. Disadvantages of this approach are the difficulty of administering the program and keeping independent schools working well together. Academic disciplines are traditionally located in separate departments or schools so it can seem somewhat unnatural for them to cooperate closely. Students belong both to many schools and also to none, so they lack a common cohort of peers.

A third school, the University of Technology, Sydney, followed a different path by creating its nanotechnology degree program in a separate school. It is controlled by a single administrative unit and students can identify a single school to which they belong – two of the benefits of a single-school approach. Although the degree program is housed separately from other disciplines, faculty do not teach duplicates of existing courses, such as materials science, to the nanotechnology students. Rather, the curriculum calls upon other schools to provide the many core STEM classes that the nanotechnology students need to complete. This is clearly efficient but the program coordinators must ensure that faculty teaching those other subjects (who are affiliated with other schools) continue to teach topics important to the nanotechnology curriculum. This problem and challenge of creating a new, independent administrative entity is solved with financial support from the university. Funding, in turn, represents a strong commitment by the university to the long-term success of the program.

Development of any nanotechnology degree, including the three discussed here, requires answering the question of what topics to include. Nanotechnology is a broad field with each of its constituent fields of chemistry, physics, biology, and engineering having a subfield of nanochemistry, nanophysics, etc. Not all students who are interested in nanotechnology will necessarily want to study all of these subjects, even if time were available. Both Flinders and UNSW elected to create a common first-year curriculum for all nanotechnology students that emphasizes basic sciences and mathematics. Students can pursue more specialized tracks with more specialized classes in engineering, math, and science during subsequent years. At Flinders University, students choose between biodevices and nanostructures starting in their second year. Students at UNSW can select an emphasis in bionanotechnology, molecular electronics, or nanomaterials beginning in their third year. Many classes appear in the curricula of both tracks. The University of Technology, Sydney, follows a more general curriculum for its students with individual classes, such as nanoscale electronics and bionanotechnology, which Flinders and UNSW students can study in more depth.

A second challenge is how to offer all classes for a new degree program to students, given the practical and financial constraints that are encountered at every university. Students enroll in new classes created especially for the nanotechnology degree programs but these new courses account for only a small fraction (between ten and 17%) of the total number of credit hours that they must complete. For all three universities, the students begin their nanotechnology courses during the first year, some during their first semester in the program. This is important for several reasons. First, students may enter a program without knowing exactly what nanotechnology is, so it is important to correct any misconceptions as soon as possible. Students at Flinders and UNSW must choose a concentration for their degree during their second or third year respectively, so they need to know about the different aspects of nanotechnology as early as possible. Finally, faculty felt that nanotechnology could be a subject that increased student interest in science so they should not wait to introduce it.

Despite the very different designs of their nanotechnology programs, students at both Flinders and UNSW graduate and go on to successful careers in a variety of fields, including those outside of science. They also seek graduate degrees at a higher rate than students from other science programs.

47.4.2 Undergraduate Nanoscience Education in Switzerland

To address the need for a more interdisciplinary approach to nanotechnology education, the University of Basel Swiss Nanoscience Institute (SNI) offers a bachelor's degree in Nanoscience that prepares undergraduates for a graduate program in Nanoscience or in a traditional science field [47.37]. The flexible curriculum includes chemistry, physics, and biology courses. Additional classes teach students communication skills and discuss ethical dilemmas encountered in nanotechnology.

During the first semester of their Nanoscience program, undergraduate students enroll in Nano I, a seminar course that introduces them to nanotechnology research performed at the University of Basel. In the Nano II class taken in the second semester, students attend site visits to Swiss companies that are active in nanotechnology manufacturing and research so that they

can see the application of the course material learned in class. The remainder of their first-year courses are math, physics, chemistry, and biology. Second-year courses emphasize nanotechnology and physics. Students become more involved in a particular field of nanotechnology (e.g., nanophysics). These classes prepare students for research experiences gained in the third year. At that point, students enroll in a series of short (one to three week) courses taught at the University of Basel or partnering institutions. Students participate in ongoing research with faculty and graduate students. These research courses prepare students for graduate-level research, which they can pursue at the SNI as well (graduate nanoscience programs at the University of Basel are discussed in the next section). As with students in many STEM programs, they often cite the research experience as a highlight of their academic career. Students form a strong, supportive network among themselves and classes are often small. The three-year curriculum is rigorous so roughly half of the students switch to other science programs before graduating with a bachelor's degree. Those who go on to study for a master's degree are well prepared. Over the past five years, 76–100% of these students entering the Nanoscience master's degree have successfully completed the program.

47.4.3 Research Experience for US Undergraduate Students

Besides individual nanotechnology topics incorporated into traditional courses, separate nanotechnology courses, and academic major and minor programs, undergraduates should have the opportunity to perform undergraduate research. This is known to be an effective means for students to learn about STEM careers and remain interested in STEM subjects [47.38–41]. The US NSF funds a Research Experience for Undergraduates (REU), bringing 80–90 students from across US universities together each year at 14 National Nanotechnology Infrastructure Network (NNIN) sites for a summer research experience [47.42]. This provides students with nanotechnology-specific training and offers them an opportunity to present their work and develop professional connections for advanced research opportunities.

The NNIN REU program also has an international component [47.42]. The formation for such a program was in response to the recognition that competence in STEM fields is necessary but not sufficient. Students need to develop the ability to work with colleagues from other countries and cultures and address global STEM problems. Beginning in 2008, the most highly qualified REU participants were offered the opportunity to apply for an international research (i-REU) experience during the subsequent summer. These students perform nanotechnology research in the laboratories of NNIN partners located in Japan, France, Germany, Belgium, and The Netherlands. Students from previous years and NNIN staff members create online resources to help future cohorts. Students travel in groups to the partner institutions and spend eleven weeks performing research. The NNIN program funds their travel, stipends, and accommodations while the host university covers all research costs. Of the 40 to 45 applications, 12 to 15 students are selected each year for a total of 109 completed i-REU appointments. Most of those who have graduated went on to graduate school and a significant portion of those graduate students have received additional research awards. Approximately half of the i-REU participants are women and about a third attended smaller, nonresearch colleges or universities.

Given that the goal of the i-REU program is to develop culturally aware STEM students, the program was evaluated using an assessment tool from the Cultural Intelligence Center that measures cultural intelligence. This self-assessment survey evaluates a person's interest and enthusiasm for multicultural experiences; knowledge of business practices, values, and behaviors observed in different cultures; the ability to understand the person's own cultural knowledge and plan for multicultural encounters accordingly; and the ability to modify verbal and nonverbal communications in different cultural settings. Participants completed the survey prior to and after completing the i-REU program. They received feedback about their scores on the preprogram survey and these results can be used by the program leaders to help better prepare participants for their international research experience. Comparing pre- and post-summer tests, results improved from moderate to high levels in three of the four areas evaluated (knowledge, strategy, and action). Participants' scores for enthusiasm/interest initially were very high and increased slightly after they completed their i-REU appointments. It is clear that this experience greatly benefited the students by raising their cultural awareness.

47.4.4 Nanotechnology Education in South Africa

Nanotechnology research leads nanotechnology education in all countries but college-level curriculum materials, courses, and programs for nanotechnology are now well known in developed countries. This is not the case in the developing world. The need to train nanotechnology workers is still acute, especially given that nanotechnology can have a relatively greater

impact on the developing world by providing clean water, better medicines, and sustainable energy. In 2009, a senior-level, introductory nanotechnology course was taught in the School of Chemistry at the University of KwaZulu-Natal (UKZN) Pietermaritzburg, a leading South African university for chemistry students [47.43]. The course content was based on a course offered in the United States and it was taught by Dr. Brian Augustine, a professor at James Madison University. This arrangement was made possible through the Fulbright Program.

Students at UKZN can major in chemistry and chemical technology and enroll in an honors program. The curriculum is typical of any college-level chemistry degree. A new nanotechnology curriculum was introduced into a materials course taught in the chemical technology program. Students learned about quantum mechanics, material properties, characterization methods, lithography, self-assembly, and other topics. Case studies were used to teach DNA self-assembly, carbon nanomaterials, and nano-imprint lithography. For the laboratory portion of the course, students synthesized gold nanoparticles, imaged surfaces with an atomic force microscope (AFM), viewed AFM tips with an electron microscope, synthesized and determined the critical micelle concentration of amphiphilic molecules, and fabricated PDMS microcontact printing masters, which they then used to create microstructures on gold surfaces.

UKZN possesses chemical research instrumentation appropriate for a Ph.D.-granting university. Interestingly, a lack of basic, relatively inexpensive laboratory supplies was a challenge. Chemicals were also more expensive than in the United States, in part due to shipping fees. The class was taught in English and students had to write laboratory reports in English, but this did not have a significant effect on grades for students who learned English as a second language. Student performance in the class (as in other UKZN classes) correlated strongly with race. Low income and poor living conditions continue for black South Africans even after the official end of apartheid. This has a negative impact on their educational preparation for college. Since South Africa is more prosperous, these problems could be even more significant in other developing countries.

Three assessment instruments were used to evaluate students' learning and attitudes. The Nanotechnology Learning Outcomes Survey developed at Northwestern University was given at the beginning and end of the semester in order to measure students' attitudes about nanotechnology. Students completed a longer and more challenging multiple choice exam to determine their knowledge of nanotechnology at the beginning of the semester and as part of the third course exam. A size and scale assessment was included in the third exam also. Students in the new nanotechnology course at UKZN responded to the size and scale activity and the Nanotechnology Learning Outcomes Survey similarly to nonscience majors at Northwestern University in the US. The UKZN students made significant pre- to postsemester gains on the nanotechnology knowledge assessment. Students improved their knowledge related to general science questions, not just those addressing nanotechnology, suggesting that a nanotechnology course can help students learn more fundamental science information as well.

47.5 Graduate Education

The previously mentioned 2014 NSF workshop identified deficiencies in graduate training for nanotechnology including interdisciplinary education and diversity [47.33]. As well, the workshop noted that graduate programs will improve as the pipeline of students funneling into the programs are better equipped with foundational nanotechnology knowledge due to strengthening of nanotechnology education in the secondary and undergraduate levels. The University of California, Santa Barbara (UCSB), is addressing the deficiencies in interdisciplinary focus with a unique research opportunity. Nanotechnology graduate students are awarded fellowships and are embedded within social science and humanities social science projects. This arrangement reveals to students the connections between the laboratory and broader societal forces. Schools around the world take different approaches to the format, structure, and curriculum of graduate nanotechnology degrees. All seek to provide a program that addresses the interdisciplinarity of nanotechnology.

47.5.1 Nanoscience Graduate Program in Switzerland

The University of Basel's SNI, mentioned earlier, offers a Nanoscience bachelor's degree as well as both a master's and Ph.D. in Nanoscience [47.37]. The University of Basel was the first European university to offer both levels of nanoscience degrees. A master's program is required for students who wish to eventually earn a Ph.D. Students with an undergraduate degree in a traditional field of science pursuing the master's degree in Nanoscience may need to complete some undergraduate courses in order to qualify for entrance in

the program. Like the SNI undergraduate degree, the master's degree is designed to provide an interdisciplinary education. Students devote more than half of their efforts to studying nanoscience within the field of either molecular biology, physics, or chemistry, and must complete classes in fields outside of their chosen discipline. Most of their research is devoted to the completion of a thesis project but they also complete two smaller projects in different disciplines. The program lasts for a year and a half.

The Ph.D. program is unusual in its design. Science faculty at the University of Basel or faculty at other institutions (many outside of Switzerland) who collaborate with them can submit a research project idea to the SNI. A committee selects the projects to be supported. Each project requires both a faculty principle investigator (PI) and coPI. These faculty are frequently from different disciplines so most projects are inherently interdisciplinary. Based on the committee's recommendations, the research opportunities are advertised around the world to potential Ph.D. students. The ratio of applicants to positions is about 50 : 1.

47.5.2 Nanoscale Science and Technology Master's Program in Great Britain

Another example of a nanotechnology postgraduate degree is the Nanoscale Science and Technology master's program, taught for fifteen years at the University of Leeds in partnership with the University of Sheffield in the United Kingdom [47.44]. The joint program recently stopped admitting students due to a change in the university's focus. (The University of Leeds now offers a Nanomaterials and Materials Engineering graduate program.) This one-year Nanoscale Science and Technology master's program followed the typical three-year undergraduate degree. While most master's degrees narrow the student's academic focus on a particular STEM topic, this program widened the scope of study so that a student progressed from a bachelor's degree in any single science or engineering discipline to an interdisciplinary nanotechnology master's degree. Students learned about electronics, materials, biology, chemistry, and physics with the emphasis on the latter two fields. Individual courses were designed to be interdisciplinary, present advanced topics, and simultaneously provide the fundamental knowledge that some students might not possess due to their varied academic backgrounds. The faculty examined the bachelor's-level courses of applicants to the program in order to determine if they have the proper preparation. The curriculum was organized so that a single course covered a broad topic, such as characterization techniques, with both theoretical and experimental information. Top-down and bottom-up approaches to nanotechnology were covered in separate semesters.

Students' coursework was evaluated using a variety of methods, including presentations, exams, essays, and laboratory experiments. Experiments were designed to be relatively brief and not require advanced instrumentation or an inordinate amount of training before use. In addition to classes, students completed a research project. With multiple STEM departments from the two universities contributing, students chose one of many projects. Preparation for this began early in the program with the student selecting a topic (and several alternate choices) and planning the research in the first semester, then collecting and reporting preliminary results in the spring. The student completed the research during the summer and gave a presentation of the work. Prior to the fall semester, the student wrote a thesis. This curriculum could be modified to accommodate students wishing to pursue the master's degree on a part-time basis or a certificate was available if students did not wish to complete the entire program. The curriculum topics were also adaptable for short courses, which better suited the needs of industrial nanotechnology workers.

47.5.3 Laboratory Instrumentation Course in Taiwan

The interdisciplinarity of nanotechnology creates a challenge for faculty and staff who train students to operate research instruments [47.45]. Potential users start with a wide range of background knowledge and they have different needs for the instruments. The National Taiwan University addressed this problem by creating a graduate-level Applied Mechanics Laboratory course for students studying bionanotechnology. Course topics covered fluid mechanics, dynamics, mechanics of materials, and nanobiomechanics. There is some flexibility in the course topics so a student can customize the curriculum to match his or her interests. Course content includes theoretical background, operation of the instrument, and the interpretation of results for device fabrication. The nanoelectromechanical systems (NEMS), nanotechnology, and nanobiology teaching laboratories are all involved in the course. Faculty, research staff, technicians, and graduate students from each lab collectively play the role of facilitators for other graduate students enrolled in the class. In total, 50 faculty members from many departments and colleges were involved in developing the learning materials. A virtual portal for students to learn about the instruments is a major component. Online content includes recorded lectures, multimedia, digitized copies of printed manuals, demonstrations, and remote access to instruments. Since each student can choose different

course material to study, facilitators do not give organized lectures. Instead, they provide assistance to the students in the lab and expect the students to seek help when they need it. This self-paced learning environment is especially appropriate for graduate students who need to develop the intrinsic motivation to learn in order to succeed as independent researchers. Students are evaluated based on the quality of their lab work, written lab reports, and an oral exam.

Students responded favorably in a survey of their perceptions of the Applied Mechanics Laboratory course, including the course materials, virtual and face-to-face learning environments, and the quality of instruction. Students were less pleased with the way the instructors taught the course. This may be due to their expectation of a traditional lecture format, which was not used. Students took advantage of the online course content, especially for the experiments that they were most interested in learning. Student felt that the virtual portal improved their learning of both the principles of the instruments as well as the operations. They felt that the online information reduced the number of potential mistakes they might make. This is an important consideration when designing a hands-on laboratory instrumentation course.

47.5.4 Collaborative, Online Graduate Program in Israel and Europe

EduNano is a comprehensive, online academic program developed and supported by a consortium of universities in Europe and Israel [47.46]. Course material is available for professional development of K-12 teachers, undergraduate and graduate degree programs, and continuing education. The online structure of the program allows multiple collaborating institutions to teach geographically dispersed students. Six universities in Israel participate along with universities in Bulgaria, France, and Italy. An electronics company, Elbit Systems in Israel, is an active partner and provides an industry perspective. Faculty at each university prepare and contribute online courses covering all fields of nanotechnology. Students completing these courses at any of the universities receive equivalent credit towards their degree.

The curriculum was developed based on the availability of existing courses taught at the member universities, the perceived need for the courses by academic researchers and industry, and a list of agreed-upon learning outcomes. Learning outcomes state the expected tasks that students should accomplish upon completing the course and are an essential guide to developing curricula and assessment. Online class sessions consisted of video lectures, a combination of video lecture and slide show, and text-based information on a web page. Video lectures were created by recording regular, face-to-face class sessions, recording a lecture in a studio, or recording the lecturer sitting at a computer with the lecture video combined with animations, a slide show, or other imagery. Each of these approaches has advantages and drawbacks, depending on the subject matter being taught and the talents of the lecturer. Assessment of student performance may take place through traditional examinations if the students are all located near the school teaching the online course. If students are far from the school, they may complete another type of assignment, such as online quizzes and presentations given to the class using video conferencing software. The EduNano program recently completed its pilot test and began offering classes in 2016.

47.6 Teacher Professional Development

In order to further nanotechnology education, educator training is essential. Educators provide the technical content and encourage excitement and creativity. It is critical to attract and educate students in the growing field of nanotechnology in order to develop a trained nanotechnology workforce. Therefore, it is imperative to ensure appropriate and sufficient educator training.

Presently, education degree programs focus on traditional STEM fields without specific training in nanotechnology. Teachers typically learn one STEM subject in college and may teach only that subject. If they are not knowledgeable in another subject, they will hesitate to teach it. Therefore, postgraduate courses, summer classes, and professional development activities are necessary to help teachers learn about nanotechnology. Reviews of education research related to nanotechnology professional development and preservice teacher training provide more background on this subject [47.15, 47]. While education students (i. e., future teachers) could enroll in nanotechnology courses in college, a course specifically designed to address their needs as STEM teachers (rather than researchers) would be more useful.

There is a wealth of information available from a variety of sources on nanotechnology [47.13]. In many cases, the deficiency is in the packaging. Teachers seeking to stay up-to-date with nanotechnology do not have the time to find, organize, and learn new information on their own. Assembling the information into courses, short courses, or learning modules is time consuming,

but necessary in order to make the information accessible and to disseminate the information to those who need it quickly. Further, assembling the information into discrete packages allows for flexibility and targeted training.

47.6.1 Teacher Training in Israel

The Chemistry Department of the Weizmann Institute of Technology in Israel provides an example of such packaging. High school teachers seeking an advanced education degree can enroll in Introduction to Materials and Nanotechnology [47.48]. Lectures focus on the essential knowledge that students need in order to understand nanotechnology. These include a brief history of materials science, a qualitative description of quantum mechanics, and material characterization methods such as probe microscopy and x-ray measurements (instrumentation was selected based on its importance in nanotechnology and its availability at the university). These lectures are given by research faculty at the university and include visits to the research laboratory where the instruments are housed. Each student then selects a topic to study in greater depth. They share what they learned with the class in a lecture-style presentation and a report, including the history of the topic, its scientific description, technological applications, and contributions made by Israeli scientists. Nanotechnology research faculty provide opportunities for the students to work in their laboratories so that students receive an authentic research experience. While completing these assignments, students meet for weekly recitations where they can ask questions about the scientific information presented in class, their individual topic and presentation, and how to apply their new content knowledge to the classroom. Students complete pre- and postsemester quizzes that cover content knowledge taught in the course. In a study of this program's effectiveness, all participating students were current high school teachers seeking an M.Sc. degree for educators. Students initially scored low, but showed significant improvement on the postsemester quiz. In interviews, students related that they felt that they gained a lot from the course and they expressed greater confidence in their ability to teach nanotechnology to their students.

47.6.2 Teacher Training in South Korea

A short course offered in the Republic of Korea (South Korea) provides training for existing high school teachers to become more fluent in new fields of technology that appear in new editions of their students' textbooks [47.49]. Begun in 2006 at Chonbuk National University with 20 students enrolled, the program quickly grew to involve other university partners and now educates more than 500 students each year. The ten-day course devotes 40% of its time to nanotechnology, with biotechnology, environmental science and technology, and other activities each comprising 20% of the course. Teachers receive a lecture about a topic then perform a related laboratory experiment. Laboratory activities are especially important since college education in South Korea focuses on memorization of knowledge rather than gaining hands-on experience. Topics covered include structural properties of nanomaterials, lithography, imaging, optical properties of light-emitting diodes (LEDs), synthesis of a variety of nanostructures, and applications of these materials. The program has been well received by its students. A drawback to these courses is that students must be geographically close to the campus.

47.6.3 Online Education for Teachers

An alternative to a traditional face-to-face class is an online course, such as Nanoscience for Teachers conducted at the University of Wisconsin–Madison [47.50]. This course is exemplary for its well-designed structure, content, and emphasis on using education research findings to improve the learning of students (in this case, teachers). Because it is an online course, students from around the world could enroll in the class.

This graduate course helps middle and high school teachers learn the fundamental knowledge required for understanding nanotechnology and helps them to stay up to date on the current state of the discipline. The online course is taught asynchronously, so the students have greater flexibility in their schedules. Based on previous research of student learning in online environments [47.51], course designers created a structured, easy-to-follow format for the course in order to maximize student learning. Instructors provide many opportunities and means for communication among students and between the instructor and students, which leads to greater student satisfaction and is consistent with social constructivism pedagogy.

During the eight-week course, teachers learn about nanotechnology through readings and online discussions activities. They complete weekly quizzes to assess their learning. Each week, a guest lecturer provides more in-depth information about a nanotechnology topic via an online chat. Weekly topics include all of the Big Ideas discussed in Sect. 47.1.2, with a significant amount of time devoted to the occurrence of nanostructures in nature, societal impacts, and applications. Each student in the course develops a module that they could present to their own students. Some teachers create a se-

ries of short lessons that would be taught throughout the year, while others design a single, in-depth lesson about nanotechnology. The goal of this final project is similar to that of the assignment given to students in the face-to-face graduate course at the Weizmann Institute of Technology discussed previously but the format differs due to the online environment. Each student creates a complete lesson plan (documents or presentation slides) and uploads them to the course website. Students engage in anonymous peer review of their classmates' work.

Since most of the students in the class lived relatively close to the university, the instructors organized a site visit to the University of Wisconsin–Madison campus during the middle of the course. The visit consisted of a lab facility tour, instrument demonstrations, and laboratory activities, which teachers could perform with their students. Materials were posted online after the tour for the benefit of those who could not attend the site visit.

Student satisfaction was assessed with weekly surveys that allowed the instructors to make small modifications as the course progressed. The Constructivist On-Line Learning Environment Survey tool (COLLES) evaluates six aspects of a learning community: professional relevance, interactivity, peer support, instructor support, reflective thinking, and understanding between the instructor and students [47.52]. Results of COLLES collected prior to beginning the course (measuring students' expectations) and after completing it (measuring their view of the course experience) showed that the course met teachers' expectations held prior to beginning it with the exception of the degree of interactivity. Teachers showed statistically significant gains in content knowledge, based on pre- and postcourse quizzes. A follow-up survey conducted a year later revealed that most of the teachers actually did introduce their nanotechnology modules created in the online class to their students.

47.7 Informal Education

Education for the general public on the benefits of nanotechnology is an important part of improving nanotechnology education. This requires supporting and engaging in community-based opportunities for science and education and making them approachable, affordable, inclusive, and interesting. Currently, this is being done mostly by a mix of science museums and university groups, separately or in collaboration [47.53, 54]. In the US, these efforts are largely funded by the NSF.

A major effort has been carried out by the Nanoscale Informal Science Education Network (NISE Net) to organize and implement broadly informal nanotechnology education to the public at large [47.55]. Public understanding and attitudes affect the environment for research and development (R&D), reputation, and market acceptance of nanotechnology products [47.56], so informal education is an important area and requires funding. There is a need to expand informal science education to ensure that all corners of society are being engaged in these topics, especially from a young, formative age. Below are two examples of informal education programs that illustrate the range of ways to inform the public about nanotechnology – one is a single activity developed for a science festival and the other is a major museum exhibition.

47.7.1 Science Festival Activity in Israel

A one-hour activity, *It's a Small World After All*, was designed for an Israeli science festival [47.57]. Four hundred children participated, and assessment data was collected for 70 children, aged 9, 10, or 11. To evaluate any changes in knowledge and opinions of nanotechnology, each child engaged in personal meaning mapping (PMM), a process in which a person writes down (in text or pictures) all thoughts or known facts about a particular word, in this case *nanotechnology*, before the activity, and then again afterwards [47.58]. This is a quick process that shows how the learner's views and knowledge of the subject changes and the extent of the change. The activity introduced children to two topics: size and scale, and applications of nanotechnology, appropriate for children. Using pre- and postactivity PMM data, instructors measured changes in children's understanding of size and scale, applications, and the definition of nanotechnology as well as changes in their attitudes about nanotechnology. Children were not given any specific instructions about what to write on their maps.

Following best practices developed through education research, the designers used many teaching methods, such as experiments, videos, hands-on activities, demonstrations, and constructing models. Instructor-led presentations focused on analogies to help the young audience understand the relative sizes of nanoscale and everyday objects. To illustrate the vast difference between a value of 1 and 1×10^{-9}, children performed a ten-fold dilution of food coloring nine times. They wetted a cloth that contained nanoparticles that imparted a superhydrophobic property to its surface and

observed that the fabric remains dry. Children held and smelled used socks that remained odor-free due to copper nanoparticles embedded in the threads. They also received materials for building a cardboard fullerene structure.

Children and their accompanying families responded positively to the activity, based on their questions asked after the event was over. Children showed improvement in all four dimensions of the PMM assessment (definition, size and scale, applications, and attitudes). For all form categories, more boys showed an initial understanding or positive attitudes about nanotechnology than girls. After the activity, the difference between the number of boys and girls responding correctly or with positive attitudes had disappeared and in three of the four dimensions, more girls provided accurate responses or showed positive perceptions of nanotechnology. Based on a percentage of possible gain, children showed a 16% increase in providing a correct definition of nanotechnology (with all of the gain due to girls' responses), a 77% increase for size and scale understanding, a 59% increase in correct information about applications, and an increase of 40% in expressing positive attitudes. Since size and scale is a big idea of nanotechnology that all other big ideas build upon, it is noteworthy that the activity led to a majority of children understanding this concept [47.23]. No children expressed negative attitudes about nanotechnology in the postactivity PMM. It is clear that the use of multiple teaching methods as well as interesting and relevant examples and applications of nanotechnology in this one-hour event led to a significant, positive effect on the children's knowledge and attitudes about nanotechnology.

47.7.2 NanoAventura in Brazil

Museums around the world have developed various exhibits portraying nanotechnology phenomena that can be experienced by visitors of all ages. Exhibits can be located in a single museum or they can tour many locations. An example of the latter type is NanoAventura (NanoAdventure), a traveling exhibit developed by the Museu Exploratório de Ciências in Brazil in 2005. The hour-long exhibit was open to the general public and designed for a target audience of children aged 9–14. Guides led the audience as they viewed videos and played nanotechnology-themed games and simulations together and in smaller groups [47.59–61].

Size and scale, the composition of matter, and applications were viewed as important topics for introducing nanotechnology to the audience. Nanotechnology presents additional challenges to designing a museum exhibit due to the new terminology (e.g., *nano*) and lack of familiarity with nanoscale objects. To address this, an introductory video compared sizes of different objects with an emphasis on biological materials. The audience, originally consisting of up to 48 visitors, was divided into 12 member groups to play four video games.

Video games were chosen as a medium for learning because children and teenagers are often regular video game players. Games required all team members to work together but the game recorded both individual and group scores, providing cooperative and competitive aspects [47.59]. Topics for the four games are nanomedicine, removing impurities from a surface using AFM, a nanomanufacturing assembly line, and a virtual tour of UNICAMP research facilities.

Previous studies of the public's attitudes towards nanotechnology indicate that a positive view is associated with the expectation that nanotechnology will improve their quality of life [47.62]. Medicine is a field that is associated with quality of life and one that nanotechnology can improve. Therefore, the NanoAventura designers felt that medicine could be a concept that would keep the audience's attention. Also, biological cells were often cited by participants as the smallest object they know about so this was viewed as a useful reference point for presenting nanoscale objects.

Not surprisingly, the general public was found to lack a basic understanding of these topics. An evaluation of NanoAventura showed that visitors more frequently provided correct answers to questions about the particulate nature of matter and applications of nanomaterials after completing the exhibit [47.61, 63]. They also changed their description of a material's composition from stating its origin (e.g., sugar is made of sugar cane) to an answer that included atoms and molecules. Visitors more often favorably associated nanotechnology with scientific advances, progress, and the future. Overall, they found the exhibit interesting and educational.

47.8 Summary and Outlook

Nanotechnology is an area of rapid growth in research, development, and production. Nanotechnology R&D and applications affect industry, academia, and consumers as well. Unfortunately, the demand for scientists, engineers, and skilled workers worldwide in nanotechnology has outpaced the supply. Additionally, research has shown a fundamental lack of nanoliteracy in the general public, further reducing the likelihood of students choosing to study nanotechnology. In order to meet the demands of the burgeoning fields, an increase in the numbers of researchers and technicians available is required, and to that end, formal and informal education efforts have been implemented in various locations around the world. These efforts have targeted all levels of education, from primary and secondary through technical and university-level education, and including continuing education for educators and informal education for the general population. The goals of introducing students to nanotechnology are to fill the jobs that require an educated and skilled workforce and to promote science literacy in the general population who participate in policy decisions and engage with nanotechnology applications as consumers. This chapter has identified creative ways of increasing excitement, creativity, content retention, and improving attitudes towards nanotechnology in potential students at all levels. Various strategies have been used to make education inclusive, accessible, and culturally relevant to students of all ages.

In the primary and secondary school arena, Taiwan, Italy, and Germany have implemented programs to increase nanotechnology understanding. In Taiwan, a field trip to Ilan University was created to engage students in hands-on lab activities promoting better awareness and understanding of nanotechnology. In Italy, educators aimed to combine content learning and soft skills to provide students a broad nano-experience. Additionally, secondary students learned by teaching, in that they researched and prepared lessons to teach to primary students. This promoted the content understanding, as well as communication, teamwork, and problem-solving skills. In Germany, the government implemented a traveling exhibit bringing hands-on nano-experience of materials and applications to students. The exhibit encouraged basic science and nanotechnology mastery with educator support, as well as industry-supported curricula with online support for additional learning opportunities. The EU examined such programs resulting in NanoEIS reports on the strengths and opportunities of them. The reports identified that compulsory activities with a lack of hands-on interaction were common, and that there was low community support and variable industry support. Opportunities exist for university and industry involvement to promote transition to university study, an objective sorely needed as current programs show this transition is difficult in the nanotechnology arena. Further, exposure to nanotechnologies and support for educators could increase successes of programs and further funnel students to technical and university STEM programs.

VET, Penn State, DCTC in Minnesota, and NAIT in Canada have created unique programs and opportunities. Penn State has created a capstone program for vocational and bachelor's degree students that inserts nanotechnology into foundational disciplines. Further, Penn State developed the NACK network to advance vocational education in nanotechnology. The DCTC relied heavily on industry needs to create a technician training program that combines hard content skills with soft skills of problem solving and critical thinking. The program serves as a model to others, encouraging local industry inquiry to tailor the program to local needs. NAIT's Nanotechnology Systems degree focuses on not just traditional content subjects, but also applied knowledge courses such as project management and manufacturing. These examples provide a foundation, but improvement in VET is needed in the development of best practices manuals and development of national curricula with sufficient rigidity to promote learning and flexibility to meet local needs. As well, diversity of the student population should be encouraged.

Undergraduate education initiatives have taken a variety of forms around the world. Australia, Switzerland, the US, and South Africa have all tackled the problem of nanotechnology education at this level. In Australia, Bachelor of Science degrees in nanotechnology were created at Flinders University and the UNSW, among the first of their kind in the world, by drawing together faculty and curricula in several existing departments. The University of Technology, Sydney also created a degree program, but did so by creating an entirely new department. These degree programs create specialized nanotechnology education, deepening students' understanding. The University of Basel's SNI improved the interdisciplinary approach with a B.S. in Nanoscience. Traditional content is combined with soft skills. Short courses emphasize specialized and cross-disciplinary content, with a research emphasis. Strong support for transition to graduate education was indicated. The US NSF has created a national summer REU providing training, research education, presentation skills, and professional development connections in nanotechnology for undergraduates. If students excel, they may pursue an international version of the program

in the subsequent summer. The international program is aimed to position US students to solve global problems on a global stage by developing culturally aware STEM students. Assessment showed significant improvements in knowledge, strategy, and action in participants. In South Africa, rather than a separate degree, the UKZN elected to develop a course in nanotechnology for chemistry students as a way to introduce the topic in the developing world. Not surprisingly, socioeconomic disparity and cultural disparities played a role in the outcomes of the program. Despite these successful programs, opportunities at the undergraduate level exist in the need to promote interdisciplinary cooperation, societal impacts, and diversity in the student population.

At the graduate level, UCSB, the University of Basel, universities in the United Kingdom, the National Taiwan University, and a consortium of European and Israeli universities have all developed interesting approaches. UCSB has embedded graduate students in nanotechnology Ph.D. programs into social science and humanities projects to reveal connections between the laboratory and broader societal forces. Further, the program promotes strong cross-disciplinary cooperation. The University of Basel's SNI graduate program covers both master's and Ph.D. students. At the master's level, students must complete a thesis in their chosen discipline, as well as complete two projects that are strongly cross-disciplinary in nature. The Ph.D. program is project driven, in that faculty PIs and coPIs propose projects, gain approval from the SNI, and then advertise worldwide for project positions (Ph.D. student openings). In this way, the projects drive the student selection. At the University of Sheffield and University of Leeds, a master's in Nanoscale Science and Technology broadens, rather than concentrates, an undergraduate degree in a single science to an interdisciplinary master's. Courses focus on cross-disciplinary topics, rather than scientific categories, e.g., characterization techniques, rather than chemistry. At the National Taiwan University, the need for students to learn instrumentation techniques coming from different science backgrounds is being addressed. The course created for biotechnology students flips the classroom: reading and study materials are examined outside the classroom, and classroom time is focused on implementation of learning, with instructor support. The European-Israeli consortium is developing an online program for continuing education incorporating university educators and researchers with industry-partnering support. Online classes include video lectures and/or text-based information (slides or web content), with first classes beginning in 2016. Missing from all these programs is an opportunity to address diversity and inclusion. While some programs target worldwide audiences, little effort can be seen in the programs identified to target all corners of society and all cultural and socioeconomic backgrounds.

In the area of professional development, the Weizmann Institute of Technology in Israel, Chonbuk National University in South Korea, and The University of Wisconsin–Madison in the US have all identified strategies for teacher professional development. At the Weizmann Institute, teacher training in their university education includes a focus on learning by teaching with essentials in nanotechnology knowledge, and then projects to increase broad understanding. The program features a laboratory research experience to provide hands-on education. At Chonbuk National University, a short course for existing high school teachers with lectures on a topic and then a laboratory experience implementing the topics has been developed. The hands-on nature of the laboratory experience is essential in South Korea where an overall lack of hands-on focus exists in education. The University of Wisconsin–Madison developed an online course *Nanoscience for Teachers* with readings, online discussions, weekly quizzes, and guest lecturers for each topic. Teachers developed a module for their own classrooms, tailored to their teaching style and the needs of their students, then anonymously peer reviewed their classmates' modules for improvement opportunities. Strong assessment showed significant gains in content knowledge. While there is a wealth of information and content for professional development currently existing, the problem is in the packaging. Materials need to be packaged for flexibility and targeted training. Further, the university education for teachers needs to be designed to meet their needs as STEM educators, rather than researchers.

In the area of informal education, Israel and Brazil provide examples of bringing nanotechnology to the general public. In Israel, a one-hour activity was developed for a science festival for children aged 9–11, and included presentations and hands-on activities. The activity focused on concepts of size, scale, and applications. Age-appropriate assessment showed significant gains in understanding of size and scale, applications, and attitudes towards nanotechnology. In Brazil, a traveling museum exhibit featuring a one-hour interactive activity was aimed at children ages 9–14, and focused on using existing public competencies in size and application to leverage new understandings and knowledge. Participants watched videos and then played nanotechnology-themed video games. Cooperative and competitive learning was highlighted, and assessment showed gains in understanding of size and applications. In general, it seems that most informal education is aimed at younger audiences, who may already be exposed to these subjects and ideas in other arenas, such

as formal schooling. A significant opportunity exists to educate an older population that may not have formal education opportunities or interest in nanotechnology. To promote the goal of nanotechnology literacy, development of programs aimed at adult populations should be encouraged.

About the Authors

Aditya Aryasomayajula

McMaster University
Dept. of Mechanical Engineering
Hamilton, Canada
adityaarya83@gmail.com,
aryasoma@mcmaster.ca

Chapter C.16

Dr Aditya Aryasomayajula received his PhD in Electrical Engineering from the Technical University Dresden. He worked as a Postdoctoral Fellow at the European Molecular Biology Laboratory on microfluidics and genomics, before joining McMaster University as a Postdoctoral Fellow researching microfluidics, electrochemical sensors, and bio-sensing technology.

W. Robert Ashurst

Auburn University
Dept. of Chemical Engineering
Auburn, USA
ashurwr@auburn.edu

Chapter I.39

Dr W. Robert Ashurst is currently the Uthlaut Family Associate Professor of Chemical Engineering at Auburn University. He received his PhD in Chemical Engineering from the University of California at Berkeley. His research focuses on design of molecular precursors for advanced monolayer films, tribology at the micro and nanoscale, and the influence of surface chemical treatments on micro and nanoscale devices.

Massood Z. Atashbar

Western Michigan University
Dept. of Electrical & Computer Engineering
Kalamazoo, USA
massood.atashbar@wmich.edu

Chapter A.3

Professor Massood Z. Atashbar received degrees in Electrical Engineering from Isfahan University of Technology and Sharif University of Technology and in 1998 a PhD from RMIT University, Melbourne. After a postdoctoral at Pennsylvania State University, University Park, he joined the Electrical and Computer Engineering Department at Western Michigan University, where he currently is a Professor. His research interests include physical and chemical microsensors development, advanced signal processing, and engineering education.

Wolfgang Bacsa

Centre National de la Recherche Scientifique, Université de Toulouse
Centre d'Elaboration de Matériaux et d'Etudes Structurales (CEMES), UPR #8011
Toulouse, France
wolfgang.bacsa@cemes.fr

Chapter B.8

Professor Wolfgang S. Bacsa received his PhD from the Swiss Federal Institute of Technology (Zurich, 1990). He worked at Pennsylvania State University and Swiss Federal Institute of Technology in Lausanne and was a Visiting Professor at Boston University and at UNIST Korea. He is now a Professor at CEMES CNRS and the University of Toulouse. His research is dedicated to optical spectroscopy on nanostructured materials and novel optical microscopy techniques.

William S. Bainbridge

National Science Foundation
Division of Information & Intelligent Systems
Arlington, USA
wbainbri@nsf.gov

Chapter J.46

William Sims Bainbridge is the Director of the Cyber-Human Systems program of the National Science Foundation. He earned his PhD in Sociology from Harvard (1976). He has participated centrally in the Nanotechnology and Convergence activities and has co-edited and edited several books.

Antoni Baldi

Barcelona Microelectronics Institute (IMB-CNM-CSIC)
Chemical Transducers Group
Bellaterra, Spain
antoni.baldi@imb-cnm.csic.es

Chapter A.3

Dr Antonio Baldi received a degree in Telecommunication Engineering from BarcelonaTech (UPC) and a PhD in Electronics Engineering from Universitat Autònoma de Barcelona (UAB), followed by a postdoctoral at the University of Minnesota, working in the field of bioMEMS. In 2003, he joined the Chemical Transducers Group at the Barcelona Microelectronics Institute (IMB-CNM, CSIC). His current research is focused on electrochemical transducers and lab-on-a-chip devices for chemical sensing and biodetection.

Wilhelm Barthlott

University of Bonn
Nees-Institute for Biodiversity of Plants
Bonn, Germany
barthlott@uni-bonn.de

Chapter H.36

Dr Wilhelm Barthlott is a Professor Emeritus and former Head of the Biodiversity Institute at the University of Bonn. He is interested in structure, function, and biomimetic application of biological surfaces and has published more than 400 papers. His discovery of the Lotus Effect in 1997 has led to innovation in surface technologies. His current interests concentrate on air retaining surfaces and the relation between biodiversity and bionics.

Pouriya Bayat

York University
Dept. of Mechanical Engineering
Toronto, Canada
pouriya@yorku.ca

Chapter C.16

Pouriya Bayat obtained his BSc in Mechanical Engineering from Isfahan University of Technology. During his studies, he focused on bio-fluid mechanics. He joined the ACUTE Lab at York University in 2015, where he works on solution exchange of microparticles.

Mehmet Z. Baykara

Bilkent University
Dept. of Mechanical Engineering & UNAM
Ankara, Turkey
mehmet.baykara@bilkent.edu.tr

Chapter E.24

Mehmet Z. Baykara received his degree in Mechanical Engineering from Boğazici University and his PhD in Mechanical Engineering and Materials Science from Yale University. He is currently an Assistant Professor at the Department of Mechanical Engineering and the National Nanotechnology Research Center at Bilkent University, where he leads the scanning probe microscopy research group.

Bharat Bhushan Chapters 1, D.22, E.23, F.27, F.32–G.35, H.36–I.38, J.47 For biographical profile, please see the section "About the Editor".

Marcie R. Black

Advanced Silicon Group
Lincoln, USA
mrkarty@yahoo.com

Chapter B.9

Dr Marcie Black is the CEO of Advanced Silicon Group (ASG). ASG commercializes silicon nanowire arrays for applications, including black silicon solar cells, biosensors for less invasive testing, and lithium ion batteries. She has had over 25 patents issued and has numerous patents pending on using nanotechnology. Marcie earned her BS, MEng, and PhD degrees from the Massachusetts Institute of Technology.

Maarten P. de Boer

Carnegie Mellon University
Dept. of Mechanical Engineering
Pittsburgh, USA
mpdebo@andrew.cmu.edu

Chapter I.39

Dr Maarten P. de Boer received his PhD in Chemical Engineering and Materials Science from the University of Minnesota in 1996. His work at Carnegie Mellon University, and prior to that at Sandia National Labs, addresses challenges in tribology and thin film mechanical properties. Current research topics include reliability of nanomechanical switches, irradiation and mechanical properties of nanocrystalline metals, strength of semi-crystalline polymers, and adjustable coefficient of thermal expansion metamaterials.

Donald W. Brenner

North Carolina State University
Dept. of Materials Science & Engineering
Raleigh, USA
brenner@ncsu.edu

Chapter F.30

Professor Donald Brenner is a Kobe Steel Distinguished Professor of Materials Science and Engineering at North Carolina State University. He received his degrees in Chemistry from the State University of New York and Penn State University. His research interests focus on using atomic and multiscale modelling to develop and understand technologically important processes and materials.

Jean-Marc Broto

Centre National de la Recherche Scientifique, Institut National des Sciences Appliquées de Toulouse, Université de Toulouse
Laboratoire National des Champs Magnétiques Intenses de Toulouse (LNCMI-T), UPR #3228
Toulouse, France
jean-marc.broto@univ-tlse3.fr

Chapter B.8

Jean-Marc Broto is a Professor at the University Paul Sabatier Toulouse III. He is a specialist in electronic transport and magnetization properties under high magnetic fields and contributed to the discovery of giant magnetoresistance in 1988.

Patrizio Candeloro

University Magna Graecia of Catanzaro
Dept. of Experimental and Clinical Medicine
Catanzaro, Italy
patrizio.candeloro@unicz.it

Chapter D.21

Dr Patrizio Candeloro is an Assistant Professor in Physics at the University Magna Graecia of Catanzaro and a Senior Researcher at BioNEM laboratory. Throughout his scientific career, he worked in the field of micro and nanotechnologies for different purposes and applications. Currently, he develops plasmonic nanostructures for SERS spectroscopy and investigates the applications of Raman techniques to biomedical issues.

Brigitte Caussat

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Laboratoire de Génie Chimique (LGC), UMR #5503
Toulouse, France
brigitte.caussat@ensiacet.fr

Chapter B.8

Brigitte Caussat is a Professor at INP Toulouse, ENSIACET. Since 1991 she has been working on thermal chemical vapor deposition (CVD) processes, either on planar substrates or on powders. Her recent research activities have dealt with CNT oxidation in dry mode using gaseous mixtures containing ozone and CNT decoration by silicon, iron, nickel, and copper using the fluidized bed CVD process.

Chunying Chen

National Center for Nanoscience & Technology of China
CAS Key Laboratory for Biomedical Effects of Nanomaterials & Nanosafety
Beijing, China
chenchy@nanoctr.cn

Chapter J.45

Dr Chunying Chen received her PhD from Huazhong University of Science and Technology. She has worked at the Institute of High Energy Physics of the Chinese Academy of Sciences, the Medical Nobel Institute for Biochemistry at Karolinska Institute of Sweden, and at the National Center for Nanoscience and Technology of China. She was one of the earliest researchers in the field of nanosafety in China.

Rui Chen

National Center for Nanoscience & Technology of China
CAS Key Laboratory for Biomedical Effects of Nanomaterials & Nanosafety
Beijing, China
chenr@nanoctr.cn

Chapter J.45

Dr Rui Chen received his PhD from the Chinese Academy of Science in 2005. He has worked at the School of Life Sciences of Tsinghua University and at the National Center for Nanoscience and Technology of China. His research on nanoscience and nanotoxicology focuses on the risk assessment of nanomaterials to the environment and human health.

Yu-Ting Cheng

National Chiao Tung University
Dept. of Electronics Engineering
Hsinchu, Taiwan
ytcheng@mail.nctu.edu.tw

Chapter I.43

Yu-Ting Cheng received degrees in Materials Science and Engineering from National Tsing Hua University and Carnegie Mellon University and a PhD in Electrical Engineering from the University of Michigan Ann Arbor. In 2002, he joined the Department of Electronics Engineering at National Chiao Tung University. His research includes the fundamental study of materials for microsystem integration and MEMS applications, SoP, and the design and fabrication of microsensors and microactuators.

Mu Chiao

University of British Columbia
Dept. of Mechanical Engineering
Vancouver, Canada
muchiao@mech.ubc.ca

Chapter I.43

Mu Chiao received his degrees in Mechanical Engineering from National Taiwan University and the University of California Berkeley. After a postdoctoral at the Berkeley Sensor and Actuator Center and a position as Senior MEMS Engineer at Intpax Inc., he joined the Department of Mechanical Engineering of the University of British Columbia as an Assistant Professor. His current research interests include design and fabrication of MEMS and nanodevices for biomedical applications.

Ciro Chiappini

King's College London
Craniofacial Development and Stem Cell Biology
London, UK
ciro.chiappini@kcl.ac.uk

Chapter D.21

Dr Ciro Chiappini is a Lecturer in Nanomaterials and Biointerfaces at King's College London. He received a PhD in Biomedical Engineering from the University of Texas at Austin in 2011. He worked as Newton Fellow and Marie Curie Fellow at Imperial College London until 2016. Dr Chiappini develops functional interfaces for tissue engineering and precision medicine.

Lilia A. Chtcheglova

Johannes Kepler University Linz
Institute of Biophysics
Linz, Austria
lilia.chtcheglova@jku.at

Chapter E.25

Dr Lilia Chtcheglova received her PhD from the Swiss Federal Institute of Technology in Lausanne. Afterwards, she joined the group of Peter Hinterdorfer and continues to work at Johannes Kepler University and Center for Advanced Bioanalysis. Her research interest is focused on nanoscopic approaches in molecular recognition studies and their applications in molecular cell biology.

Alessandro Coclite

Italian Institute of Technology
Laboratory of Nanotechnology for Precision Medicine
Genova, Italy
alessandro.coclite@iit.it

Chapter D.21

Dr Alessandro Coclite received his PhD from Politecnico di Bari in 2015. He is now a Postdoctoral Fellow in the Laboratory of Nanotechnology for Precision Medicine. His research deals with the vascular transport of nanoconstructs via lattice Boltzmann-immersed boundary models, analyzing their properties in terms of shape, adhesive coating, and stiffness.

Maria Laura Coluccio

University Magna Graecia of Catanzaro
Dept. of Experimental and Clinical Medicine
Catanzaro, Italy
coluccio@unicz.it

Chapter D.21

Dr Maria Laura Coluccio received her PhD in Chemical and Materials Engineering from the University of Pisa. She worked at the Italian Institute of Technology, the University of Reggio Calabria, and the University of Pisa before joining the University Magna Graecia of Catanzaro. Her research focuses on nanotechnology applied to biomedicine, including membranes, plants for bioextractions, drug delivery, and tissue engineering.

Paolo Decuzzi

Italian Institute of Technology
Laboratory of Nanotechnology for Precision Medicine
Genova, Italy
paolo.decuzzi@iit.it

Chapter D.21

Professor Paolo Decuzzi is a Senior Researcher at the Italian Institute of Technology in Genova, where he founded the Laboratory of Nanotechnology for Precision Medicine in July 2015 with the support of a European Research Council Consolidator Grant. He investigates how to rationally design polymeric nanoconstructs for multi-modal imaging and combination therapy in cancer, cardiovascular, and neurological diseases.

Frank W. DelRio

National Institute of Standards & Technology
Material Measurement Laboratory
Boulder, USA
frank.delrio@nist.gov

Chapter I.39

Dr Frank W. DelRio is a Research Scientist in the Material Measurement Laboratory at the National Institute of Standards and Technology. His research interests include measurements and standards related to the elastic, plastic, fracture, interfacial, and transport properties of thin films and small-scale structures, with an emphasis on advance dmaterials in nanoelectronics, biomedical and health, and energy applications.

Enzo Di Fabrizio

King Abdullah University of Science and Technology
Dept. of Physical Science and Engineering
Thuwal, Saudi Arabia
enzo.difabrizio@kaust.edu.sa

Chapter D.21

Professor Enzo Di Fabrizio is a Full Professor at King Abdullah University of Science and Technology and Director of the BioNEM Laboratory at the University of Catanzaro. He is coauthor of more than 400 papers and inventor of more than 13 international patents. His scientific activity is interdisciplinary research between physics and biology, which includes basic and applied studies in nanotechnology.

Daniele Di Mascolo

Italian Institute of Technology
Laboratory of Nanotechnology for Precision Medicine
Genova, Italy
daniele.dimascolo@iit.it

Chapter D.21

Daniele Di Mascolo received his PhD in Biomedical and Computer Engineering from Magna Graecia University in 2014. He worked at the Houston Methodist Research Institute before joining the Italian Institute of Technology. His research focuses on nano and micro-drug delivery systems for the pharmacological treatment of different pathologies.

Lixin Dong

Michigan State University
Dept. of Electrical & Computer Engineering
East Lansing, USA
ldong@egr.msu.edu

Chapter C.18

Lixin Dong is an Associate Professor at Michigan State University. Prior to joining MSU in December 2008, he held a Senior Research Scientist position at ETH Zurich, where he led the NanoRobotics Group in the Institute of Robotics and Intelligent Systems. He is Associate Editor of IEEE Trans. on Nanotechnology and the IEEE Trans. on Automation Science and Engineering. His research interests include nanorobotics, nanoelectromechanical systems, mechatronics, and nanobiomedical devices.

Mildred S. Dresselhaus (deceased)

Chapter B.9

Professor Mildred Dresselhaus (1930-2017) received her PhD in Physics from the University of Chicago in 1958. She joined the MIT faculty in 1967. She was active in research across broad areas of solid state physics. Her research activities focused on carbon nanomaterials, transition metal dichalcogenides, and phosphorene. She received several major international awards in physics and 37 honorary degrees.

Andreas Ebner

Johannes Kepler University Linz
Institute of Biophysics
Linz, Austria
andreas.ebner@jku.at

Chapter E.25

Professor Andreas Ebner is an Associate Professor in the Institute of Biophysics at the Johannes Kepler University Linz. He received his PhD in Technical Chemistry from Johannes Kepler University Linz. After a postdoctoral fellowship at the Comenius University Bratislava he habilitated in bionanotechnology in 2016. His expertise lies in biosensing techniques, including AFM force spectroscopy and recognition imaging on biological samples.

Toshiaki Enoki

Tokyo Institute of Technology
Dept. of Chemistry
Tokyo, Japan
tenoki@chem.titech.ac.jp

Chapter B.10

Toshiaki Enoki has received his PhD from Kyoto University in 1974. He has worked at the Institute for Molecular Science in Japan and at Tokyo Institute of Technology. He is an honorary member of Ioffe Institute, Russia, and a Visiting Fellow of the Toyota Physical and Chemical Research Institute. His research in physical chemistry focuses on carbon-based nanostructures.

Haig Alexander Eskandarian

Swiss Federal Institute of Technology Lausanne (EPFL)
Dept. of Bioengineering
Lausanne, Switzerland
alex.eskandarian@epfl.ch

Chapter D.19

Dr Haig Alexander Eskandarian received his PhD from the Pasteur Institute in Paris, in 2013. He is a microbiologist working as an EMBO Long Term Post-Doctoral Fellow at the Swiss Federal Institute of Technology Lausanne (EPFL), in the microbiology lab of John D. McKinney and the bioengineering lab of Georg Fantner.

Georg E. Fantner

Swiss Federal Institute of Technology
Lausanne (EPFL)
Dept. of Bioengineering
Lausanne, Switzerland
georg.fantner@epfl.ch

Chapter D.19

Dr Georg Fantner received his PhD from the University of California Santa Barbara. After a postdoctoral position at MIT, he joined the faculty of the Swiss Federal Institute of Technology Lausanne (EPFL). His research focuses on the interface of micro/nanotechnology and biology. His group develops new time resolved scanning probe microscopy methods and related technologies, primarily for applications in life-science.

Philip X.-L. Feng

Case Western Reserve University
Dept. of Electrical Engineering &
Computer Science
Cleveland, USA
philip.feng@case.edu

Chapter C.13

Philip Feng is an Associate Professor for Electrical Engineering at Case Western Reserve University. His research is primarily focused on emerging nanoscale devices and integrated microsystems. He received a PhD from the California Institute of Technology. He is a recipient of the NSF CAREER Award and the NAE Grainger Foundation Frontiers of Engineering Award.

Emmanuel Flahaut

Centre National de la Recherche
Scientifique, Université de Toulouse,
Institut National Polytechnique de
Toulouse
Centre Interuniversitaire de Recherche
et d'Ingénierie des Matériaux (CIRIMAT),
UMR #5085
Toulouse, France
flahaut@chimie.ups-tlse.fr

Chapter B.8

Emmanuel Flahaut is a CNRS Senior Scientist and works at the CIRIMAT in Toulouse. After receiving a PhD in Materials Science from the University of Toulouse in 1999, he worked as a postdoctoral research fellow at ICL, University of Oxford. His research deals with nanocarbons (carbon nanotubes, graphene, and related materials), with a special focus on biomedical applications as well as potential health and environmental impacts.

Francesco Gentile

University Naples Federico II
Dept. of Electrical Engineering and
Information Technology
Naples, Italy
francesco.gentile77@gmail.com

Chapter D.21

Francesco Gentile is an Associate Professor at the University Federico II in Naples. He received his PhD in Biomedical Engineering from the University Magna Graecia of Catanzaro in 2008. Afterwards he worked at the Synchrotron Laboratories in Trieste, at the University of Texas-Houston, and at the Italian Institute of Technology, Genova. His research is within the field of biomedical nanotechnology.

Christoph Gerber

University of Basel
Dept. of Physics
Basel, Switzerland
christoph.gerber@unibas.ch

Chapter C.15

Christoph Gerber is a Professor in Physics at the University of Basel and an Emeritus Researcher in Nanoscale Science at IBM Rüschlikon. He has made major contributions to scanning tunneling microscopy and is co-inventor of the atomic force microscope, for which he was awarded the Kavli Prize in Nanoscience in 2016. His recent work is focused on biochemical cantilever array sensors based on AFM technology.

Thilo Glatzel

University of Basel
Dept.of Physics
Basel, Switzerland
thilo.glatzel@unibas.ch

Chapter F.29

Dr Thilo Glatzel received his PhD from the Free University of Berlin in 2003. His dissertation was focused on the nanoscale analysis of interfaces and surfaces of chalcopyrite thin film solar cells. Now, as a Senior Researcher at the University of Basel, his work focuses on high-resolution scanning probe microscopy of molecules on insulating and semiconducting surfaces.

Enrico Gnecco

Friedrich Schiller University Jena
Otto Schott Institute of Materials
Research
Jena, Germany
enrico.gnecco@uni-jena.de

Chapter F.29

Enrico Gnecco is Professor of Physics at Friedrich Schiller University Jena. He received his PhD from the University of Genova, and worked as Postdoctoral Researcher at the University of Basel and as independent Group Leader at IMDEA Nanoscience Madrid. His research focuses on nanoscale friction, scanning probe-based manipulation of metal clusters and nanocrystals, nanomechanisms of abrasive wear in polymers and glasses, and the influence of ultrasonic vibrations on friction.

Miroslav Haluška

ETH Zürich
Dept. of Mechanical & Process Engineering
Zurich, Switzerland
haluska@micro.mavt.ethz.ch

Chapter C.14

Dr Miroslav Haluška received his degree from the Slovak Technical University in Bratislava and his PhD in Physics from the University of Vienna. He was a Postdoctoral Fellow and Visiting Researcher at the Max Planck Institute, Wake Forest University, and Eindhoven University of Technology. In 2009, he joined the Micro and Nanosystems Group at ETH Zurich. His research includes the synthesis of SWCNTs, and their characterization and integration into nanosensors.

Judith A. Harrison

U.S. Naval Academy
Dept. of Chemistry
Annapolis, USA
jah@usna.edu

Chapter F.30

Judith A. Harrison is a Professor of Chemistry at the US Naval Academy. She received her degrees from St. Anselm College and the University of New Hampshire. Before joining the faculty of the Naval Academy, she was a Postdoctoral Associate at the Naval Research Laboratory. Her research focuses on the theoretical examination of nanometer-scale processes, such as indentation, friction, wear, and tribochemistry of hydrocarbon systems.

Martin Hegner

Trinity College Dublin
School of Physics, CRANN
Dublin, Ireland
martin.hegner@tcd.ie

Chapter C.15

Professor Martin Hegner received his PhD from the Swiss Federal Institute of Technology in Zurich. Since 2007 he has been a Professor in the School of Physics at Trinity College Dublin and Principal Investigator at the CRANN Nanocenter. Martin Hegner's scientific interests are focused on interdisciplinary research in the fields of single biomolecule manipulation, biophysics, diagnostics, and development and application of biological sensing devices.

Thomas Helbling

greenTEG AG
Zurich, Switzerland
thomas.helbling@greenteg.com

Chapter C.14

Dr Thomas Helbling received his MSc in Electrical Engineering from the ETH Zurich with a specialization in MEMS technology. In 2009, he received his PhD in Mechanical Engineering from ETH Zurich for the use of carbon nanotubes as strain gauge and gas sensing material. Since 2010 Thomas has been with greenTEG, a Swiss spin-off company from ETH Zurich that produces and sells thermal sensor solutions.

Seong-Jun Heo

Lam Research Corp.
Fremont, USA
heogyver@gmail.com

Chapter F.30

Dr Seong-Jun Heo is a Process Engineer in the Conductor Etch Division at Lam Research Corp. He received his degrees in Materials Engineering from Hanyang University in Seoul. He worked as a Research Engineer in the Semiconductor Division of Samsung Electronics, before pursuing his PhD at the University of Florida. He is interested in semiconductor processes as well as computational simulation related to nanotechnology.

Barbara Herr Harthorn

University of California Santa Barbara
Dept. of Anthropology
Santa Barbara, USA
barbara.harthorn@ucsb.edu

Chapter J.44

Professor Barbara Herr Harthorn received her PhD in Anthropology from the UCLA. She is Professor of Anthropology and the Director of the NSF Center for Nanotechnology in Society at the University of California at Santa Barbara, as well as an Executive Committee member of the UC Center for Environmental Implications of Nanotechnology at UCLA. Her research focuses on multi-stakeholder risk perception and public deliberation on societal aspects of new technologies.

Christofer Hierold

ETH Zürich
Dept. of Mechanical & Process Engineering
Zurich, Switzerland
hierold@micro.mavt.ethz.ch

Chapter C.14

Professor Christofer Hierold has been Professor of Micro and Nanosystems at ETH Zurich since 2002, after having worked with Siemens AG and Infineon Technologies AG. At ETH Zurich, his research is focused on the evaluation of new materials for MEMS, on advanced microsystems, and on nanotransducers, mainly carbon nanotube sensors. Christofer Hierold is a member of the Swiss Academy of Engineering Sciences.

Peter Hinterdorfer

Johannes Kepler University Linz
Institute of Biophysics
Linz, Austria
peter.hinterdorfer@jku.at

Chapter E.25

Peter Hinterdorfer is Head of the Department of Applied Experimental Biophysics at the Institute of Biophysics of Johannes Kepler University Linz. In 2001 he was appointed Associate Professor and in 2010 Professor at the Institute of Biophysics at Johannes Kepler University Linz. He is a recognized expert in single-molecule force spectroscopy and high-resolution topography imaging of biological samples and inventor of simultaneous topography and recognition imaging.

Maria Iliut

University of Manchester
School of Materials
Manchester, UK
maria.iliut@manchester.ac.uk

Chapter B.12

Dr Maria Iliut received her PhD in Physics from Babes-Bolyai University. She now works as a Research Associate at the University of Manchester. Her research focuses on the production, properties, and applications of graphene and other two-dimensional materials.

Douglas L. Irving

North Carolina State University
Dept. of Materials Science & Engineering
Raleigh, USA
dlirving@ncsu.edu

Chapter F.30

Douglas L. Irving is an Associate Professor of Materials Science and Engineering at North Carolina State University. He received his degree in physics from Furman University and his degrees in materials science and engineering from the University of Florida. His research focuses on the study of materials in extreme environments using theoretical and computational approaches that range from multi-scale to electronic structure methods.

Jacob N. Israelachvili

University of California Santa Barbara
Dept. of Chemical Engineering & Materials Dept.
Santa Barbara, USA
jacob@engineering.ucsb.edu

Chapter F.28

Jacob Israelachvili earned his PhD in 1971 at the University of Cambridge. He held positions in the Department of Applied Mathematics at the Australian National University before joining the faculty at the University of California, Santa Barbara in 1986 as Professor of Chemical Engineering and Materials. He is Fellow of the Royal Society of London and member of the US National Academy of Engineering and the National Academy of Sciences.

Esmaiel Jabbari

University of South Carolina
Dept. of Chemical Engineering
Columbia, USA
jabbari@cec.sc.edu

Chapter B.11

Esmaiel Jabbari is a Full Professor of Chemical and Biomedical Engineering and Director of the Biomaterials and Tissue Engineering Laboratory at the University of South Carolina. He received his PhD in Chemical Engineering from Purdue University and is a Fellow of AIMBE. His research focuses on the development of multi-cellular tissue models for applications in regenerative medicine and cancer therapy.

Anne Jourdain

IMEC
Leuven, Belgium
jourdain@imec.be

Chapter I.40

Dr Anne Jourdain received the MSc degree in Opto-Microelectronics from the Ecole Nationale Supérieure d'Ingénieurs de Caën. She received her PhD from the University Joseph Fourier of Grenoble. In 1999, she joined the Interuniversity Microelectronics Center (IMEC) in Leuven, where she was involved in the MEMS processing development. In 2000, she joined the RF-MEMS team and is currently in charge of the packaging of RF-MEMS devices.

Harold Kahn

Charlottesville, USA
hxkahn@gmail.com

Chapter I.41

Dr Harold Kahn received his BS in Metallurgical Engineering from Lafayette College and his PhD in Electronic Materials from the Massachusetts Institute of Technology. He retired as Research Associate Professor in Materials Science and Engineering at Case Western Reserve University in Cleveland, where his research focused on wafer-level mechanical testing of MEMS devices.

Gopakumar Kamalakshakurup

University of California Irvine
Dept. of Biomedical Engineering
Irvine, USA
gkamalak@uci.edu

Chapter C.17

Dr Gopakumar Kamalakshakurup received his PhD from Wayne State University. He worked at BioRad Laboratories, Lawrence Berkeley National Labs prior to joining the University of California Irvine as a Postdoctoral Fellow. His research includes developing microfluidic platforms for low cost diagnostics. His work on optofluidic tweezers has resulted in a US patent.

Roger D. Kamm

Massachusetts Institute of Technology
Depts. of Mechanical Engineering
& Biological Engineering
Cambridge, USA
rdkamm@mit.edu

Chapter F.31

Roger Kamm is the Cecil and Ida Green Distinguished Professor of Biological and Mechanical Engineering. He received his PhD in Mechanical Engineering from MIT, where he has stayed for his entire career. Roger Kamm's research focuses on the application of fluid and solid mechanics to better understand essential biological and physiological phenomena.

Josef A. Käs

University of Leipzig
Peter Debye Institute
Leipzig, Germany
jkaes@uni-leipzig.de

Chapter D.20

Professor Josef A. Käs is Head of the Soft Matter Physics Division at the University of Leipzig. He received his PhD from the Technical University of Munich and did postdoctoral work at Harvard Medical School. His research interests include all fields of cell biophysics with a particular focus on cellular biomechanics probed by optical traps, as well as soft matter physics.

Jongbaeg Kim

Yonsei University
School of Mechanical Engineering
Seoul, Republic of Korea
kimjb@yonsei.ac.kr

Chapter I.43

Jongbaeg Kim received his degrees in mechanical engineering from Yonsei University, the University of Texas Austin, and the University of California, Berkeley. After working with DiCon Fiberoptics, Inc., where he designed and developed high-performance optical MEMS components for telecommunication applications, he joined Yonsei University. He is Assistant Professor in the School of Mechanical Engineering. His research interests are modeling, design and fabrication of microsystems, and integrated nanostructures on MEMS.

Marcin Kisiel

University of Basel
Dept. of Physics
Basel, Switzerland
marcin.kisiel@unibas.ch

Chapter F.29

Dr Marcin Kisiel received his PhD from Marie Curie-Sklodowska University of Lublin. Currently, he is a Postdoctoral Researcher at the University of Basel. His research interest focuses on friction and energy dissipation at the nanoscale under ultra-high vacuum conditions and at low temperatures.

Kerstin Koch

Rhine-Waal University of Applied Science
Dept. of Life Science, Biology & Nanobiotechnology
Kleve, Germany
koch@hochschule-rhein-waal.de

Chapter H.36

Professor Kerstin Koch received her Diploma, PhD and Habilitation in Biology from the University of Bonn. Her main topics of research include molecular self-assembly, molecular architecture of plant surface lipids, biological surfaces, origin and functions of micro and nanostructures, and superhydrophobic and superhydrophilic biomimetic surfaces. Since 2009 she has been Professor of Biology and Nanobiotechnology at the Rhine-Waal University of Applied Science, Kleve.

Melanie Koehler

Université Catholique de Louvain
Institute of Life Sciences
Louvain-la-Neuve, Belgium
melanie.kohler@uclouvain.be

Chapter E.25

Melanie Köhler received her PhD in Biophysics from the Johannes Kepler University of Linz. Her research focuses on single-molecule force spectroscopy, high-resolution imaging, and mapping of biological samples. Currently, she is a Postdoctoral Fellow in the Nanobiophysics Group at the Université Catholique de Louvain.

Anders Kristensen

Technical University of Denmark
DTU Nanotech
Kongens Lyngby, Denmark
anders.kristensen@nanotech.dtu.dk

Chapter A.5

Professor Anders Kristensen received his PhD in Physics from the University of Copenhagen in 1994. He joined DTU Nanotech in 2001, where he investigates optofluidics – the integration of micro/nano photonics and fluidics for novel sensing and actuation schemes. Professor Kristensen has headed national and European research programs on advancing polymer nano and micro fabrication technology for industrial production. He has pioneered nano-imprint lithography in Denmark.

Jan Lammerding

Cornell University
Meinig School of Biomedical Engineering
Ithaca, USA
jan.lammerding@cornell.edu

Chapter F.31

Jan Lammerding is Associate Professor in the Meinig School of Biomedical Engineering and the Weill Institute for Cell and Molecular Biology at Cornell University. He received degrees from Dartmouth College, RWTH Aachen University, and the Massachusetts Institute of Technology. His research focuses on developing novel experimental techniques to investigate the interplay between cellular mechanics and function, with a particular emphasis on the cell nucleus and its response to mechanical forces.

Constanze Lamprecht

Johannes Kepler University Linz
Institute of Biophysics
Linz, Austria
constanze.lamprecht@gmx.de

Chapter E.25

Dr Constanze Lamprecht received her PhD in Biophysics from the Johannes Kepler University Linz. She worked as Postdoctoral Fellow at the University of Waterloo and the Christian-Albrechts-University of Kiel. She is currently affiliated again with the Institute of Biophysics at the Johannes Kepler University, where she uses AFM and fluorescence microscopy to study cell transformations that lead to the initiation and progression of cancer.

Hans Peter Lang

University of Basel
Dept. of Physics
Basel, Switzerland
hans-peter.lang@unibas.ch

Chapter C.15

Dr Hans Peter Lang received a PhD in Physics from the University of Basel in 1994. As Postdoctoral Fellow, he directed research on low temperature scanning tunneling microscopy in Basel, followed by work in the emerging field of nanomechanical cantilever array sensors at IBM Rüschlikon. At Basel University, he focuses on biochemical applications of cantilever array sensors.

Christophe Laurent

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Centre Interuniversitaire de Recherche et d'Ingénierie des Matériaux (CIRIMAT), UMR #5085
Toulouse, France
laurent@chimie.ups-tlse.fr

Chapter B.8

Christophe Laurent is a Professor of Materials Chemistry at the University of Toulouse and Director of the Interuniversity Center of Materials Research and Engineering (CIRIMAT). For over 20 years, he has dedicated his research to carbon nanotubes (CNTs), notably to the synthesis and characterization of double-walled CNTs and the preparation and properties of CNT-ceramic and CNT-metal nanocomposites in the form of powders, foams, and dense materials.

Abraham Lee

University of California Irvine
Dept. of Biomedical Engineering
Irvine, USA
aplee@uci.edu

Chapter C.17

Professor Abraham P. Lee is the William J. Link Professor and Chair of the Biomedical Engineering Department at the University of California Irvine. He is Director of the NSF I/UCRC Center for Advanced Design and Manufacturing of Integrated Microfluidics. Professor Lee is an Associate Editor for the Lab on a Chip journal and Fellow of the AIMBE and ASME.

Aeju Lee

Kumamoto University
International Research Organization for Advanced Science and Technology
Kumamoto, Japan
aeju-lee@kumamoto-u.ac.jp

Chapter D.21

Dr Aeju Lee received her PhD in Medicine from Korea University in 2013. She worked at the Korea Institute of Science and Technology and the Italian Institute of Technology, before joining Kumamoto University as an Associate Professor. Her research focuses on developing activatable NIR fluorescence imaging sensors, multimodality imaging, and therapy systems for early disease detection and therapy.

Dong Woog Lee

Ulsan National Institute of Science & Technology
School of Energy & Chemical Engineering
Ulsan, Republic of Korea
dongwoog.lee@unist.ac.kr

Chapter F.28

Dr Dong Woog Lee received his PhD from the University of California, Santa Barbara in 2014 and then did postdoctoral research at the same university. He is currently an Assistant Professor at Ulsan National Institute of Science and Technology (UNIST). His current research focuses on the adhesion and friction of bio and biomimetic materials. He received the Doh Wonsuk Memorial Award in 2013.

Stephen C. Lee

The Ohio State University
Dept. of Biomedical Engineering
Columbus, USA
lee.1996@osu.edu

Chapter D.22

Stephen C. Lee is a pioneer in the field of semi-biological nanodevices, having published the first monograph devoted to the topic in 1998. His interests are in enabling technologies for the incorporation of functional proteins and nucleic acids into nanodevices, particularly for application in oncology and cardiovascular disease. He is currently Associate Professor of Cellular and Molecular Biochemistry, Chemical Engineering and Biomedical Engineering at the Ohio State University.

Liwei Lin

University of California Berkeley
Dept. of Mechanical Engineering
Berkely, USA
lwlin@me.berkeley.edu

Chapter I.43

Liwei Lin is Professor in the Mechanical Engineering Department and Co-Director of the Berkeley Sensor and Actuator Center at the University of California Berkeley. His research interests are design, modeling, and fabrication of micro/nano structures, micro/nano sensors, and micro/nano actuators, and mechanical issues in micro/nano systems, including heat transfer, solid/fluid mechanics and dynamics. He led the effort to establish the MEMS division in ASME and served as its founding Chairman.

Matthias Mail

University of Bonn
Nees-Institute for Biodiversity of Plants
Bonn, Germany
matthias.mail@uni-bonn.de

Chapter H.36

Matthias Mail is a graduate physicist from the Karlsruhe Institute of Technology and doctoral student of Wilhelm Barthlott. He leads the working group on functional aspects of plant surfaces at the Institute of Crop Science and Resource Conservation at the University of Bonn. His main interests are structures, functions, and biomimetic applications of plant surfaces.

Othmar Marti

Ulm University
Institute of Experimental Physics
Ulm, Germany
othmar.marti@uni-ulm.de

Chapter E.23

Professor Othmar Marti is a specialist for scanning probe microscopy and optical force measurements. His current research is focused on life science (cell mechanics, cytoskeleton systems), optics, plasmonics, and combinations thereof. He is the Director of the Institute of Experimental Physics and a Chair for Experimental Physics at Ulm University.

Shinji Matsui

University of Hyogo
Laboratory of Advanced Science & Technology for Industry
Hyogo, Japan
matsui@lasti.u-hyogo.ac.jp

Chapter A.4

Dr Shinji Matsui is Professor at the University of Hyogo. He obtained his PhD degree in Electrical Engineering from Osaka University in 1981. Prior to joining the University of Hyogo, he worked at NEC Corporation. His significant work included the demonstration of electron-beam induced deposition and atomic-beam holography. His current research is focused on three-dimensional nanofabrication by focused-ion-beam chemical-vapor-deposition and nanoimprinting at room temperature.

Etienne Menard

HeliosLite
Le Bourget du Lac, France
etienne.menard@helioslite.com

Chapter A.6

Dr Etienne Menard received a PhD in Chemistry from the University *Pierre et Marie Curie* and the Department of Material Science and Engineering at the University of Illinois at Urbana-Champaign. He is the lead inventor of Semprius' core transfer printing technology. He is currently the Chief Technical Officer and co-founder of the company HéliosLite, which develops innovative solar trackers for high concentration photovoltaic systems and standard flatplate photovoltaic modules.

David Mesguich

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Centre Interuniversitaire de Recherche et d'Ingénierie des Matériaux (CIRIMAT), UMR #5085
Toulouse, France
mesguich@chimie.ups-tlse.fr

Chapter B.8

David Mesguich is an Assistant Professor for Materials Chemistry at University Paul Sabatier Toulouse III. He is part of the Nanocomposites and Carbon Nanotubes team in the Interuniversity Center of Materials Research and Engineering (CIRIMAT). Here he works on nanocarbon synthesis by catalytic chemical vapor Deposition and preparation of metal matrix nanocomposites and carbides, both as powders and bulk materials sintered by SPS.

Vincent Meunier

Rensselaer Polytechnic Institute
Dept. of Physics, Applied Physics, & Astronomy
Troy, USA
meuniv@rpi.edu

Chapter B.9

Professor Vincent Meunier is the Head of the Physics, Applied Physics, and Astronomy Department at Rensselaer Polytechnic Institute, where he holds the Kodosky Constellation Chair since 2010. He earned his PhD from the University of Namur. He has published approximately 200 papers in peer-reviewed journals and is a Fellow of the American Physical Society.

Ernst Meyer

University of Basel
Dept. of Physics
Basel, Switzerland
ernst.meyer@unibas.ch

Chapter F.29

Ernst Meyer is a Professor of Physics at the University of Basel. He is interested in friction force and dynamic force microscopy with true atomic resolution. He is active in the field of sensors based upon micromechanics and magnetic spin resonance detection with force microscopy. He is member of the Swiss and American Physical Society, of the Editorial Board of Tribology Letters, and co-editor of books on atomic force microscopy.

Tom D. Milster

University of Arizona
College of Optical Sciences
Tucson, USA
milster@optics.arizona.edu

Chapter E.26

Professor Tom D. Milster graduated with a degree in electrical engineering from the University of Missouri-Rolla and received a PhD in Optical Sciences from the University of Arizona. He worked for IBM Corporation before joining the University of Arizona in 1989. Professor Milster teaches physical optics and has active research programs in microscopy, lithography, and data storage.

Hiroaki Misawa

Hokkaido University
Research Institute of Electronic Science
Sapporo, Japan
misawa@es.hokudai.ac.jp

Chapter A.4

Hiroaki Misawa is a Professor at Hokkaido University. He received his PhD in Chemistry from the University of Tsukuba in 1984. Prior to joining Hokkaido University, he worked at the University of Tsukuba, Microphotoconversion project (ERATO) of JST, and the University of Tokushima. Since 2015, he has also been a Professor at National Chiao Tung University, Taiwan. He studies plasmonic chemistry.

Robert Modliński

EPCOS AG
Munich, Germany
robert.modlinski@epcos.com

Chapter I.40

Dr Robert Modliński received his degrees in electronics and microsystems from Wrocław University of Technology and KU Leuven. His main research activities are NEMS/MEMS and CMOS-MEMS integrated products with a strong focus on competitiveness, reliability and price, testing, and characterization. At EPCOS, a TDK Group Company, he focuses on failure mechanisms and degradation models to predict the remaining useful life of MEMS devices and RF front-end modules for mobile applications.

Seyedsina Moeinzadeh

University of South Carolina
Dept. of Chemical Engineering
Columbia, USA
moeinzad@email.sc.edu

Chapter B.11

Dr Seyedsina Moeinzadeh is a Postdoctoral Fellow at the University of South Carolina. He received his PhD in Chemical Engineering from the University of South Carolina for his research on the development of degradable nanostructured hydrogels for musculoskeletal tissue engineering. His primary research interests include tissue engineering, biomaterials, nanomaterials, polymers, and nano/microfabrication.

Mohammad R. K. Mofrad

University of California Berkeley
Depts. of Bioengineering & Mechanical Engineering
Berkeley, USA
mofrad@berkeley.edu

Chapter F.31

Dr Mohammad R.K. Mofrad is a Professor of Bioengineering and Mechanical Engineering at the University of California Berkeley. His research focuses on the development of molecular and multiscale models of cell mechanobiology, with the ultimate aim to shed light on human diseases. He received the National Science Foundation CAREER award in 2010 and the American Heart Association Innovative Research Grant Award in 2016. He is Fellow of AIMBE.

Marc Monthioux

Centre National de la Recherche Scientifique, Université de Toulouse
Centre d'Elaboration de Matériaux et d'Etudes Structurales (CEMES), UPR #8011
Toulouse, France
marc.monthioux@cemes.fr

Chapter B.8

Marc Monthioux has been working on carbon materials for over 35 years, including carbon nanoforms since 1998. He is Director of Research at the French National Center for Scientific Research in Toulouse, and served as Editor for the journal Carbon for 13 years. He is former Chair of the French Carbon Society, former Chair of the European Carbon Association, and was Chair of the World Conference on Carbon in 2009.

Markus Morgenstern

RWTH Aachen University
II. Institute of Physics B & JARA-FIT
Aachen, Germany
mmorgens@physik.rwth-aachen.de

Chapter E.24

Markus Morgenstern earned his PhD from the Institute of Interface Research and Vacuum Physics of the Forschungszentrum Jülich (1996). In 2002 he completed his habilitation at the University of Hamburg with the subject scanning tunneling spectroscopy on semiconductor systems and nanostructures. In 2004 he became Full Professor at RWTH Aachen University. From 2007–2014, he was Scientific Director of JARA-FIT, the Jülich–Aachen Research Alliance – Fundamentals of Future Information Technology.

Bradley J. Nelson

Swiss Federal Institute of Technology
Institute for Robotics & Intelligent Systems, ETH Zentrum, CLA H 1.1
Zurich, Switzerland
bnelson@ethz.ch

Chapter C.18

Brad Nelson is Professor and Director of the Institute of Robotics and Intelligent Systems at ETH Zurich. He received a PhD in Robotics from Carnegie Mellon University. In 2002, he became a Professor at ETH Zurich. His primary research direction lies in extending robotics research into emerging areas of science and engineering, with a special emphasis in the area of micro and nanorobotics.

T. Kieran Nunan

Kieran Nunan Consulting
Carlisle, USA
tknunan25@gmail.com

Chapter I.42

T. Kieran Nunan received his degree in electronics from the University of Limerick Ireland, while working with Analog Devices Inc. Kieran's career with ADI has landed him multiple roles on both sides of the Atlantic. He was the Engineering Group Leader in Diffusion CVD and TF manufacturing and also helps process development roles in BICMOS and MEMS, including managing the MEMS development group.

Pascal D. Odermatt

Swiss Federal Institute of Technology
Lausanne (EPFL)
Dept. of Bioengineering
Lausanne, Switzerland
pascal.odermatt@epfl.ch

Chapter D.19

Dr Pascal D. Odermatt received his PhD from the Swiss Federal Institute of Technology Lausanne in 2016. He is currently working at the University of California San Francisco and Stanford University as a Postdoctoral Scholar. His research focuses on studying functional and mechanical aspects of physiological processes at the nanoscale on a tissue and single-cell level.

Yoojin Oh

Johannes Kepler University Linz
Institute of Biophysics
Linz, Austria
yoo_jin.oh@jku.at

Chapter E.25

Dr Yoojin Oh received her PhD from Ewha Womans University in Seoul. She is currently working at the Institute of Biophysics, Johannes Kepler University Linz. Her main focus of research is the investigation of bacteria and their strategies to adhere to abiotic and biotic surfaces, and their capability of forming biofilms using different atomic force microscopy-based methods.

Anna Lisa Palange

Italian Institute of Technology
Laboratory of Nanotechnology for Precision Medicine
Genova, Italy
annalisa.palange@iit.it

Chapter D.21

Anna Lisa Palange received her PhD from the University Magna Graecia of Catanzaro in 2015. She is now a Postdoctoral Researcher in the Laboratory of Nanotechnology for Precision Medicine. Her actual interests deal with the synthesis, characterization, and in vitro and in vivo application of discoidal polymeric nanoconstructs for imaging and therapeutic studies.

Rémy Pawlak

University of Basel
Dept. of Physics
Basel, Switzerland
remy.pawlak@unibas.ch

Chapter F.29

Dr Rémy Pawlak received his PhD from the Aix-Marseille University in 2010. He is currently a Postdoctoral Fellow at the University of Basel. His research focuses on low-temperature investigations of single molecules and atoms by means of atomic force microscopy and scanning tunneling microscopy. He is particularly interested in high-resolution imaging and force spectroscopy.

Alain Peigney

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Centre Interuniversitaire de Recherche et d'Ingénierie des Matériaux (CIRIMAT), UMR #5085
Toulouse, France
peigney@chimie.ups-tlse.fr

Chapter B.8

Professor Alain Peigney is a Ceramic Engineer with a PhD in Physical Chemistry. He is an Associate Professor of Materials Chemistry at the University Paul Sabatier Toulouse III. His research encompasses the synthesis, sintering, and microstructural characterization of ceramics and ceramic matrix nanocomposites. Since 1994, he has been concentrating on the synthesis of single and double-walled carbon nanotubes and the preparation of nanocomposites containing carbon nanotubes.

Gerardo Perozziello

University Magna Graecia of Catanzaro
Dept. of Experimental and Clinical Medicine
Catanzaro, Italy
gerardo.perozziello@unicz.it

Chapter D.21

Dr Gerardo Perozziello works in the nanotechnology laboratory of the Department of Experimental and Clinical Medicine of the University Magna Graecia of Catanzaro, after receiving degrees in Mechanical Engineering and Micro- and Nanotechnology. His research interests and activities range from microfluidics to micro and nanofabrication technologies applied to biomedical issues.

Sandra Posch

Johannes Kepler University Linz
Institute of Biophysics
Linz, Austria
sandra.posch@jku.at

Chapter E.25

Sandra Posch received her PhD in Biophysics from the Johannes Kepler University of Linz. As a Postdoctoral Fellow, she studies the blood protein von Willebrand factor by AFM and SPR. In 2012, she visited the Institute of Biomedical Technology in Tampere to learn standard techniques of molecular biology. In 2013, she received the Upper Austria Research Award.

Robert Puers

KU Leuven
ESAT/MICAS
Leuven, Belgium
robert.puers@kuleuven.be

Chapter I.40

Professor Robert Puers is a Full Professor at KU Leuven.. In 1986, he became Director of the Clean Room Facilities for Silicon and Hybrid Circuit Technology at the ESAT-MICAS Laboratories of the same university. He was a pioneer in the European research efforts in silicon micromachined sensors, MEMS, and packaging techniques, for biomedical implantable systems as well as for industrial devices.

Oded Rabin

University of Maryland
Dept. of Materials Science & Engineering
College Park, USA
oded@umd.edu

Chapter B.9

Oded Rabin is an Associate Professor of Materials Science and Engineering at the University of Maryland. He earned degrees in chemistry from the Technion – Israel Institute of Technology and the Weizmann Institute of Science, and received a PhD in Physical Chemistry from the Massachusetts Institute of Technology. His research interests include electrical and thermal transport in low dimensional systems, plasmonic nanostructures for spectroscopy, and nanoparticles as biomedical contrast agents.

Françisco M. Raymo

University of Miami
Dept. of Chemistry
Coral Gables, USA
fraymo@miami.edu

Chapter A.2

Françisco M. Raymo is a Professor in the Department of Chemistry at the University of Miami. His research interests lie at the interface of chemistry and biology. In particular, he develops photo-switchable fluorescent probes to image biological samples with nano-scaled resolution and to monitor dynamic processes.

Manitra Razafinimanana

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Laboratoire des Plasmas et de Conversion de l'Energie (LAPLACE), UMR #5002
Toulouse, France
razafinimanana@laplace.univ-tlse.fr

Chapter B.8

Manitra Razafinimanana is a Professor in the Laboratory on Plasma and Conversion of Energy (LAPLACE – UMR 5213) at the University Paul Sabatier Toulouse III. He has worked on plasma diagnostics, transport coefficients, and calculation of thermodynamical properties. His research at LAPLACE focuses both on arc–material interaction and synthesis of nanomaterials by arc plasma.

Pouya Rezai

York University
Dept. of Mechanical Engineering
Toronto, Canada
pouya.rezai@lassonde.yorku.ca,
prezai@yorku.ca

Chapter C.16

Professor Pouya Rezai works in the field of bio-microfluidics. He was a Postdoctoral Fellow at the Public Health Agency of Canada before joining York University as an Assistant Professor in 2013. He received his PhD from McMaster University. His research interests include advancing microfabrication techniques to develop Lab-on-a-Chip for studying interactions between bio-substances and fluids in microenvironments.

Gemma Rius

Barcelona Microelectronics Institute
(IMB-CNM-CSIC)
NEMS & Nanofabrication Group
Bellaterra, Spain
gemma.rius@imb-cnm.csic.es

Chapter A.3

Dr Gemma Rius graduated from UAB. From 2002 to 2008, she was a Nanolithography Engineer and PhD student at the Barcelona Microelectronics Institute (IMB-CNM, CSIC). After postdoctoral work at the Toyota Technological Institute at Tohoku University and an Assistant Professorship at Nagoya Institute of Technology, she became a Beatriu de Pinós Postdoctoral Fellow at IMB-CNM and Principal Investigator for the SPS-NATO project RAWINTS, mainly working in applications of nanostructured materials.

John A. Rogers

Northwestern University
Dept. of Materials Science & Engineering
Evanston, USA
jrogers@northwestern.edu

Chapter A.6

Professor John A. Rogers received a PhD in Physical Chemistry from MIT. He was a Technical Staff Member at Bell Laboratories and served as Director of the Condensed Matter Physics Research Department there. He joined Northwestern University in 2016 as the Louis Simpson and Kimberly Querrey Professor of Materials Science and Engineering, Biomedical Engineering and Medicine, where he is the founding Director of the newly endowed Center on Bio-Integrated Electronics.

Cosmin I. Roman

ETH Zürich
Dept. of Mechanical & Process Engineering
Zurich, Switzerland
cosmin.roman@micro.mavt.ethz.ch

Chapter C.14

Dr Cosmin Roman received his MSc in Electrical Engineering from the Polytechnic University of Bucharest, and his PhD in Micro/Nanoelectronics from the National Polytechnic Institute of Grenoble for his work on modeling carbon nanotube sensors. Since 2006, he has been a Senior Researcher at ETH Zurich. His current research interests include micro and nanotransducers for energy-efficient sensor systems.

Marina Ruths

University of Massachusetts Lowell
Dept. of Chemistry
Lowell, USA
marina_ruths@uml.edu

Chapter F.28

Marina Ruths received her PhD from the University of California, Santa Barbara in 1996. She then did postdoctoral research at the University of Illinois at Urbana-Champaign, at the Max-Planck-Institute for Polymer Research in Mainz, and at Åbo Akademi University. Her current research includes friction, adhesion, and nanorheology studies of polymer, liquid crystal, and surfactant systems.

Hélder A. Santos

University of Helsinki
Division of Pharmaceutical Chemistry and Technology
Helsinki, Finland
helder.santos@helsinki.fi

Chapter D.21

Dr Hélder A. Santos obtained his degree in chemical engineering at the Helsinki University of Technology. Currently, he is an Adjunct Professor in Pharmaceutical Nanotechnology at the University of Helsinki. Dr Santos has published more than 160 scientific publications. He also serves as journal editor and is on the Editorial Board of several international journals.

Shintaro Sato

Fujitsu Laboratories Ltd.
Devices & Materials Laboratories
Atsugi, Kanagawa, Japan
sato.shintaro@jp.fujitsu.com

Chapter B.10

Shintaro Sato received his PhD from the University of Minnesota. He joined Fujitsu Limited in 2001. From 2010–2014 he was a group leader at the National Institute of Advanced Industrial Science and Technology. As a Research Manager at Fujitsu Laboratories Ltd. he now researches and develops nanoelectronics devises using graphene and carbon nanotubes.

Helmut Schift

Paul Scherrer Institute
Laboratory for Micro- & Nanotechnology
Villigen PSI, Switzerland
helmut.schift@psi.ch

Chapter A.5

Dr Helmut Schift is Head of the Polymer Nanotechnology Group in the Laboratory for Micro and Nanotechnology (LMN) at the Paul Scherrer Institute in Villigen. He received his PhD from the Institute of Microtechnology Mainz. His work includes all aspects of replication technology, from stamp manufacturing to polymer nanorheology. He has more than 20 years of experience in the development of nanoimprint lithography as an alternative nanopatterning method.

Jörg Schnauß

University of Leipzig
Peter Debye Institute
Leipzig, Germany
joerg.schnauss@uni-leipzig.de

Chapter D.20

Dr Jörg Schnauß received his PhD in Physics from the University of Leipzig. Subsequently, he joined the Division of Soft Matter Physics of the University of Leipzig and the Fraunhofer Institute for Cell Therapy and Immunology as a Postdoctoral Researcher. His research focuses on biological and biomimetic, semiflexible polymers. He transfers concepts to the cellular and subcellular level to explore new therapeutic approaches.

Alexander Schwarz

University of Hamburg
Institute of Nanostructure and Solid State Physics
Hamburg, Germany
aschwarz@physnet.uni-hamburg.de

Chapter E.24

Dr Alexander Schwarz belongs to the scientific staff of the Center of Microstructure Research at the Institute of Applied Physics at the University of Hamburg. He has over 20 years of experience in his field. He is a Senior Scientist and works on atomic-force microscopy with atomic resolution as well as related magnetically sensitive techniques, i.e., magnetic force microscopy and magnetic exchange force microscopy.

Udo D. Schwarz

Yale University
Dept. of Mechanical Engineering & Materials Science
New Haven, USA
udo.schwarz@yale.edu

Chapter E.24

Dr Udo D. Schwarz received his PhD from the University of Basel. Subsequently he moved to the University of Hamburg, specializing in low-temperature scanning force microscopy and nanotribology. After 1 year at the Lawrence Berkeley National Laboratory, he accepted a position as Associate Professor at Yale University and was promoted to Full Professor in 2009. Since 2012, he has been Chair of the Department of Mechanical Engeering and Materials Science.

P. Ravi Selvaganapathy

McMaster University
Dept. of Mechanical Engineering
Hamilton, Canada
selvaga@mcmaster.ca

Chapter C.16

P. Ravi Selvaganapathy is a Professor in Mechanical Engineering and the Canada Research Chair in Biomicrofluidics at McMaster University. He received his PhD from the University of Michigan in 2002 and worked at the Sandia National Laboratories. His research interests are in the development of microfluidic devices for drug discovery, drug delivery, diagnostics, and artificial organs.

Philippe Serp

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Laboratoire de Chimie de Coordination (LCC), UPR #8241
Toulouse, France
philippe.serp@ensiacet.fr

Chapter B.8

Philippe Serp has been Professor of Inorganic Chemistry at Toulouse University since 2005. His research interests include the preparation and use of nanostructured catalytic materials, a field in which he has published over 150 papers. He holds 20 patents and received Division Awards of the French Chemical Society in Catalysis (2004) and Industrial Chemistry (2012).

Sameer S. Shroff

Carnegie Mellon University
Dept. of Mechanical Engineering
Pittsburgh, USA
sshroff@alumni.cmu.edu

Chapter I.39

Dr Sameer S. Shroff received his degree in mechanical engineering from the University of Pittsburgh. He worked in the Micro and Nanomechanics Division of Professor de Boer at Carnegie Mellon University and received his PhD in 2015, where he was supported by the NSF Graduate Research Fellowship Program. He is currently employed by the Bechtel Marine Propulsion Corporation.

Mark G. da Silva

Analog Devices Inc.
High Performance Sensors
Wilmington, USA
mark.dasilva@analog.com

Chapter I.42

Dr Mark G. da Silva received his PhD from The Johns Hopkins University at Baltimore. He worked in academia at the University of Maryland and then in industry at Coventor, and Analog Devices in the US. Over the past 20 years, he has worked extensively in MEMS product development and currently manages development of breakthrough MEMS inertial sensor products for high performance applications.

Susan B. Sinnott

The Pennsylvania State University
Dept. of Materials Science & Engineering
University Park, USA
sbs5563@psu.edu

Chapter F.30

Dr Susan B. Sinnott is Professor and Department Head of Materials Science and Engineering at Pennsylvania State University. She received her PhD in Physical Chemistry from Iowa State University and was on the faculty at the University of Kentucky and the University of Florida. Her research focuses on the development and application of computational methods to design and develop new materials and to reveal structure–property relationships.

David M. Smith

Fraunhofer Institute for Cell Therapy & Immunology (IZI)
DNA Nanodevices Group
Leipzig, Germany
david.smith@izi.fraunhofer.de

Chapter D.20

Dr David M. Smith received his PhD for studies on phase transitions in active polymer networks from the University of Leipzig. After a postdoctoral at Ludwig Maximilian University of Munich focusing on DNA nanotechnology, he joined the Fraunhofer Institute for Cell Therapy and Immunology as the Head of the DNA Nanodevices Unit. His research explores new biomedical applications of DNA nanostructures and to study fundamental aspects of soft matter physics.

W. Merlijn van Spengen

Falco Systems
Amsterdam, The Netherlands
w.m.vanspengen@tudelft.nl

Chapter I.40

Dr W. Merlijn van Spengen is the Director of Falco Systems, a company that designs and manufactures technology leading high voltage amplifiers for company R&D, institutes, and universities worldwide. His part-time university research at the Technical University Delft blends physics, chemistry, electronics, and micromechanics to understand the reliability of micromachines. He received the prestigious Dutch Veni and Vidi grants.

Jürgen Strasser

Center for Advanced Bioanalysis GmbH
Linz, Austria
juergen.strasser@cbl.at

Chapter E.25

Jürgen Strasser studied medical and pharmaceutical biotechnology as well as biophysics, and is currently a PhD student at the Johannes Kepler University and the Center for Advanced Bioanalysis GmbH in Linz. His work involves the detailed biophysical investigation of immune responses in the human body using single-molecule force spectroscopy, high-speed atomic force microscopy and quartz crystal microbalance.

Yu-Chuan Su

National Tsing Hua University
Dept. of Engineering & System Science
Hsinchu, Taiwan
ycsu@ess.nthu.edu.tw

Chapter I.43

Yu-Chuan Su received his degree in power mechanical engineering from the National Tsing Hua University. He received his PhD in Mechanical Engineering from the University of California Berkeley. In 2004, he joined the National Tsing Hua University and is currently a Professor in the Department of Engineering and System Science. His research interests are design and fabrication of polymer-based nano and microfluidic systems for biomedical and energy related applications.

Quan Sun

Hokkaido University
Research Institute of Electronic Science
Sapporo, Japan
quansun@es.hokudai.ac.jp

Chapter A.4

Quan Sun is an Assistant Professor at Hokkaido University. He received his PhD in Physics from Peking University in 2006. Prior to working at Hokkaido University, he worked at Laval University, Canada, as a postdoctoral researcher. His main research interests include femtosecond laser micro/nanofabrication and nanophotonics.

Flavien Valensi

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Laboratoire des Plasmas et de Conversion de l'Energie (LAPLACE), UMR #5002
Toulouse, France
valensi@laplace.univ-tlse.fr

Chapter B.8

Flavien Valensi is an Associate Professor in the Laboratory of Plasma and Conversion of (LAPLACE – UMR 5213) in Toulouse. He received a PhD in Plasma Physics from Orleans University in 2007. Since 2009 his research at LAPLACE has been dealing with the experimental study of continuous and transient arcs, with applications such as synthesis of nanoparticles (carbon, metal) by arc plasma.

Derek Vallejo

University of California Irvine
Dept. of Biomedical Engineering
Irvine, USA
dhvallej@gmail.com

Chapter C.17

Dr Derek Vallejo received his PhD in 2016 from the University of California Irvine (UCI) under the guidance of Dr Abraham Lee. His thesis focused on the microfluidic production of biocompatible and storable vesicles and multisomes. Currently, Derek is a Postdoctoral Scholar in Dr John Chaput's laboratory at UCI, developing a microfluidic system for rapid directed evolution of XNA polymerases.

Aravind Vijayaraghavan

University of Manchester
School of Materials
Manchester, UK
aravind@manchester.ac.uk

Chapter B.12

Dr Aravind Vijayaraghavan received his PhD in Materials Engineering from Rensselaer Polytechnic Institute in 2006. He was an Alexander von Humboldt Fellow at the Karlsruhe Institute of Technology, before he started to work as a Lecturer in Nanomaterials at the University of Manchester. His research focuses on the production, properties, and applications of graphene and other two-dimensional materials.

Alicia Weibel

Centre National de la Recherche Scientifique, Université de Toulouse, Institut National Polytechnique de Toulouse
Centre Interuniversitaire de Recherche et d'Ingénierie des Matériaux (CIRIMAT), UMR #5085
Toulouse, France
weibel@chimie.ups-tlse.fr

Chapter B.8

Dr Alicia Weibel received her PhD in Materials Science in 2004. Since 2006, she has been an Assistant Professor at the University Paul Sabatier Toulouse III. Her research activities involve the synthesis, spark plasma sintering, and microstructural and mechanical characterization of ceramics and nanocomposites containing carbon nanotubes.

Kurt Winkelmann

Florida Institute of Technology
Dept. of Chemistry
Melbourne, USA
kwinkel@fit.edu

Chapter J.47

Kurt Winkelmann is an Associate Professor in the Chemistry Department at the Florida Institute of Technology. His research interests include kinetics of nanoparticle-catalyzed photochemical reactions, toxicology of engineered and naturally occurring nanoparticles, and chemical education research of student learning and attitudes in the teaching laboratory.

Darrin J. Young

University of Utah
Dept. of Electrical & Computer Engineering
Salt Lake City, USA
darrin.young@utah.edu

Chapter C.13

Darrin J. Young received his degrees and PhD from UC Berkeley. He pioneered RF MEMS high-Q tunable passive devices for wireless communications. He worked at the Electrical Engineering and Computer Science Department at Case Western Reserve University, before joining the Electrical and Computer Engineering Department of the University of Utah as USTAR Associate Professor in 2009. His research interests include MEMS design, fabrication, low power ASIC design, and microsystem integration.

Rong Zhu

Johannes Kepler University Linz
Institute of Biophysics
Linz, Austria
rong.zhu@jku.at

Chapter E.25

Dr Rong Zhu earned received his PhD in Biomedical Engineering from Southeast University in China. Currently he is working in Professor Hinterdorfer's group at the Institute of Biophysics of the Johannes Kepler University Linz, focusing on nanopharmacology and molecular recognition.

Babak Ziaie

Purdue University
School of Electrical & Computer Engineering
West Lafayette, USA
bziaie@purdue.edu;
ziaiebabak@gmail.com

Chapter A.3

Babak Ziaie received his PhD in Electrical Engineering from the University of Michigan in 1994. From 1995 to 1999 he was a postdoctoral researcher at the Center for Integrated Microsystems (CIMS) of the University of Michigan. He subsequently joined the Electrical and Computer Engineering Department of the University of Minnesota as an Assistant Professor. Since 2005, he has been with the School of Electrical and Computer Engineering of Purdue University, where he is currently a Professor. His research interests are related to BioMEMS and include implantable microsystems, micromachined interfaces with the central nervous system, and ultra-sensitive sensors for biological applications. Dr Ziaie is the recipient of the NSF Career Award in Biomedical Engineering (2001) and McKnight Endowment Fund Award for Technological Innovations in Neuroscience (2002), and a member of the IEEE and the American Association for the Advancement of Science.

Christian A. Zorman

Case Western Reserve University
Dept. of Electrical Engineering & Computer Science
Cleveland, USA
caz@case.edu

Chapters A.7, C.13

Christian A. Zorman is a Professor for Electrical Engineering at Case Western Reserve University with secondary appointments in Biomedical Engineering and Mechanical Engineering. He has authored over 250 peer-reviewed technical publications on topics related to the development of novel, enabling materials and the requisite processing techniques for MEMS and NEMS with an emphasis on applications in challenging environments.

Detailed Contents

List of Abbreviations XXXIII

1 **Introduction to Nanotechnology**
Bharat Bhushan 1
1.1 Nanotechnology – Definitions and Examples 2
1.1.1 Nanomanufacturing 2
1.1.2 MEMS/NEMS 2
1.1.3 Convergence 4
1.1.4 Industrial Applications 4
1.2 History and Early Research Expenditures 6
1.3 Governance of the National Nanotechnology Initiative 7
1.4 Nanotechnology R&D Funding Since 2001 8
1.5 Worldwide R&D Investments and Output 11
1.5.1 R&D Investments 11
1.5.2 Output 11
1.6 Translation of Basic Research to Technology Commercialization 15
1.7 Nanoscience and Nanotechnology Education 16
1.7.1 Interdisciplinary Education 16
1.7.2 K–12 Education, Excitement, and Creativity 16
1.7.3 Vocational, Undergraduate, Graduate, and Continuing Education Programs 16
1.7.4 Educator Training 17
1.7.5 Informal Science Education 17
1.8 Summary and Outlook 17
1.9 Organization of the Handbook 18

15 **Nanomechanical Cantilever Array Sensors**
Hans Peter Lang, Martin Hegner, Christoph Gerber 457
15.1 Technique 458
15.1.1 Cantilevers 458
15.1.2 History of Cantilever Sensors 458
15.2 Cantilever Array Sensors 459
15.2.1 Concept 459
15.2.2 Compressive and Tensile Stress 459
15.2.3 Disadvantages of Single Microcantilevers 459
15.2.4 Reference and Sensor Cantilevers in an Array 460
15.3 Modes of Operation 460
15.3.1 Static mode 460
15.3.2 Dynamic Mode 462
15.3.3 Heat Mode 463
15.3.4 Further Operation Modes 464
15.4 Microfabrication 464
15.5 Measurement Setup 465
15.5.1 Measurements in Gaseous or Liquid Environment 465
15.5.2 Readout Principles 466
15.5.3 Miniaturized Piezoresistive Arrays 468
15.5.4 Membrane Surface Stress Sensors 468
15.6 Functionalization Techniques 468
15.6.1 General Strategy 468
15.6.2 Functionalization Methods 469
15.6.3 Microfluidics 469
15.6.4 Array of Dimension-Matched Capillaries 469
15.6.5 Inkjet Spotting 469
15.7 Applications 470
15.7.1 Chemical Detection 470
15.7.2 Biochemical Environment 472
15.7.3 Microcantilever Sensors to Measure Physical Properties 475
15.7.4 Recent Developments 476
15.8 Conclusions and Outlook 476
References 477

16 **Microfluidic Devices and Their Applications**
Aditya Aryasomayajula, Pouriya Bayat, Pouya Rezai, P. Ravi Selvaganapathy 487
16.1 Preface 487
16.1.1 Why Miniaturize? 488
16.1.2 Advantages of Microfluidics and Nanofluidics 488
16.2 Historical Developments 489
16.3 Dominant Phenomenon and Micro–Nanofluidic Design 491
16.3.1 Laminar Flow 492
16.3.2 Diffusion in Microfluidics 492
16.3.3 Rapid Heating–Cooling 492
16.3.4 Surface Tension 493
16.3.5 Electrokinetics 494
16.3.6 Geometric Control of Two Phase Flow 495

16.3.7 Nanoscale Phenomena 495
16.4 Fabrication of Micro–Nanofluidic Devices 496
16.4.1 Silicon and Glass 496
16.4.2 Polymers 497
16.4.3 Paper 499
16.4.4 Threads 501
16.4.5 Hydrogels 502
16.5 Applications 504
16.5.1 Commercial Applications and Their Working Mechanism 504
16.5.2 Research Applications 519
16.6 Outlook and Future Directions 521
16.6.1 Additive Manufacturing 521
16.6.2 Artificial Organs 521
16.6.3 Biopharmaceutical Production 521
16.6.4 Droplets in Food and Cosmetics 522
16.6.5 Continuous Health Monitoring 522

ultra-low power consumption 449
ultrananocrystalline diamond (UNCD) 178, 1451
ultrathin DLC coating 1144
ultraviolet (UV) 52, 113, 175, 500, 820, 1266, 1404
– exposure 123
– light 285
– reflection 1290
Umklapp process 274
unfolded protein response (UPR) 1574
unified modeling language (UML) 697, 699
unit cell 1085
unloading curve 1023
unnatural AA (UAA) 709
unpaired electron 306

V

vacancy
– chain 1597
– diffusion 1445
van der Waals (vdW) 565
– attraction 743
– force 901, 942, 1390, 1392, 1439
– interaction 1391
– surface 789
Van Hove singularity 215
vapor 936
– deposition 336, 348, 353
– -grown carbon nanofilament (VGCNF) 199
– phase cocondensation 150
– -phase etching (VPE) 61
– –solid–solid (VSS) 257
vapor–liquid–solid (VLS) 210, 251, 255, 269, 288
– mechanism 255
vapor-phase epitaxy (VPE) 56
– organic (OMVPE) 1407
variable force mode 761
variable heavy–heavy (VHH) 712
vascular endothelial (VE) 825
– growth factor (VEGF) 352, 660
vascular plants 1270, 1279
velocity
– -dependent friction model 973
– effect 1225
– rescaling 1017
– strengthening of friction 999
– weakening 999
vertical
– -cavity surface-emitting laser (VCSEL) 135, 465
– coupling 729
– manipulation 793
– nanotube 1055
– nanowire array integrated nanogenerator (VING) 287
vertical-cavity surface-emitting laser (VCSEL) 135
very large-scale integration (VLSI) 52
very low density lipoprotein (VLDL) 345
vibrometry 1438
Vickers indentation 1104, 1109
vinculin binding site (VBS) 1093
virus-like particle 345
viscoelastic
– mapping 878
– solid 1083
viscoelasticity mapping 917
vital-sign monitoring (VSM) 1494
volatile organic compound (VOC) 468, 471
voltage-controlled oscillator (VCO) 409
vortex 796
V-shaped cantilever 740, 989

W

W tip 730
wafer acceptance test (WAT) 1494

wafer-level chip-scale packaging (WLCSP) 1492, 1495
Washburn equation 253
water
– loss reduction 1291
– plants 1297
– -repellent surface 1285
– treatment 335, 353
– vapor content 1171
wave interference 307
waveguiding 289
– nanowire 285
wax
– aggregate 1274
– chemical composition 1271
– compound 1272
– crystal 1267, 1274
– crystal morphology 1271
– ester 1274
– intracuticular 1268
– platelet 1274
– rodlet 1274
– self-assembly 1275
– superimposed 1268
– tubule 1274
wear 1013, 1231, 1425
– damage 1171
– depth 716
– detection 1237, 1245
– fullerene 1052
– map 1384
– mark 1400
– measurement 725, 1470
– of biomolecule 1382
– process 1168
– resistance 1167, 1170, 1196
– test 716, 1169, 1365
– tip 1039
– track 1034
– tribopolymer 1430
wearless friction 1041
Weibull distribution function 1529
wet etching 59
wettability 1268, 1275, 1283, 1291, 1360
wetting
– behavior 1285
– surface 1019
Weyl equation 307
Wheatstone bridge 466, 755
wire
– cantilever 738
– grating polarizer 134
– grid polarizer 132
woodpiles architecture 105
worm-like micelle 349

X

x-ray
– absorption fine structure (XAFS) 1576
– absorption near-edge structure (XANES) 1568, 1577
– diffraction (XRD) 253, 265, 1275
– fluorescence (XRF) 1577
– imaging 1453
– lithography 1404
– photoelectron spectroscopy (XPS) 502, 1143, 1190, 1244, 1254

Y

yield point 957
yield strength simulation 1025
Young–Dupre equation 1193
Young–Laplace equation 493
Young's modulus 91, 127, 461, 568, 595, 654, 745, 761, 834, 1000, 1072, 1394, 1459, 1464

Z

Z-DOL (fully bonded) 1360
zero-dimensional (0-D) 363, 564
zero-mode waveguide (ZMW) 517
ZGNR 321
– half-metallic 328
zigzag
– edge 304
– -edged nanographene 306
– -type nanotube 195
ZnO
– nanowire 261, 266, 284, 288

Recently Published Springer Handbooks

Springer Handbook of Nanotechnology (4th) (2017)
ed. by Bhushan, 1698 p., 978-3-662-54355-9

Springer Handbook of Electronic and Photonic Materials (2nd) (2017)
ed. by Kasap, Capper, 1450 p., 978-3-319-48931-5

Springer Handbook of Global Navigation Satellite Systems (2017)
ed. by Teunissen, Montenbruck, 1328 p., 978-3-319-42926-7

Springer Handbook of Model-Based Science (2017)
ed. by Magnani, Bertolotti, 1157 p., 978-3-319-30525-7

Springer Handbook of Odor (2017)
ed. by Buettner, 1151 p., 978-3-319-26930-6

Springer Handbook of Electrochemical Energy (2017)
ed. by Breitkopf, Swider-Lyons, 1016 p., 978-3-662-46656-8

Springer Handbook of Robotics (2nd) (2016)
ed. by Siciliano, Khatib, 2227p., 978-3-319-32550-7

Springer Handbook of Ocean Engineering (2016)
ed. by Dhanak, Xiros, 1345 p., 978-3-319-32550-7

Springer Handbook of Computational Intelligence (2015)
ed. by Kacprzyk, Pedrycz, 1633 p., 978-3-662-43505-2

Springer Handbook of Marine Biotechnology (2015)
ed. by Kim, 1512 p., 978-3-642-53970-1

Springer Handbook of Acoustics (2nd) (2015)
ed. by Rossing, 1286 p., 978-1-4939-0754-0
