Springer

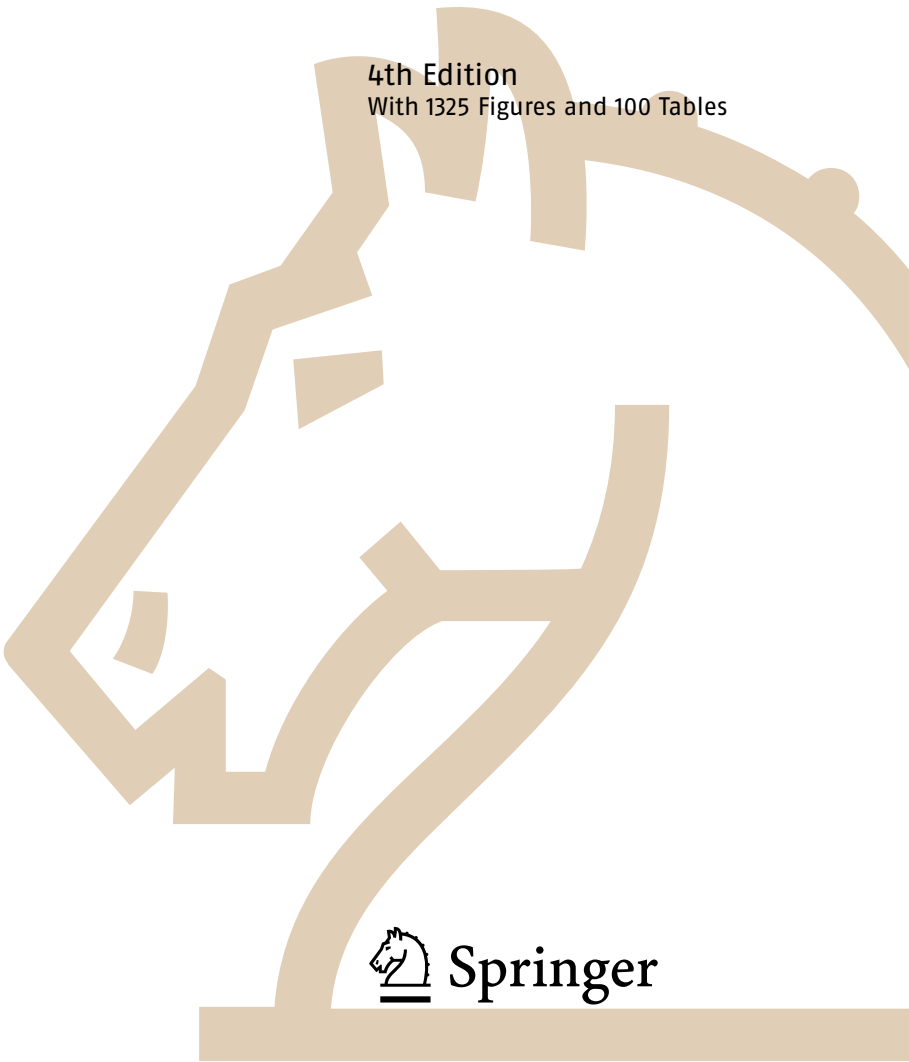
Handbook of Nano-technology

Bhushan
Editor

4th Edition

Springer

Springer Handbook of Nanotechnology



Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Nanotechnology

Bharat Bhushan (Ed.)

4th Edition
With 1325 Figures and 100 Tables

Foreword

When President W. J. Clinton approved the National Nanotechnology Initiative in 2000, we could not really imagine its full impact on science, technology and the economy. Nanotechnology refers to technology at the nanoscale that has applications in the real world. It is a broad and highly interdisciplinary field that is still evolving. The field involves the discovery and development of novel materials, processes, and phenomena at the nanometer scale, as well as the development of new experimental and theoretical techniques for research. These discoveries provide the foundations for further development of innovative nanosystems and nanostructured materials. There is an increasing need for a multidisciplinary, systems-oriented approach to manufacturing micro/nanodevices that function reliably. This can only be achieved through the cross-fertilization of ideas from different disciplines and the systematic flow of information and people among research groups.

To encourage this multidisciplinary approach, Professor Bharat Bhushan has harnessed his own knowledge and experience, gained in several industries and universities, to assemble internationally recognized academic and industry authorities from around the world to write chapters for this handbook. The topics include the latest major advances in many fields where nanoscale science and engineering are being pursued, and illustrate how the field of nanotechnology has continued to emerge and blossom.

Covering even the most important aspects of nanotechnology in a single book that reaches readers ranging from students to active senior researchers in academia and industry is an enormous challenge. Adding to this challenge is the accelerating pace of discovery and applications in nanotechnology. However, as in earlier editions, Professor Bhushan does an admirable job bringing together disparate topics and areas of study and practice to create a cohesive and wide-ranging handbook, sure to serve as the bedrock for anyone interested in the field.

Professor Bhushan's comprehensive book is intended to serve as both a textbook for university courses and a reference for researchers. It is a testament to the quality of the handbook contents that continuing editions have been created. The three editions were timely additions to the literature on nanotechnology, and stimulated further interest in this important new field while serving as invaluable resources to members of the international scientific and industrial community. The increasing demand for up-to-date information on this fast moving field led to the third edition. It is increasingly important that scientists and engineers, whatever their specialty, have a solid grounding in the fundamentals and potential applications of nanotechnology. This fourth edition addresses that need by paying particular attention to the widening audience of readers, discussing nanotechnology and nanoscience education, and providing timely and useful information on new and burgeoning nanotechnology areas. It also includes a discussion of the societal, ethical, and political issues that tend to surround emerging technology.

The Editor-in-Chief and his team are to be warmly congratulated for bringing together this exclusive, opportune, and useful *Springer Handbook of Nanotechnology*.

Prof. Neal Lane

Malcolm Gillis University
Professor Emeritus
Department of Physics and Astronomy Emeritus
Senior Fellow, Rice University's Baker Institute for Public Policy
Rice University
Houston, Texas
September 2016

Prof. Lane served in the Clinton Administration as Assistant to the President for Science and Technology and Director of the White House Office of Science and Technology Policy (1998–2001) and, prior to that, as Director of the National Science Foundation (1993–1998). While at the White House, he was instrumental in creating the National Nanotechnology Initiative (NNI).

Preface for the Fourth Edition

On 29 December 1959, at the California Institute of Technology, Nobel Laureate *Richard P. Feynman* gave a talk at the Annual Meeting of the American Physical Society titled *There's Plenty of Room at the Bottom*, which has become one of the classic science lectures of the 20th century. He presented a technological vision of extreme miniaturization in 1959, several years before the word *chip* became part of the lexicon. He talked about the problem of manipulating and controlling things on a small scale. Extrapolating from known physical laws, Feynman envisioned a technology using the ultimate toolbox of nature: building nano-objects atom by atom or molecule by molecule. Since the 1980s, the many inventions and discoveries in the fabrication of nano-objects have been testaments to his vision.

In a January 2000 speech, also at the California Institute of Technology, President William J. Clinton talked about the exciting promise of nanotechnology and the importance of expanding research in nanoscale science and technology more broadly. Later that month, in the State of the Union Address, he announced an ambitious $ 497 million federal, multiagency National Nanotechnology Initiative (NNI) in the 2001 fiscal year (FY) budget, and made the NNI a top science and technology priority. The objective of this initiative was to form a broad-based coalition in which academia, the private sector, and local, state, and federal governments worked together to push the envelope of nanoscience and nanoengineering and to reap nanotechnology's potential social and economic benefits.

Nanotechnology refers to technology done at the nanoscale that has applications in the real world. The unique physical and chemical properties of nanomaterials can be exploited for applications that benefit society. The National Nanotechnology Initiative was formalized with the 21st Century Nanotechnology Research and Development Act in 2003. Since 2001, the US Congress has appropriated about $ 20 billion for nanotechnology research and development (R&D) through FY 2015, with about $ 1.5 billion spent annually. US private sector R&D funding is more than double that of federal and state funding with a focus on translating fundamental research into commercial products. The revenues from nanoenabled products continue growing, with over $ 200B in FY 2012 in the US alone, and over $ 700B worldwide. This represents an impressive return on investment.

The integration of nanotechnology into larger systems gives us breakthrough solutions to many current environmental, medical, and industrial problems, including smart materials, nanomanufacturing, electronics, targeted drug delivery, energy, water, biotechnology, information technology, and national security. Nanotechnology will have a profound impact on our economy and society; it is a modern industrial revolution. Nanotechnology represents a megatrend and has become a general purpose technology. It is now a household word and a buzzword often used in marketing products.

There is an increasing need for a multidisciplinary, system-oriented approach to design and manufacturing of micro/nanodevices that function reliably. This can only be achieved through the cross-fertilization of ideas from different disciplines and the systematic flow of information and people among research groups. Reliability is a critical technology for many micro- and nanosystems and nanostructured materials. A broad-based handbook was needed, and so the first edition of the *Springer Handbook of Nanotechnology* was published in April 2004. It presented an overview of nanomaterial synthesis, micro/nanofabrication, micro- and nanocomponents and systems, scanning probe microscopy, reliability issues for nanotechnology, and industrial applications. When the handbook went on sale in Europe, it was sold out in ten days. Reviews on the handbook were very flattering.

Given the explosive growth in nanoscience and nanotechnology, the publisher and the editor decided to develop a second edition only six months after the publication of the first edition. The second edition (2007) came out in December 2006. The publisher and the editor again decided to develop a third edition six months after the publication of the second edition, which came out in 2010.

There continue to be significant developments in bio- and nanotechnology, and many products have been commercialized. Now, politicians, investors, and industrialists can see return on their R&D investments. Societal, ethical, and political effects as well as environmental and health and safety issues need to be addressed. As nanoproducts become real and interest in this exploding field grows, there emerges a need to develop nanoscience and nanotechnology curricula and textbooks that can be used in academia. The need exists starting from K-12 through college and continuing education, as well as technical training. The present

fourth edition was launched after five years after the publication of the third editiom. The objective of this edition is to cover the latest developments and introduce new areas of nanoscience and nanotechnology. This edition integrates knowledge from nanostructures, nanofabrication, materials science, nanodevices, and reliability. It covers various industrial applications. It also addresses societal, ethical, and political issues, as well as environmental, health and safety aspects, and nanotechnology education. Given the significant interest in biomedical applications and biomimetics, a number of additional chapters in this arena were added.

Almost all chapters are either new or substantially revised with coverage of new areas. The fourth edition consists of 47 chapters. The chapters have been written by over 130 internationally recognized experts in the field, from academia, national research labs and industry from all over the world.

This handbook is intended for three types of readers: graduate students of nanotechnology, researchers in academia and industry who are active or intend to become active in this field, and practicing engineers and scientists who have encountered a problem and hope to solve it as expeditiously as possible. The handbook should serve as an excellent text for one- or two-semester graduate courses in nanotechnology in mechanical engineering, materials science, applied physics, or applied chemistry.

I wish to sincerely thank the authors for offering to write comprehensive chapters on a tight schedule. This is generally an added responsibility in the hectic work schedules of researchers today. I depended on a large number of reviewers who provided critical reviews. Last but not the least, I would like to thank my assistant Renée L. Ripley for various administrative duties; her tireless efforts are highly appreciated.

I hope that this handbook will stimulate further interest in this important new field, and that readers of this handbook will find it useful.

Bharat Bhushan
Editor
September 2017

About the Editor

Dr. Bharat Bhushan received an M.S. in mechanical engineering from the Massachusetts Institute of Technology in 1971, an M.S. in mechanics and a Ph.D. in mechanical engineering from the University of Colorado at Boulder in 1973 and 1976 respectively, an MBA from Rensselaer Polytechnic Institute at Troy, NY in 1980, Doctor Technicae from the University of Trondheim at Trondheim, Norway in 1990, a Doctor of Technical Sciences from the Warsaw University of Technology at Warsaw, Poland in 1996, and Doctor Honouris Causa from the National Academy of Sciences at Gomel, Belarus in 2000 and University of Kragujevac, Serbia in 2011. He is a registered professional engineer. He is presently an Ohio Eminent Scholar, The Howard D. Winbigler Professor, and the Director of the Nanoprobe Laboratory for Bio- & Nanotechnology and Biomimetics (NLB2) in the College of Engineering, and affiliated faculty in the John Glenn College of Public Affairs, at the Ohio State University, Columbus, Ohio. In 2013–14, he served as an ASME/AAAS (American Society of Mechanical Engineers/American Association for the Advancement of Science) Science & Technology Policy Fellow, House Committee on Science, Space & Technology, United States Congress, Washington, DC. His research interests include fundamental studies with a focus on scanning probe techniques in the interdisciplinary areas of bio/nanotribology, bio/nanomechanics and bio/nanomaterials characterization and applications in bio/nanotechnology and biomimetics. He is an internationally recognized expert in bio/nanotribology and bio/nanomechanics using scanning probe microscopy, and is one of the most prolific authors on the topic. He is considered by some a pioneer of the tribology and mechanics of magnetic storage devices. He has authored eight scientific books, 90+ handbook chapters, 800+ scientific papers (One of Google Scholar's 1612 highly cited researchers (h > 100) and h-index 110+ with 60k+ citations; Web of Science h-index 857+; ISI Highly Cited Researcher in Materials Science since 2007 and in Biology and Biochemistry in 2013; ISI Top 5% Cited Authors for Journals in Chemistry, 2011), and 60+ technical reports. He has also edited 50+ books and holds 20 US and foreign patents. He is coeditor of Springer NanoScience and Technology Series and also of Microsystem Technologies, and is a PNAS Editorial Board member. He has given more than 400 invited presentations on six continents and more than 200 keynote/plenary addresses at major international conferences.

Dr. Bhushan is an accomplished organizer. He organized the first Symposium on Tribology and Mechanics of Magnetic Storage Systems in 1984 and the first International Symposium on Advances in Information Storage Systems in 1990, both of which are now held annually. He organized two international NATO institutes in Europe. He is the founder of an ASME Information Storage and Processing Systems Division founded in 1993 and served as the founding chair from 1993–1998. His biography has been listed in over two dozen Who's Who books including Who's Who in the World. He has received more than two dozen awards for his contributions to science and technology from professional societies, industry, and US government agencies including the Life Achievement Tribology Award and the Institution of Chemical Engineers (UK) Global Award. His research was listed in the top ten science stories of 2015. He is also the recipient of various international fellowships including the Alexander von Humboldt Research Prize for Senior Scientists, the Max Planck Foundation Research Award for Outstanding Foreign Scientists, and the Fulbright Senior Scholar Award. He is a foreign member of the International Academy of Engineering (Russia), the Byelorussian Academy of Engineering and Technology and the Academy of Triboengineering of Ukraine, an honorary member of the Society of Tribologists of Belarus and STLE (Society of Tribologists and Lubrication Engineers), a fellow of ASME, IEEE (Institute of Electrical and Electronics Engineers) and the New York Academy of Sciences, and a member of ASEE (American Society for Engineering Education), Sigma Xi and Tau Beta Pi.

Dr. Bhushan has previously worked for Mechanical Technology Inc., Latham, NY; SKF Industries Inc., King of Prussia, PA; IBM, Tucson, AZ; and IBM Almaden Research Center, San Jose, CA. He has held visiting professorships at University of California at Berkeley, USA; University of Cambridge, UK; Technical University Vienna, Austria; University of Paris, Orsay, France; ETH Zurich, Switzerland; EPFL Lausanne, Switzerland; University of Southampton, UK; University of Kragujevac, Serbia; Tsinghua University; China, Harbin Institute, China; and KFUPM, Saudi Arabia.

Contents

List of Abbreviations XXXIII

1 **Introduction to Nanotechnology**
Bharat Bhushan 1
1.1 Nanotechnology – Definitions and Examples 2
1.2 History and Early Research Expenditures 6
1.3 Governance of the National Nanotechnology Initiative 7
1.4 Nanotechnology R&D Funding Since 2001 8
1.5 Worldwide R&D Investments and Output 11
1.6 Translation of Basic Research to Technology Commercialization 15
1.7 Nanoscience and Nanotechnology Education 16
1.8 Summary and Outlook 17
1.9 Organization of the Handbook 18
References 18

Part A Micro/Nanofabrication Techniques

2 **Molecule-Based Devices**
Françisco M. Raymo 23
2.1 Chemical Approaches to Nanostructured Materials 24
2.2 Molecular Switches and Logic Gates 28
2.3 Solid-State Devices 35
2.4 Conclusions and Outlook 46
References 47

3 **Introduction to Micro-/Nanofabrication**
Gemma Rius, Antoni Baldi, Babak Ziaie, Massood Z. Atashbar 51
3.1 Basic Microfabrication Techniques 52
3.2 MEMS Fabrication Techniques 62
3.3 Nanofabrication Techniques 74
3.4 Summary and Conclusions 82
References 82

4 **3-D Nanostructure Fabrication by Focused-Ion Beam, Electron- and Laser Beam**
Shinji Matsui, Hiroaki Misawa, Quan Sun 87
4.1 Various 3-D Nanostructure Fabrication Techniques 88
4.2 3-D Nanostructure Fabrication by Focused Ion Beam 88
4.3 3-D Nanostructure Fabrication by Electron Beam 97
4.4 3-D Nanostructure Fabrication by Laser 103
References 109

5 **Nanoimprint Lithography**
Helmut Schift, Anders Kristensen 113
5.1 Emerging Nanopatterning Methods 115
5.2 Nanoimprint Process 119
5.3 Tools and Materials for Nanoimprint 125

5.4 Applications 132
5.5 Conclusion and Outlook 137
References 138

6 **Stamping Techniques for Micro- and Nanofabrication**
John A. Rogers, Etienne Menard 143
6.1 High-Resolution Stamps 144
6.2 Microcontact Printing 146
6.3 Nanotransfer Printing 148
6.4 Applications 152
6.5 Conclusions 159
References 159

7 **Materials Aspects of Micro- and Nanoelectromechanical Systems**
Christian A. Zorman 163
7.1 Silicon and its Commonly-Used Derivatives 163
7.2 Germanium-Based Materials 170
7.3 Metals 171
7.4 Semiconductors for Harsh Environment Applications 173
7.5 GaAs, InP and Related III-V Materials 178
7.6 Piezoelectric Materials 180
7.7 Polymer Materials 183
7.8 Future Trends 185
References 185

Part B Nanomaterial and Nanostructures

8 **Carbon Nanotubes**
Marc Monthioux, Philippe Serp, Brigitte Caussat, Emmanuel Flahaut, Manitra Razafinimanana, Flavien Valensi, Christophe Laurent, Alain Peigney, David Mesguich, Alicia Weibel, Wolfgang Bacsa, Jean-Marc Broto 193
8.1 Structure of Carbon Nanotubes 194
8.2 Synthesis of Carbon Nanotubes 199
8.3 Growth Mechanisms of Carbon Nanotubes 210
8.4 Properties of Carbon Nanotubes 213
8.5 Carbon Nanotube-Based Nano-Objects (Carbon Meta-Nanotubes) 217
8.6 Carbon-Nanotube-Containing Materials (Composites) 223
8.7 Current Applications of Carbon Nanotubes (on the Market) 227
8.8 Toxicity and Environmental Impact of Carbon Nanotubes 231
8.9 Concluding Remarks 233
References 233

9 **Nanowires**
Mildred S. Dresselhaus, Marcie R. Black, Vincent Meunier, Oded Rabin 249
9.1 Synthesis 250
9.2 Characterization and Physical Properties of Nanowires 262
9.3 Applications 282
9.4 Concluding Remarks 290
References 290

10 **Nanoribbons**
Toshiaki Enoki, Shintaro Sato 303
10.1 Graphene Nanoribbons 303
10.2 Electronic and Magnetic Properties 305
10.3 Characterizations 310
10.4 Syntheses: Top-Down Methods and Bottom-Up Methods 317
10.5 Potential Applications 324
10.6 Conclusions 330
References 331

11 **Nanoparticles and Their Applications**
Seyedsina Moeinzadeh, Esmaiel Jabbari 335
11.1 Overview 335
11.2 NPs Classification and Synthesis 336
11.3 Properties of NPs 348
11.4 Applications of NPs 351
11.5 Summary 353
References 353

12 **Graphene**
Aravind Vijayaraghavan, Maria Iliut 363
12.1 Methods of Production 365
12.2 Properties 369
12.3 Characterization 372
12.4 Applications 376
12.5 Conclusions and Outlook 385
References 386

Part C MEMS/NEMS

13 **MEMS/NEMS Devices and Applications**
Philip X.-L. Feng, Darrin J. Young, Christian A. Zorman 395
13.1 MEMS Devices and Applications 397
13.2 NEMS Devices and Applications 415
13.3 Challenges and Perspectives 425
References 426

14 **Single-Walled Carbon Nanotube Sensor Concepts**
Cosmin I. Roman, Thomas Helbling, Miroslav Haluška, Christofer Hierold . 431
14.1 Sensor Design Considerations 432
14.2 Sensor Fabrication: SWNT Synthesis and Integration 439
14.3 Summary of State-of-the-Art, Applications Examples 445
14.4 Concluding Remarks 451
References 451

15 **Nanomechanical Cantilever Array Sensors**
Hans Peter Lang, Martin Hegner, Christoph Gerber 457
15.1 Technique 458
15.2 Cantilever Array Sensors 459
15.3 Modes of Operation 460
15.4 Microfabrication 464

15.5 Measurement Setup 465
15.6 Functionalization Techniques 468
15.7 Applications 470
15.8 Conclusions and Outlook 476
References 477

16 **Microfluidic Devices and Their Applications**
Aditya Aryasomayajula, Pouriya Bayat, Pouya Rezai, P. Ravi Selvaganapathy 487
16.1 Preface 487
16.2 Historical Developments 489
16.3 Dominant Phenomenon and Micro–Nanofluidic Design 491
16.4 Fabrication of Micro–Nanofluidic Devices 496
16.5 Applications 504
16.6 Outlook and Future Directions 521
References 522

17 **Microfluidic Micro/Nano Droplets**
Gopakumar Kamalakshakurup, Derek Vallejo, Abraham Lee 537
17.1 Introduction to Micro/Nano Droplet Microfluidic Technologies 537
17.2 Overview of Current Trends in Droplet Microfluidic Technologies 546
17.3 Fundamental Designs and Techniques for Microfluidic Generation of Droplets 547
17.4 Microfluidic Micro-/Nanodroplet Applications 550
17.5 Conclusion 556
References 556

18 **Nanorobotics**
Bradley J. Nelson, Lixin Dong 559
18.1 Overview of Nanorobotics 560
18.2 Actuation at Nanoscales 561
18.3 Nanorobotic Manipulation Systems 563
18.4 Nanorobotic Assembly 568
18.5 Applications 576
References 580

Part D BioMEMS/NEMS

19 **Applications of MEMS to Cell Biology**
Georg E. Fantner, Pascal D. Odermatt, Haig Alexander Eskandarian 587
19.1 Biological Background 588
19.2 High Resolution Microscopy Methods for Live Cell Imaging 592
19.3 Measuring Mechanical Properties on Living Cells 593
19.4 Cancer Detection Using Nanomechanical Sensors 596
19.5 Measurement of Cell Adhesion Using Cantilever Based Force Sensor 599
19.6 Manipulation of Cells Using MEMS Cantilevers 602
19.7 Mass Measurements of Single Cells Using Resonant Cantilevers 603
19.8 Characterization of Antibiotic Action Using MEMS Devices 606
19.9 Conclusions and Outlook 609
References 609

20 **Contact-free Mechanical Manipulation of Biological Materials**
Jörg Schnauß, Josef A. Käs, David M. Smith 617
20.1 Interaction of Laser Light with Biological Material 618
20.2 Optical and Magnetic Tweezers for Single-Molecule Manipulations 621
20.3 Optical and Electric Forces for the Manipulation of Whole Cells 629
20.4 Hydrodynamic Shear Forces for the Manipulation of Single Cells ... 636
20.5 Conclusion and Outlook 638
References 638

21 **Nano-Particles for Biomedical Applications**
Paolo Decuzzi, Alessandro Coclite, Aeju Lee, Anna Lisa Palange, Daniele Di Mascolo, Ciro Chiappini, Hélder A. Santos, Maria Laura Coluccio, Gerardo Perozziello, Patrizio Candeloro, Enzo Di Fabrizio, Francesco Gentile 643
21.1 Overview 644
21.2 Rational Design of Nanoconstructs 646
21.3 Multifunctional Polymeric Nanoconstructs 650
21.4 Sensing and Drug Delivery with Porous Silicon Nanomaterials 655
21.5 Nanomedicine Synthesis by Microfluidics Technology 662
21.6 Electroless Formation of Metal Nanoparticle Aggregates 669
21.7 2-D and 3-D Optical Nanostructures 677
References 681

22 **Biological Molecules in Therapeutic Nanodevices**
Stephen C. Lee, Bharat Bhushan 693
22.1 Definitions and Scope 694
22.2 Assembly Approaches 700
22.3 Sensing Devices 710
22.4 Concluding Remarks: Barriers to Practice 717
References 718

Part E Nanometrology

23 **Scanning Probe Microscopy – Principle of Operation, Instrumentation and Probes**
Bharat Bhushan, Othmar Marti 725
23.1 Scanning Tunneling Microscope 727
23.2 Atomic Force Microscope 731
23.3 AFM Instrumentation and Analyses 747
23.4 Conclusion 763
References 763

24 **Low-Temperature Scanning Probe Microscopy**
Mehmet Z. Baykara, Markus Morgenstern, Alexander Schwarz, Udo D. Schwarz 769
24.1 Microscope Operation at Low Temperatures 771
24.2 Instrumentation 772
24.3 Scanning Tunneling Microscopy and Spectroscopy 773
24.4 Scanning Force Microscopy and Spectroscopy 788
24.5 Summary 799
References 799

25 **Biomedical Sensing with the Atomic Force Microscope**
Constanze Lamprecht, Jürgen Strasser, Melanie Koehler, Sandra Posch, Yoojin Oh, Rong Zhu, Lilia A. Chtcheglova, Andreas Ebner, Peter Hinterdorfer 809
25.1 Topographical Imaging of Biological Samples 810
25.2 Single-Molecule Force Spectroscopy (SMFS) 814
25.3 Simultaneous Topography and Recognition Imaging (TREC) 821
25.4 AFM Biomedical Sensing – Examples 827
25.5 Perspectives and Concluding Remarks 836
References 837

26 **Superresolution Microscopy**
Tom D. Milster 845
26.1 Overview 845
26.2 Scanning Aperture Techniques 849
26.3 4-Pi Microscopy 853
26.4 Enhancement/Depletion Techniques 854
26.5 Photoactivated Localization 856
26.6 Structured Illumination 858
26.7 Light-Sheet Microscopy 862
26.8 Comparison of Techniques for Live-Cell Imaging 863
26.9 Summary 864
References 864

Part F Bio/Nanotribology and Bio/Nanomechanics

27 **Nanotribology, Nanomechanics and Materials Characterization**
Bharat Bhushan 869
27.1 Description of AFM/FFM and Various Measurement Techniques 871
27.2 Surface Imaging, Friction, and Adhesion 882
27.3 Micro/Nanoscale Wear and Scratching, Local Deformation, and Nanofabrication/Nanomachining 906
27.4 Indentation 915
27.5 Boundary Lubrication 919
27.6 Conclusion 928
References 929

28 **Surface Forces and Nanorheology of Molecularly Thin Films**
Dong Woog Lee, Marina Ruths, Jacob N. Israelachvili 935
28.1 Types of Surface Forces 936
28.2 Methods Used to Study Surface Forces 938
28.3 Normal Forces Between Dry (Unlubricated) Surfaces 941
28.4 Normal Forces Between Surfaces in Liquids 942
28.5 Adhesion and Capillary Forces 951
28.6 Introduction: Different Modes of Friction 956
28.7 Relationship Between Adhesion and Friction 957
28.8 Liquid Lubricated Surfaces 966
28.9 Effects of Nanoscale Texture on Friction 976
References 978

29 **Atomic Scale Friction Phenomena**
Enrico Gnecco, Rémy Pawlak, Marcin Kisiel, Thilo Glatzel, Ernst Meyer 987
29.1 Friction Force Microscopy in Selected Environments 988
29.2 The Prandtl–Tomlinson Model 993
29.3 Friction Experiments on the Atomic Scale 996
29.4 Thermal Effects on Atomic Friction 998
29.5 Friction on the Nanometer Scale 999
29.6 Wear on the Atomic Scale 1002
29.7 Noncontact Friction 1003
29.8 Single Molecule Friction 1005
29.9 Conclusion 1008
References 1008

30 **Computer Simulations of Nanometer-Scale Indentation and Friction**
Susan B. Sinnott, Seong-Jun Heo, Donald W. Brenner, Judith A. Harrison, Douglas L. Irving 1013
30.1 Computational Details 1014
30.2 Indentation 1019
30.3 Friction and Lubrication 1033
30.4 Conclusions 1058
References 1058

31 **Cellular Nanomechanics**
Roger D. Kamm, Jan Lammerding, Mohammad R. K. Mofrad 1069
31.1 Overview 1069
31.2 Structural Components of a Cell 1071
31.3 Experimental Methods 1077
31.4 Theoretical and Computational Descriptions 1082
31.5 Mechanics of Subcellular Structures 1086
31.6 Current Understanding and Future Needs 1095
References 1096

32 **Nanomechanical Properties of Nanostructures and Scale Effects**
Bharat Bhushan 1101
32.1 Experimental Techniques for Measurement of Mechanical Properties of Nanostructures 1103
32.2 Experimental Results and Discussion 1109
32.3 Finite Element Analysis of Nanostructures with Roughness and Scratches 1125
32.4 Summary 1131
32.A Appendix: Fabrication Procedure for the Double-Anchored and Cantilever Beams 1132
References 1134

Part G Molecularly-Thick Films for Lubrication

33 **Nanotribology of Ultrathin and Hard Amorphous Carbon Films**
Bharat Bhushan 1141
33.1 Description of Commonly Used Deposition Techniques 1145
33.2 Chemical Characterization and Effect of Deposition Conditions on Chemical Characteristics and Physical Properties 1149
33.3 Micromechanical and Tribological Characterizations of Coatings Deposited by Various Techniques 1154
33.4 Conclusion 1174
References 1175

34 **Self-Assembled Monolayers for Nanotribology and Surface Protection**
Bharat Bhushan 1179
34.1 Background 1179
34.2 A Primer on Organic Chemistry 1182
34.3 Self-Assembled Monolayers: Substrates, Spacer Chains, and End Groups in the Molecular Chains..... 1186
34.4 Contact Angle and Nanotribological Properties of SAMs..... 1189
34.5 Conclusion 1209
References 1210

35 **Nanoscale Boundary Lubrication Studies**
Bharat Bhushan 1215
35.1 Nanodeformation, Molecular Conformation, Spreading, Nanotribological and Electrical Studies, and Environmental Effects of Commonly Used PFPE Lubricant Films 1216
35.2 Nanotribological, Electrical, and Chemical Degradations Studies and Environmental Effects in Novel PFPE Lubricant Films .. 1233
35.3 Nanotribological and Electrical Studies of Ionic Liquid Films..... 1242
35.4 Conclusion 1257
References 1258

Part H Biomimetics and Bioinspired Surfaces

36 **Plant Surfaces: Structures and Functions for Biomimetic Applications**
Wilhelm Barthlott, Matthias Mail, Bharat Bhushan, Kerstin Koch 1265
36.1 500 Million Years of Evolution for Innovative Technologies 1266
36.2 Chemistry of Plant Surfaces..... 1270
36.3 Structuring of Plant Surfaces: Hierarchical Architecture Between Nano- and Macrostructures..... 1279
36.4 Physical Basis of Surface Wetting 1285
36.5 Superhydrophilic and Superhydrophobic Plant Surfaces..... 1286
36.6 Functional Diversity of Plant Surfaces 1289
36.7 Biomimetic Application 1294
36.8 Living Prototypes: Evolution of Plant Surfaces and Biodiversity..... 1297
36.9 Conclusions 1298
References 1298

37 **Bioinspired Nanostructured Antibiofouling and Anti-inorganic Surfaces**
Bharat Bhushan 1307
37.1 Fields Susceptible to Fouling 1307
37.2 Biofouling and Inorganic Fouling Formation Mechanisms 1310
37.3 Antifouling Strategies from Living Nature 1313
37.4 Antifouling: Current Prevention and Cleaning Techniques 1315
37.5 Bioinspired Rice Leaf Surfaces for Antifouling 1318
37.6 Closure 1324
References 1324

Part I Micro/Nanodevice Reliability

38 **MEMS/NEMS and BioMEMS/BioNEMS: Tribology, Mechanics, Materials and Devices**
Bharat Bhushan 1331
38.1 MEMS/NEMS Basics 1332
38.2 Nanotribology and Nanomechanics Issues in MEMS/NEMS and BioMEMS/BioNEMS 1336
38.3 Nanotribology and Nanomechanics Studies of Silicon and Related Materials 1352
38.4 Lubrication Studies for MEMS/NEMS 1359
38.5 Nanoscale Friction, Wear, and Mechanical Behavior of Nano-Objects 1365
38.6 Nanotribological Studies of Biological Molecules on Polystyrene and Silicon Surfaces and Coated Polymer Surfaces 1376
38.7 Trajectory of Submicron Particles for Therapeutics and Diagnostics 1390
38.8 Component-Level Studies 1392
38.9 Conclusion 1403
38.A Appendix: Micro/Nanofabrication Techniques 1404
References 1407

39 **Friction and Wear in Micro- and Nanomachines**
Maarten P. de Boer, Sameer S. Shroff, Frank W. DelRio, W. Robert Ashurst 1417
39.1 From Single- to Multiple-Asperity Friction 1419
39.2 Rate-State Friction 1422
39.3 Putting MEMS Friction to Use: Making Motors and Friction Instruments 1429
39.4 Wear and Tribopolymer Evolution in Micro- and Nanoswitches 1430
39.5 Concluding Remarks 1432
References 1432

40 **Failure Mechanisms in MEMS/NEMS Devices**
W. Merlijn van Spengen, Robert Modliński, Robert Puers, Anne Jourdain 1437
40.1 Failure Modes and Failure Mechanisms 1438
40.2 Stiction and Charge-Related Failure Mechanisms 1439
40.3 Creep, Fatigue, Wear, and Packaging-Related Failures 1445
40.4 Conclusions 1454
References 1454

41 **Mechanical Properties of Micromachined Structures**
Harold Kahn 1459
41.1 Measuring Mechanical Properties of Films on Substrates 1459
41.2 Micromachined Structures for Measuring Mechanical Properties 1460
41.3 Measurements of Mechanical Properties 1471
41.4 Summary 1475
References 1476

42 **High Volume Manufacturing and Field Stability of MEMS Products**
T. Kieran Nunan, Mark G. da Silva 1481
42.1 High-Volume Manufacturing Strategy 1482
42.2 Robust Design for Volume Manufacturing 1491
42.3 Stable Field Performance 1496
42.4 Internet of Things (IoT) 1498
42.5 Conclusions and Outlook 1503
References 1503

43 **Packaging and Reliability Issues in Micro/Nano Systems**
Yu-Chuan Su, Jongbaeg Kim, Yu-Ting Cheng, Mu Chiao, Liwei Lin 1505
43.1 Introduction to MEMS Packaging 1505
43.2 Hermetic and Vacuum Packaging 1511
43.3 Emerging Packaging Approaches 1518
43.4 Thermal Issues and Packaging Reliability 1526
43.5 Future Trends and Summary 1533
References 1534

Part J Nanotechnology and Society and Education

44 **Nanotechnologies in Societal Context**
Barbara Herr Harthorn 1543
44.1 Assessing Technological Progress in Societal Terms 1545
44.2 Nanotechnologies and Upstream Societal Engagement 1547
44.3 Ethics 1549
44.4 Governance, Law and Regulation 1550
44.5 Public Perceptions and Participation in Decision-Making 1552
44.6 Integrating the Societal with the Technical 1553
44.7 Concluding Remarks 1554
References 1554

45 **Environment, Health and Safety Issues in Nanotechnology**
Rui Chen, Chunying Chen 1559
45.1 Impacts of the Development of Nanotechnology on Environment, Health, and Safety Issues 1559
45.2 Current Progress of the Most Important Nanomaterials 1562
45.3 Physicochemical Characteristics of Nanoparticles that Determine the Toxicity Impacts 1569
45.4 Novel Techniques and Biomarker Development in Nanotoxicology . 1574
45.5 Conclusion and Perspectives 1580
References 1580

46 **Nanoscience and Nanotechnology Convergence**
William S. Bainbridge 1587
46.1 Background 1587
46.2 Convergence with Society 1591
46.3 Concepts and Methods 1595
46.4 Convergence in Education 1598
46.5 Conclusions 1600
References 1600

47 **Global Perspectives of Nanotechnology Education**
Kurt Winkelmann, Bharat Bhushan 1603
47.1 Growth and Trends of Nanotechnology Education 1605
47.2 Primary and Secondary Education 1608
47.3 Vocational Education Training 1610
47.4 Undergraduate Education 1611
47.5 Graduate Education 1614
47.6 Teacher Professional Development 1616
47.7 Informal Education 1618
47.8 Summary and Outlook 1620
References 1622

About the Authors 1625
Detailed Contents 1645
Subject Index 1671

List of Abbreviations

μCP	microcontact printing
μTAS	micro total analysis system
0-D	zero-dimensional
1-D	one-dimensional
2-D	two-dimensional
2-DES	two-dimensional electron system
3-D	three-dimensional
5-FU	5-fluorouracil

A

a-C	amorphous carbon
ABP	actin binding protein
AC	alternating current
ADC	analog to digital converter
ADME	absorption, distribution, metabolism and excretion
AES	Auger electron spectroscopy
AF	acceleration factor
AFAM	atomic force acoustic microscopy
AFM	atomic force microscopy
AgNP	silver nanoparticle
AGNR	armchair nanoribbon
ALD	atomic layer deposition
AM	amplitude modulation
AM-SFM	amplitude modulation scanning force microscopy
AOD	acousto-optical deflector
AOM	acousto-optical modulator
AP	adhesion proteoglycan
APCVD	atmospheric-pressure chemical vapor deposition
APDMES	(3-aminopropyl)-dimethyl-ethoxysilane
APTES	(3-aminopropyl)-triethoxysilane
ARPES	angle-resolved photoemission spectroscopy
ASIC	application-specific integrated circuit
ASL	antistiction layer
ASNOM	apertureless scanning near-field optical microscopy
ATP	adenosine triphosphate
ATRP	atom transfer radical polymerization

B

BCB	benzocyclobutene
BCP	block copolymer
BCS	Bardeen–Cooper–Schrieffer
BDCS	biphenyldimethylchlorosilane
BECC	bottom effect cone correction
BEN	biased enhanced nucleation
BFg	fibrinogen
BGA	ball grid array
BHF	buffered HF
BHPET	(3,6,9,12,15-pentaoxapentadecane-1,15-diyl)bis(3-hydroxyethyl-1*H*-imidazolium-1-yl) di[bis(trifluoromethanesulfonyl)imide]
BHPT	(pentane-1,5-diyl)bis(3-hydroxyethyl-1*H*-imidazolium-1-yl) di[bis(trifluoromethanesulfonyl)imide]
BiCMOS	bipolar complementary metal oxide semiconductor
bioMEMS	biological microelectromechanical systems
bioNEMS	biological nanoelectromechanical systems
BiP	binding immunoglobulin protein
BIPY	bipyridinium
BMP-2	bone morphogenic protein-2
BOE	buffered oxide etch
BP	binding probability
BPAG1	bullous pemphigoid antigen 1
BPEI	branched polyethyleneimine
BPM	bit-patterned media
BPSG	borophosphosilicate glass
BPT	1,1′-biphenyl-4-thiol
BPTC	1,1′-biphenyl-4-thiol crosslinked
BSA	bovine serum albumin

C

c-side	cytosolic side
CA	contact angle
CAH	contact-angle hysteresis
CAIBE	chemically assisted ion beam etching
CAM	cell-adhesion molecule
CAS	Crk-associated substrate
CBA	cantilever beam array
CCD	charge-coupled device
CCVD	catalytic chemical vapor deposition
CDM	charge discharge model
cDNA	complementary DNA
CDR	complementarity determining region
CDW	charge density wave
CFM	chemical force microscopy
CFU	colony forming unit
CG	controlled geometry
CIC	cantilever-in-cantilever
CLSM	confocal laser scanning microscopy
CMA	cylindrical mirror analyzer
CMC	critical micelle concentration
CMOS	complementary metal-oxide-semiconductor
CMP	chemical mechanical polishing
CNFET	carbon nanotube field-effect transistor

CNH	carbon nanohorn
CNT	carbon nanotube
COC	cyclic olefin copolymer
COOH-PS	charged carboxylated polystyrene
CP	circularly permuted
CPA	chirped-pulsed amplifier
CPB	Al Cooper pair box
CPG	compute pattern generator
CRP	C-reactive protein
CS	circular dichroism spectroscopy
CSK	cytoskeleton
CSM	continuous stiffness measurement
CT	computed tomography
CTAB	hexadecyl trimethyl ammonium bromide
CTE	coefficient of thermal expansion
CU	control unit
CURC	curcumin
CVD	chemical vapor deposition
CW	continuous wave

D

dATP	deoxyadenosine triphosphate
DBBA	10,10-dibromo-9,9-bianthryl
DBR	distributed Bragg reflector
DBTF	dibromoterfluorene
DC	direct current
DC/RF	direct current/radio frequency
DCE	1,2-dichloroethane
dCTP	deoxycytidine triphosphate
dDAT	*Drosophila melanogaster* dopamine transporter
DDMS	dimethyldichlorosilane
ddNTP	dideoxynucleotide triphosphate
ddPCR	droplet digital polymerase chain reaction
DDT	dichlorodiphenyltrichloroethane
DDV	dichlorvos
DEP	dielectrophoresis
DFB	distributed feedback
DFS	dynamic force spectroscopy
DFT	density functional theory
dGTP	deoxyguanosine triphosphate
DGU	density gradient ultracentrifugation
DI	deionized
DIMP	diisopropyl methylphosphonate
DIP	dual-in-line packaging
DLA	diffusion-limited aggregation
DLC	diamond-like carbon
DLD	deterministic lateral displacement
DLP	digital light processing
DLS	dynamic light scattering
DLVO	Derjaguin–Landau–Verwey–Overbeek
DLW	direct laser writing
DMA	*N*,*N*-dimethylamide
DMAc	dimethylacetamide
DMD	digital micromirror device
DMF	dimethylformamide
DMMP	dimethylmethylphosphonate
DMSO	dimethyl sulfoxide
DMT	Derjaguin–Muller–Toporov
DNA	deoxyribonucleic acid
DNS	direct numerical simulation
DOE	design of experiments
DOF	degree of freedom
DOPC	1,2-dioleoyl-*sn*-glycero-3-phosphocholine
DOS	density of states
DOTA	1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid
Dox	doxorubicin
DP	*n*-decylphosphonate
DPN	dip-pen nanolithography
DPPC	1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine
DPW	die per wafer
DRC	design rule check
DRIE	deep reactive-ion etching
DSA	directed self-assembly
DSC	differential scanning calorimetry
DSP	digital signal processor
DSPE-PEG	1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-N-[amino(polyethyleneglycol)-2000] (carboxylic acid)
dSTORM	direct stochastic optical reconstruction microscopy
DTR	discrete track recording
dTTP	deoxythymidine triphosphate
DTXL	docetaxel
DUV	deep ultraviolet
DWNT	double-wall nanotube

E

EAM	embedded atom method
EB	electron beam
EBID	electron-beam-induced deposition
EBL	electron-beam lithography
EC	erythrocyte
ECD	electrochemical deposition
ECM	extracellular matrix
ECR	electron cyclotron resonance
ECR-CVD	electron cyclotron resonance chemical vapor deposition
ED	electron diffraction
EDC	1-ethyl-3-(3-dimethylaminopropyl) carbodiimide
EDL	electrostatic double layer
EDLC	electrical double-layer capacitor
EDP	ethylenediamine pyrocatechol
EDS	energy-dispersive x-ray spectroscopy
EELS	electron energy loss spectroscopy
EFM	electric field gradient microscopy
EHL	elastohydrodynamic lubrication
EIP	emulsion inversion point
EL	electroluminescence
ELISA	enzyme-linked immunosorbent assay
ELNES	electron energy loss near edge structure

ELP	elastin-like polypeptide
EMI	electromagnetic interference
EMT	epithelial–mesenchymal transition
ENM	engineered nanomaterial
ENP	engineered nanoparticle
EPR	enhanced permeability and retention
EPS	extracellular polymeric substance
ER	endoplasmic reticulum
ERK	extracellular signal-regulated kinase
ESD	electrostatic discharge
EUV	extreme ultraviolet
EWOD	electrowetting-on-dielectric

F

FADS	fluorescence-activated droplet sorting
FAK	focal adhesion kinase
FB	fluidized bed
FBAR	film bulk acoustic resonator
FBGC	foreign body giant cell
FBS	fetal bovine serum
FCA	filtered cathodic arc
fcc	face-centered cubic
FCP	force calibration plot
FDM	fused deposition modeling
FDTD	finite-difference time-domain
FDTS	1*H*,1*H*,2*H*,2*H*-perfluoro-decyltrichlorosilane
FE-SEM	field electron SEM
FEA	finite element analysis
FEM	finite element modeling
FESEM	field-emission scanning electron microscopy
FET	field-effect transistor
FFM	friction force microscope
FFT	fast Fourier transform
FIB	focused ion beam
FK	Frenkel–Kontorova
FKT	Frenkel–Kontorova–Tomlinson
FLG	few-layer graphene
FluidFM	fluid force microscopy
FM	frequency modulation
FM-SFM	frequency-modulation scanning force microscopy
FMEA	failure modes and effects analysis
fPALM	fluorescent photoactivated localization microscopy
FPGA	field-programmable logic arrays
FRET	fluorescence (or Förster) resonant energy transfer
FRS	forward recoil spectrometry
fs-laser	femtosecond laser
FWHM	full-width at half-maximum

G

GF	gauge factor
GFP	green fluorescent protein
GIC	graphite intercalation compounds
GLAD	glancing angle deposition
GLUT4	glucose transporter 4
GMR	giant magnetoresistive
GNP	gold nanoparticle
GNR	graphene nanoribbon
GO	graphene oxide
GSD	ground-state depletion
GSH-Px	glutathione peroxidase
GTP	guanosine triphosphate
GW	Greenwood and Williamson

H

HAADF-STEM	high-angle annular dark-field-scanning transmission electron microscope
HARMEMS	high-aspect-ratio MEMS
HARPSS	high-aspect-ratio combined poly- and single-crystal silicon
HART	high aspect ratio tip
HAS-CtW	hybrid self-assembly-based chip-to-wafer bonding
HBM	human body model
hBN	hexagonal boron nitride
hcp	hexagonal close-packed
HCS	high content screening
HDI	high density interconnect
HDL	high density lipoprotein
HDT	hexadecane thiol
HEL	hot embossing lithography
HEMT	high electron mobility transistor
HEPES	2-[4-(2-hydroxyethyl)-1-piperazinyl]-ethanesulfonic acid
HER	hydrogen evolution recovery
HEXSIL	hexagonal honeycomb polysilicon
HFCVD	hot filament chemical vapor deposition
hIL	human interleukin
HMDS	hexamethyldisilazane
HOMO	highest occupied molecular orbital
HOPG	highly oriented pyrolytic graphite
HOT	holographic optical tweezers
HP	hot pressing
HPLC	high-pressure liquid chromatography
HRTEM	high-resolution transmission electron microscopy
HSA	human serum albumin
HSQ	hydrogen silsesquioxane
HTS	high-throughput screening
HTSC	high-temperature superconductor
HVM	high-volume manufacturing

I

I/O	input/output
IA	isogeometric analysis
IB	ion beam
IBD	ion beam deposition
IBM	immersed boundary method
IC	integrated circuit

IC3D	integrated comprehensive droplet digital detection
ICA	independent component analysis
ICP	inductively coupled plasma
ICP-MS	inductively coupled plasma mass spectrometry
ICP-OES	inductively coupled plasma optical emission spectroscopy
IFEM	immersed finite element method
IgG	immunoglobuline G
IKVAV	isoleucine–lysine–valine–alanine–valine
IMU	inertial measurement unit
IoT	internet of things
IP	ion pump
IPA	isopropanol alcohol
IPTG	isopropyl-β-D-thiogalactoside
IR	infrared
IRE1	inositol-requiring protein 1
IT	isotopic tracing
ITO	indium tin oxide

J

JC	jump-to-contact
JFIL	jet-and-flash imprint lithography
JKR	Johnson–Kendall–Roberts

K

KPFM	Kelvin probe force microscopy

L

L–B	Langmuir–Blodgett
LAMP	loop-mediated isothermal amplification
LBL	layer-by-layer
LBM	lattice Boltzmann method
LCD	liquid-crystal display
LCoS	liquid crystal on silicon
LCPD	local contact potential difference
LDA	local density approximation
LDL	low-density lipoproteins
LDOS	local density of states
LED	light-emitting diode
LEED	low-energy electron diffraction
LFM	lateral force microscope
LIF	light-induced fluorescent
LIGA	lithography, electroforming and molding
LINC	linker of nucleoskeleton and cytoskeleton
LING	laterally integrated nanogenerator
LJ	Lennard-Jones
LNA	locked nuclei acid
LoC	lab-on-chip
LoD	limit-of-detection
LOEC	lowest observable effect concentration
LPCVD	low-pressure chemical vapor deposition
LSI	large-scale integrated circuit
LSP	localized surface plasmon
LT	low-temperature
LT-STM	low-temperature scanning tunneling microscopy
LTM	laser tracking microrheology
LTO	low-temperature oxide
LTRS	laser tweezers Raman spectroscopy
LUMO	lowest unoccupied molecular orbital
LVDT	linear variable differential transformer

M

m-SWNT	metallic single-walled carbon nanotube
MACE	metal-assisted chemical etching
MALDI	matrix-assisted desorption or ionization
MALDI-TOF	matrix-assisted laser desorption ionization-time of flight mass spectrometer
MAPK	mitogen-activated protein kinase
MBE	molecular beam epitaxy
MC	microcantilever
MCBJ	mechanically controlled break junction
MCM	multichip module
MD	molecular dynamics
MDA	malondialdehyde
ME	metal evaporated
MEAM	modified EAM
MED	monolithic elastomer device
MEMS	microelectromechanical system
MExFM	magnetic exchange force microscopy
MExFS	magnetic exchange force spectroscopy
MFC	mass flow controller
MFFD	microflow-focusing device
MFM	magnetic force microscopy
MHD	magnetohydrodynamic
MIC	minimum inhibitory concentration
micro-CT	micro-computer tomography
MIM	metal/insulator/metal
MLE	maximum likelihood estimator
MLG	multilayer graphene
MM	machine model
MMS	methylmethanesulfonate
MOCVD	metalorganic chemical vapor deposition
MOEMS	microoptoelectromechanical systems
MOS	metal–oxide–semiconductor
MOSFET	metal–oxide–semiconductor field-effect transistor
MP	metal particle
MPCVD	microwave plasma CVD
MPECVD	microwave-PECVD
MPPD	multiple path particle dosimetry
MPTMS	3-mercaptopropyltrimethoxysilane
MR	magnetoresistance
MRAM	magnetoresistive random access memory
MRFM	magnetic resonance force microscopy
MRI	magnetic resonance imaging
mRNA	messenger ribonucleic acid
MRP	molecular recognition phases

mSBF	modified simulated body fluid
MSCK	magnetic shell cross-linked knedel-like nanoparticles
MscL	mechanosensitive channel of large conductance
MSS	membrane-type surface stress sensor
MST	microsystem technology
MTTF	mean time to failure
MTX	methotrexate
MUMP	multi-user MEMS process
MWNT	multiwalled (carbon) nanotube

N

NAA	neutron activation analysis
NAC	*N*-acetyl-cysteine
NAT	nuclear analytical technique
NCG	glass nanochannel
NE	nuclear envelope
NEMS	nanoelectromechanical system
NEXAFS	near-edge x-ray absorption fine structure
NGL	next-generation lithography
NHS	*N*-hydroxysuccinimide
NIL	nanoimprint lithography
NIR	near-infrared
NMP	nitroxide mediated polymerization
NMR	nuclear magnetic resonance
NOEMS	nanooptoelectromechanical systems
NP	nanoparticle
NPC	nuclear pore complex
NR	nanorod
NRAM	nonvolatile random access memory
NRM	nanorobotic manipulator
NSOM	near-field scanning optical microscopy
NSS	neurotransmitter sodium symporter
NST	nanosystem technology
NT	nanotube
NTA	nitrile-tri-acetic acid
nTP	nanotransfer printing
NW	nanowire

O

O-E-O	optical-electronic-optical switches
ODDMS	*n*-octadecylmethyl (dimethylamino) silane
ODMS	*n*-octyldimethyl (dimethylamino) silane
ODP	*n*-octadecylphosphonate
ODTS	octadecyltrichlorosilane
OLED	organic light-emitting device
OM	optical microscope
OMCTS	octamethylcyclotetrasiloxane
OMVPE	organometallic vapor phase epitaxy
OS	optical stretcher
OTF	optical transfer function
OTRS	optical tweezers Raman spectroscopy
OTS	octadecyltrichlorosilane

P

PA	peptide amphiphile
PA-GFP	photoactivatable green fluorescent protein
PA-PF	photoactivatable protein fluorophores
PAH	polycyclic aromatic hydrocarbon
PALM	photoactivated localization microscopy
PAMAM	polyamidoamine
PANI	polyaniline
PBC	periodic boundary condition
PBD	polybutadiene
PBG	photonic band gap
PBS	phosphate buffered saline
PCL	polycaprolactone
PCR	polymerase chain reaction
PCR-CE	polymerase chain reaction-capillary electrophoresis
PDF	probability density function
PDGF	platelet-derived growth factor
PDK	process design kit
PDMS	poly(dimethylsiloxane)
PE	polyethylene
PECVD	plasma-enhanced chemical vapor deposition
PEDOT	polyethylene dioxythiophene
PEEK	polyether ether ketone
PEG	polyethylene glycol
PEGMA	poly(ethylene glycol) methacrylate
PEI	polyethylenimine
PERK	PKR-like endoplasmic reticulum kinase
PES	photoemission spectroscopy
PET	poly(ethylene terephthalate)
PETN	pentaerythritol tetranitrate
PEUT	poly(ether urethane)
PFDA	perfluorodecanoic acid
PFDP	perfluorodecylphosphonate
PFDTES	perfluorodecyltriethoxysilane
PFPE	perfluoropolyether
PFTS	perfluorodecyltricholorosilane
PGA	polyglycolic acid
PhC	photonic crystal
PI	polyimide
PI3K	phosphatidylinositol-3-kinase
PIN	p-type/intrinsic/n-type
PIT	phase inversion temperature
PKA	protein kinase
PKC	protein kinase C
PKI	protein kinase inhibitor
PL	photoluminescence
PLA	polylactic acid
PLAF	poly(lactide fumarate)
PLD	pulsed laser deposition
PLGA	poly(lactic-*co*-glycolic acid)
PLGF	poly(lactide-*co*-glycolide fumarate)
PLL	phase lock loop
PMAA	poly(methacrylic acid)
PMMA	poly(methyl methacrylate)
PMN	polymorphonuclear

PMN–PT	lead magnesium niobate-lead titanate
PmPV	poly[(*m*-phenylenevinylene)-*co*-(2,5-dioctoxy-*p*-phenylenevinylene)]
PMT	photomultiplier tube
PN	purine nucleotide
PNA	peptide nucleic acid
PNIPAm	poly(*N*-isopropylacrylamide)
poly-Si	polysilicon
POM	polyoxymethylene
PP	plasmon polariton
PPDDAC	poly(diallyldimethylammonium chloride)
PPGMA	poly(propylene glycol) methacrylate
PPMA	poly(propyl methacrylate)
PPNF	polypropylene nonwoven fabric
PS	polystyrene
PS-b-PDMS	poly(styrene-*b*-dimethylsiloxane)
PSA	prostate-specific antigen
PSD	position-sensitive detector
PSF	point spread function
PSG	phosphosilicate glass
PT	Prandtl–Tomlinson
PTCDA	perylenetetracarboxylic dianhydride
PTFE	polytetrafluoroethylene
PTR	pole-tip recession
PTX	paclitaxel
PVD	physical vapor deposition
PZT	lead zirconate titanate

Q

QB	quantum boxes
QCM	quartz crystal microbalance
QD	quantum dot
QEM	quantum electromechanics
QHE	quantum Hall effect
QPD	quadrant photodiode
QSAR	quantitative structure–activity relationship
QWR	quantum wire

R

RAFT	reversible addition and fragmentation transfer
RAM	random access memory
RBC	red blood cell
RDL	redistribution layer
RESLOFT	reversible saturable optical fluorescence transition
RF	radio frequency
RF MEMS	radio frequency MEMS
RGD	arginine–glycine–aspartic acid
RH	relative humidity
RHEED	reflection high-energy electron diffraction
RIE	reactive ion etching
RKKY	Ruderman–Kittel–Kasuya–Yoshida
RMS	root mean square
RNA	ribonucleic acid
RO	reverse osmosis
ROS	reactive oxygen species
RSF	rate-and-state friction
RT	room temperature
RT-DC	real-time deformability cytometry
RT-PCR	reverse-transcription PCR
RTA	rapid thermal annealing
RTP	rapid thermal processing

S

s-SWNT	semiconducting single-walled carbon nanotube
SA-MCtW	self-assembly-based multi-chip-to-wafer bonding
SAED	selected area electron diffraction
SAIL	self-aligned imprint lithography
SAM	self-assembled monolayer
SAW	surface acoustic wave
SB	Schottky barrier
SCC	stress corrosion cracking
SCFv	single-chain fragment variable
SCIL	substrate conformal imprint lithography
SCM	scanning capacitance microscopy
SCPM	scanning chemical potential microscopy
SCREAM	single-crystal reactive etching and metallization
SDA	scratch drive actuator
SEcM	scanning electrochemical microscopy
SEFM	scanning electrostatic force microscopy
SEM	scanning electron microscopy
SERT	serotonin transporter
SET	single electron transistor
SFA	surface force apparatus
SFAM	scanning force acoustic microscopy
SFM	scanning force microscopy
SHG	second harmonic generation
SHiMMeR	Sandia high-volume measurement of micromachine reliability
SHO	simple harmonic oscillator
SICM	scanning ion conductance microscopy
SKPM	scanning Kelvin probe microscopy
SL	soft lithography
SLIPS	slippery liquid-infused surfaces
SLS	solution–liquid–solid
SMA	shape memory alloy
SMFS	single molecule force spectroscopy
SMLM	single molecule localization microscopy
SMM	scanning magnetic microscopy
SMR	suspended micro-channel resonator
SMRT	single-molecule real-time
SNOM	scanning near-field optical microscopy
SNR	signal-to-noise ratio
SNS	superconductor–normal metal–superconductor
SOD	superoxide dismutase
SOFI	superresolution optical fluctuation imaging

SOG	spin-on-glass
SOI	silicon-on-insulator
SOIMEMS	silicon-on-insulator microelectromechanical systems
SoS	silicon-on-sapphire
SP	sputtering
SP-STM	spin-polarized scanning tunneling microscopy
SPECT	single-photon emission computed tomography
SPIM	selective plane illumination microscopy
SPM	scanning probe microscopy
SPN	spherical polymeric nanoconstruct
SPR	surface plasmon resonance
SPS	spark plasma sintering
sptPALM	single-particle tracking PALM
SQL	standard quantum limit
SRAM	static random access memory
SRCD	synchrotron radiation circular dichroism spectroscopy
SSIL	step-and-stamp imprinting lithography
SSRM	scanning spreading resistance microscopy
STED	stimulated emission depletion
STEM	scanning transmission electron microscope
SThM	scanning thermal microscopy
STM	scanning tunneling microscopy
STORM	stochastic optical reconstruction microscopy
STP	standard temperature and pressure
STS	scanning tunneling spectroscopy
SUN	Sad1p/UNC-84
SVR	surface-to-volume ratio
SWNT	single-walled (carbon) nanotube

T

TASA	template assisted self-assembly
TB-BGA	top–bottom ball grid array
TCP	tricresyl phosphate
TEM	transmission electron microscopy
TEP	thermoelectric power
TFET	tunnel field-effect transistor
TFM	traction force microscopy
TGA	thermogravimetric analysis
TGF	transforming growth factor
THC	tetrahydrocurcumin
THF	tetrahydrofuran
THG	third harmonic generation
TIRF	total internal reflection fluorescence

XANES	x-ray absorption near-edge structure
XPS	x-ray photoelectron spectroscopy
XRD	x-ray diffraction
XRF	x-ray fluorescence

Z

ZMW	zero-mode waveguide

1. Introduction to Nanotechnology

Bharat Bhushan

Nanotechnology refers to technology that is implemented at the nanoscale and has applications in the real world. Unique physical and chemical properties of nanomaterials can be exploited for applications that benefit society. Nanotechnology represents a *megatrend* and has become a *general purpose* technology. An executive action of 2000, the National Nanotechnology Initiative was formalized with the 21st Century Nanotechnology Research and Development Act in 2003. Through FY 2015 in the United States, federal R&D investment has been about $20 billion, with annual investment in FY 2015 of about $1.5 B, and more than double that by the private sector. The revenues from nanoenabled products continue growing, with over $200 B in FY 2012 in the US alone, and over $700 B worldwide. This represents an impressive return on investment. Basic research and development as well as research on potential safety issues of nanotechnology, workforce development, and education and curriculum should be continued.

> *A biological system can be exceedingly small. Many of the cells are very tiny, but they are very active; they manufacture various substances; they walk around; they wiggle; and they do all kinds of marvelous things – all on a very small scale. Also, they store information. Consider the possibility that we too can make a thing very small which does what we want – that we can manufacture an object that maneuvers at that level.*

1.1 Nanotechnology – Definitions and Examples

Nanotechnology refers to any technology that is implemented at the nanoscale and has applications in the real world. It is defined as the control or restructuring of matter at the atomic and molecular levels in the size range of about 1 to 100 nm [1.1, 2]. The underlying science is referred to as nanoscience. The properties of matter at the nanoscale are different from those at a larger scale. When the dimensions of a material are reduced from a large size, the properties remain the same at first, then small changes occur. Finally, when the size drops below 100 nm, dramatic changes in properties can occur. The unique physical and chemical properties of nanomaterials can be exploited for commercial applications and for novel performance that benefits society. The discovery of novel materials, processes, and phenomena at the nanoscale and the development of new experimental and theoretical techniques for research at the end of the 20th century provide fresh opportunities for the development of innovative nanosystems and nanomaterials. This field is opening new avenues in science and technology [1.3–5].

Nanotechnology encompasses the nanomanufacturing, nanomaterials, and application of physical, chemical, and biological systems at scales ranging from individual atoms or molecules to submicron dimensions, as well as the integration of the resulting nanostructures into larger systems. It spans scientific fields, including chemistry, physics, material science, engineering, and manufacturing. Its impact on our society and economy in the 21st century is comparable to that of semiconductor technology, information technology, or cellular and molecular biology in the 20th century. The integration of nanotechnology into larger systems has provided breakthrough solutions to many current environmental, medical, and industrial problems, including smart materials, nanomanufacturing, electronics, drug delivery, energy and water, biotechnology, information technology, and national security. Nanotechnology will have a profound impact on our economy and society; it is a modern industrial revolution. Nanotechnology represents a megatrend, bringing disruptive innovation. It has become a general purpose technology, being applicable across various industrial sectors [1.3, 4].

1.1.1 Nanomanufacturing

Manufacturing at the nanoscale, referred to as nano-manufacturing, is accomplished by using either a *bottom–up* or *top–down* approach to the production of nanomaterials, structures, devices, and systems [1.4–6].

In the bottom–up approach, nanoscale features are mainly built up from their elemental constituents. Elemental constituents are combined using various nanomanufacturing processes including self-assembly, chemical synthesis, molecular beam epitaxy, nanoimprint lithography, roll-to-roll processing, and dip pen lithography (http://www.nano.gov). Molecular self-assembly, the spontaneous self-assembly of molecular clusters, can occur from simple reagents in solution or from biological molecules (e.g., DNA) used as building blocks for the production of three-dimensional nanostructures. Chemical synthesis is carried out using gaseous precursors and solvents. These chemicals react to produce nanostructures. A variety of vacuum deposition and nonequilibrium plasma chemistry techniques are then used to produce layered nanocomposites and nanotubes. Molecular beam epitaxy is a method for deposition of thin films with a thickness of one atom on a surface. Nanoprint lithography is used to fabricate nanostructures by stamping or printing them on a surface. Roll-to-roll processing is a high volume process used to produce nanodevices on a flexible substrate. Dip pen lithography uses an atomic force microscope tip in a fluid to produce nanoscale features on a surface.

The top–down approach uses lithographic and nonlithographic fabrication technologies. Lithographic technology is an underlying technology to make semiconductor chips and components. Continued improvements in lithography for use in the production of nanocomponents have resulted in line widths as small as 10 nanometers. The top–down approach is commonly used to fabricate micro- and nanosystem components, which range in size from micro- to nanometers.

1.1.2 MEMS/NEMS

Micro- & nanosystems include Micro/NanoElectroMechanical Systems (MEMS/NEMS). The acronym MEMS originated in the US. The term commonly used in Europe is micro/nanosystem technology (MST/NST), and in Japan it is micro/nanomachines. Another term generally used is micro/nanodevices. Advances in silicon photolithographic process technology since the 1960s led to the development of MEMS in the early 1980s. MEMS combine electrical and mechanical components to create microscopic devices that have a characteristic length between 100 nm and 1 mm. In the early 2000s, with the development of nanofabrication techniques, NEMS were fabricated. NEMS combine electrical and mechanical components to create nanoscopic devices that have a characteristic length of less than 100 nm. In mesoscale devices, if the functional components are on the micro- or nano-

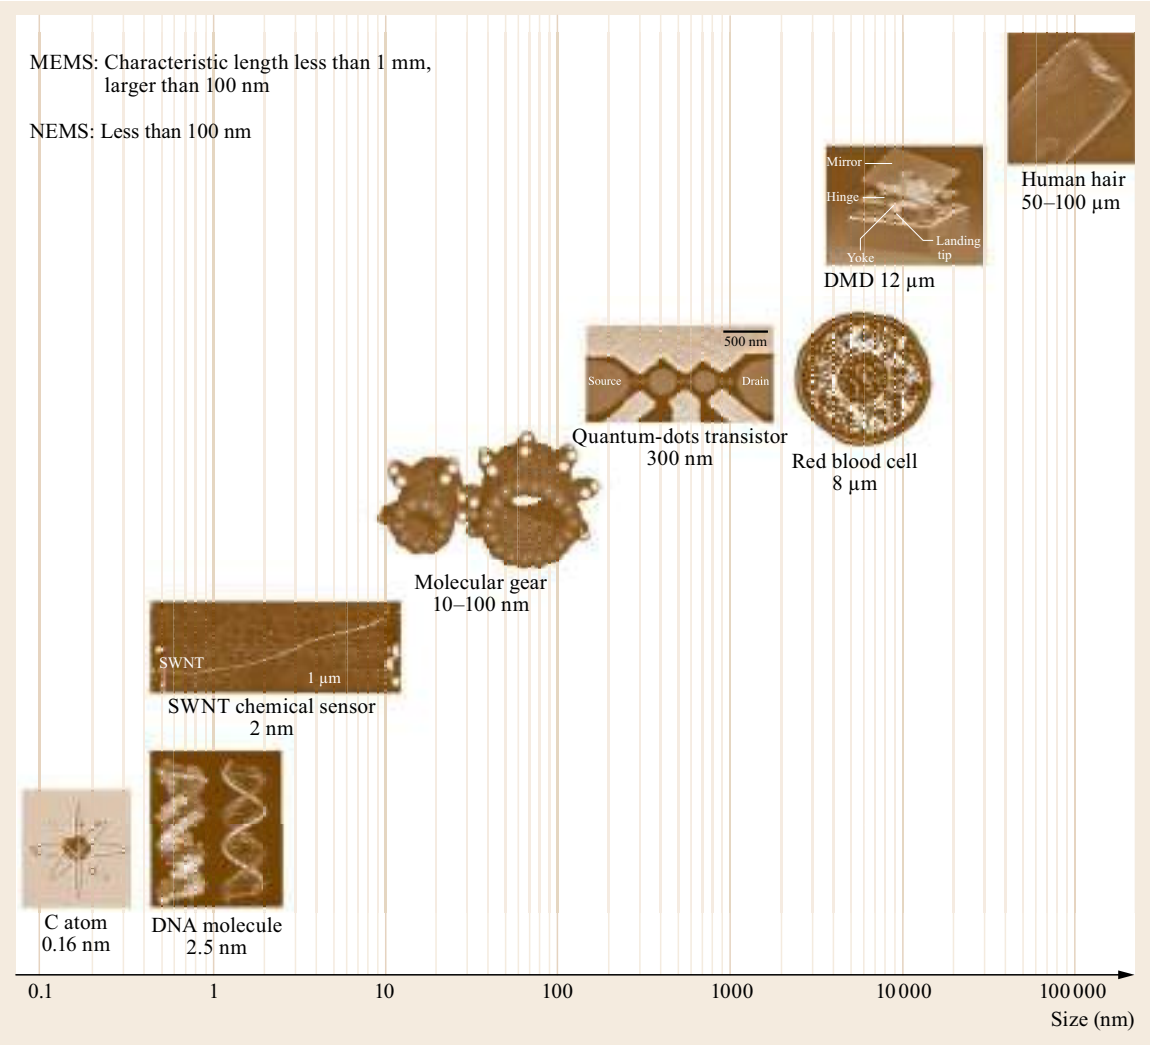

Fig. 1.1 Characteristic dimensions of nanomaterials, MEMS/NEMS, and BioNEMS in perspective (after [1.3]). Examples shown are a single-walled carbon nanotube (SWNT) chemical sensor (after [1.7]), molecular dynamic simulations of carbon nanotube-based gears (after [1.8]), a quantum-dot transistor (after [1.9]), and a digital micromirror device (DMD) (after [1.10])

scale, they may be referred to as MEMS or NEMS, respectively. These are intelligent miniaturized systems comprised of sensing, processing, and/or actuating functions that combine electrical and mechanical components [1.4]. The MEMS/NEMS terms are also now used in a broad sense and include electrical, mechanical, fluidic, optical, and/or biological function. MEMS/NEMS for optical applications are referred to as micro/anooptoelectromechanical systems (MOEMS/NOEMS). MEMS/NEMS for electronic applications are referred to as radio-frequency-MEMS/NEMS or RF-MEMS/RF-NEMS. MEMS/NEMS for biological applications are referred to as bioMEMS/bioNEMS.

To put the dimensions and weights of nanomaterials, MEMS/NEMS, and BioNEMS in perspective, see Fig. 1.1 and Table 1.1. Examples shown are a single-walled carbon nanotube (SWNT) chemical sensor (adapted from [1.7]), molecular dynamic simulations of carbon nanotube-based gears (adapted from [1.8]), a quantum-dot transistor (adapted from [1.9]), and a digital micromirror device (adapted from [1.10]). Individual atoms are typically a fraction of a nanometer in diameter, DNA molecules are about 2.5 nm wide, biological cells are in the range of thousands of nm in diameter, and human hair is about 75 000 nm (75 µm) in diameter. The smaller length of a BioNEMS shown

Table 1.1 Characteristic dimensions and weights of various objects in perspective (after [1.3])

Characteristic dimensions in perspective	
Fabricated	
NEMS characteristic length	< 100 nm
MEMS characteristic length	< 1 mm and > 100 nm
SWNT chemical sensor	≈ 2 nm
Molecular gear	≈ 10 nm
Quantum-dots transistor	300 nm
Digital micromirror	12 000 nm
Natural	
Individual atoms	Typically a fraction of a nm in diameter
DNA molecules	≈ 2.5 nm wide
Biological cells	In the range of thousands of nm in diameter
Human hair	$\approx 75\,000$ nm in diameter
Weight in perspective	
Fabricated	
NEMS built with cross-sections of about 10 nm	As low as 10^{-20} N
Micromachine silicon structure	As low as 1 nN
Natural	
Eyelash	≈ 100 nN
Water droplet	$\approx 10\,\mu$N

in the figure is about 2 nm. NEMS shown range in size from 10 to 300 nm, and the size of MEMS is on the order of 12 000 nm (12 μm). The weight of a micromachined silicon structure can be as low as 1 nN, and NEMS can be built with weights as low as 10^{-20} N with cross-sections of about 10 nm. In comparison, the weight of a drop of water is about 10 μN, and the weight of an eyelash is about 100 nN.

1.1.3 Convergence

Roco and *Bainbridge* [1.11] have discussed convergence of nanotechnology, biotechnology, information, and cognitive science for emerging technologies. Convergence is the process of bringing disparate technologies together into a unified field. Convergence is progressing in stages, beginning with foundational interdisciplinary research at the nanoscale between 2001 and 2010, followed by integration of nanoscience and nanotechnology for general purpose technology from approximately 2010 onwards.

1.1.4 Industrial Applications

MEMS/NEMS and BioMEMS/BioNEMS are used for applications in the industrial, consumer, defense, and biomedical fields and include electromechanical, electronics, information/communication, chemical, and biological applications, to name a few. Growth of Si-based MEMS/NEMS appears to have slowed down, while growth of nonsilicon MEMS/NEMS and BioMEMS/BioNEMS has been picking up since the first decade of the 21st century [1.4]. It is expected that nanomaterials and biomedical applications as well as nanoelectronics or molecular electronics would continue to expand. Because of the enabling nature of these systems and the significant impact they can have on both commercial and defense applications, both industry and national governments have taken a special interest in nurturing growth in this field.

The first MEMS were commercially introduced around 1990. These were accelerometers for the deployment of an air bag in a car in the event of a crash, piezoresistive pressure sensors for manifold absolute pressure sensing in car engines, and thermal inkjet print heads. In 2015, additional examples of MEMS with large and established markets with production volumes of several hundred million units per year include piezoresistive pressure sensors for disposable blood pressure sensors, capacitive pressure sensors for tire pressure measurements, digital micromirror arrays for digital projection display, and optical cross-connections in telecommunications. Other applications of MEMS devices include chemical/biosensors and gas sensors, microresonators, infrared detectors and focal plane arrays for earth observations, space science and missile defense applications, picosatellites for space applications, fuel cells, and many hydraulic, pneumatic, and other consumer products.

NEMS applications include both biological and nonbiological fields. Examples include: microcantilevers with integrated sharp nanotips for scanning tunneling microscopy (STM) and atomic force microscopy (AFM), quantum corral formed by one-by-one placing of atoms using STM, AFM tips for nanolithography, dip pen lithography for printing molecules, quantum dot transistors, nanotube-based sensors, biological (DNA) motors, molecular gears made by attaching benzene molecules to the outer walls of carbon nanotubes, devices incorporating nm-thick films (e.g., in giant magnetoresistive or GMR read/write magnetic heads and magnetic media) for magnetic rigid disk and magnetic tape drives, and nanopatterned magnetic rigid disks.

Nanomaterials include nanoparticles (aggregate of $10-10^5$ atoms bonded together), nanowires, nanotubes, and quantum wires. Nanomaterials have many applications. For example, nanoparticles are used in magnetic coatings for information storage devices and drug delivery, and nanotubes and nanowires are used in various sensor applications. Nanoelectronics are being developed from these nanomaterials. They are used to build computer memory using individual molecules or nano-

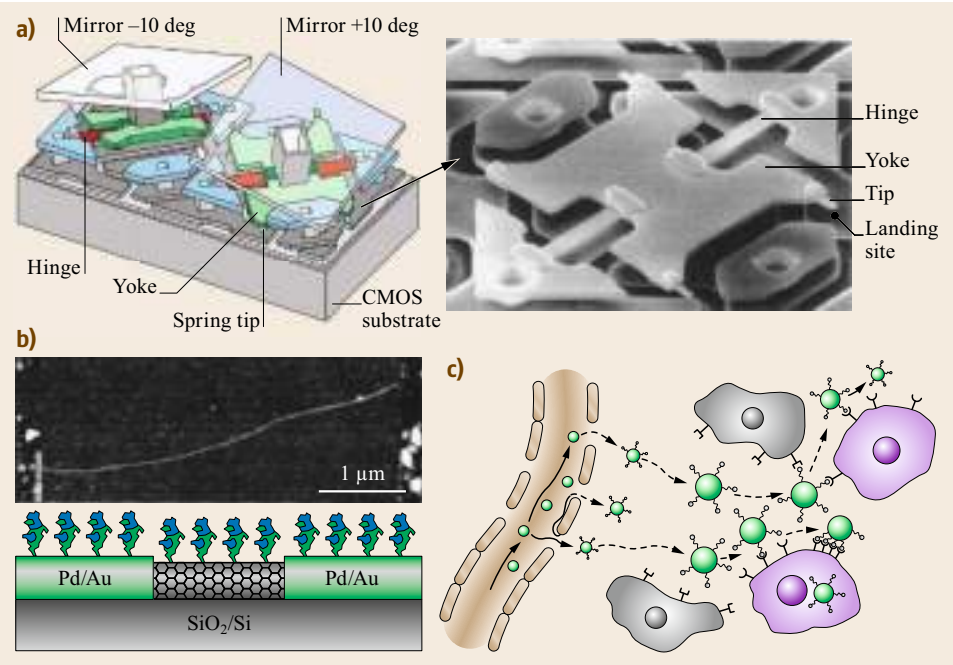

Fig. 1.2a–c Examples of **(a)** MEMS – digital micromirror device used for digital projection display (after [1.10] reprinted with permission, courtesy of Texas Instruments), **(b)** NEMS – SWNT chemical sensor (after [1.7]), and **(c)** functionalized nanoparticles for cancer detection and drug delivery (after [1.12])

tubes to store bits of information, molecular switches, molecular or nanotube transistors, nanotube flat-panel displays, nanotube integrated circuits, fast logic gates, switches, nanoscopic lasers, and nanotubes as electrodes in fuel cells.

BioMEMS/BioNEMS are increasingly being used in commercial and defense applications. They are used for chemical and biochemical analyses (biosensors) in medical diagnostics (e.g., DNA, RNA, proteins, cells, blood pressure and assays, and toxin identification), tissue engineering, and implantable pharmaceutical drug delivery. Biosensors, also referred to as biochips, deal with liquids and gases. There are two types of biosensors. The first type of biosensors are micro/nanofluidic devices. A large variety of biosensors are based on micro/nanofluidics. Micro/nanofluidic devices offer the ability to work with smaller reagent volumes and shorter reaction times, and perform analyses multiple times at once. The second type of biosensors are micro/nanoarrays, which perform one type of analysis thousands of times. Micro/nanoarrays are a tool used in biotechnology research to analyze DNA or proteins, to diagnose diseases, or discover new drugs. One microarray of silicon nanowires is used to selectively bind to and detect even a single biological molecule, such as DNA or protein. It is roughly a few nanometers in size and uses nanoelectronics to detect the slight electrical charge caused by the selective binding. Another type is a microarray of carbon nanotubes used to electrically detect glucose.

After the tragedy of 11 Sept. 2001, concern surrounding biological and chemical warfare led to the development of handheld units with bio- and chemical sensors for detection of biological germs, chemical or nerve agents, and mustard agents, as well as chemical precursors to protect subways, airports, water supplies, and the population at large. BioMEMS/BioNEMS are also being developed for minimally invasive surgery, including endoscopic surgery, laser angioplasty, and microscopic surgery. Other applications include implantable drug-delivery devices: micro/nanoparticles with drug molecules encapsulated in functionalized shells for site-specific targeting applications, and a silicon capsule with a nanoporous membrane filled with drugs for long-term delivery.

Figure 1.2 shows an example of (a) MEMS – a digital micromirror device (DMD) used for digital projection display (adapted from [1.10]), (b) NEMS – a single-walled nanotube (SWNT) chemical sensor (adapted from [1.7]), and (c) functionalized nanoparticles for cancer detection and drug delivery (adapted from [1.12]).

In this chapter, we will first discuss history and early research expenditures in relation to nanotechnology followed by governance of the National Nanotechnology Initiative, nanotechnology research and development (R&D) funding since 2001, worldwide R&D investments, nanoscience and nanotechnology education, and a summary and outlook. Finally, we will present the organization of the Handbook.

1.2 History and Early Research Expenditures

On 29 Dec. 1959 at the California Institute of Technology, Nobel Laureate Richard P. Feynman gave a talk at the Annual Meeting of the American Physical Society that has become one of the classic science lectures of the 20th century, titled, *There's Plenty of Room at the Bottom* [1.13]. He presented a technological vision of extreme miniaturization, several years before the word *chip* became part of the lexicon. He talked about the problem of manipulating and controlling things on a small scale. Extrapolating from known physical laws, Feynman envisioned a technology using the ultimate toolbox of nature, building nano-objects atom-by-atom or molecule-by-molecule. Since the 1980s, many inventions and discoveries in the fabrication of nano-objects have been testaments to his vision.

In 1998, the National Science and Technology Council (NSTC) of the White House Office of Science and Technology Policy (OSTP) created the Interagency Working Group on Nanoscience, Engineering and Technology (IWGN), recognizing the reality of the

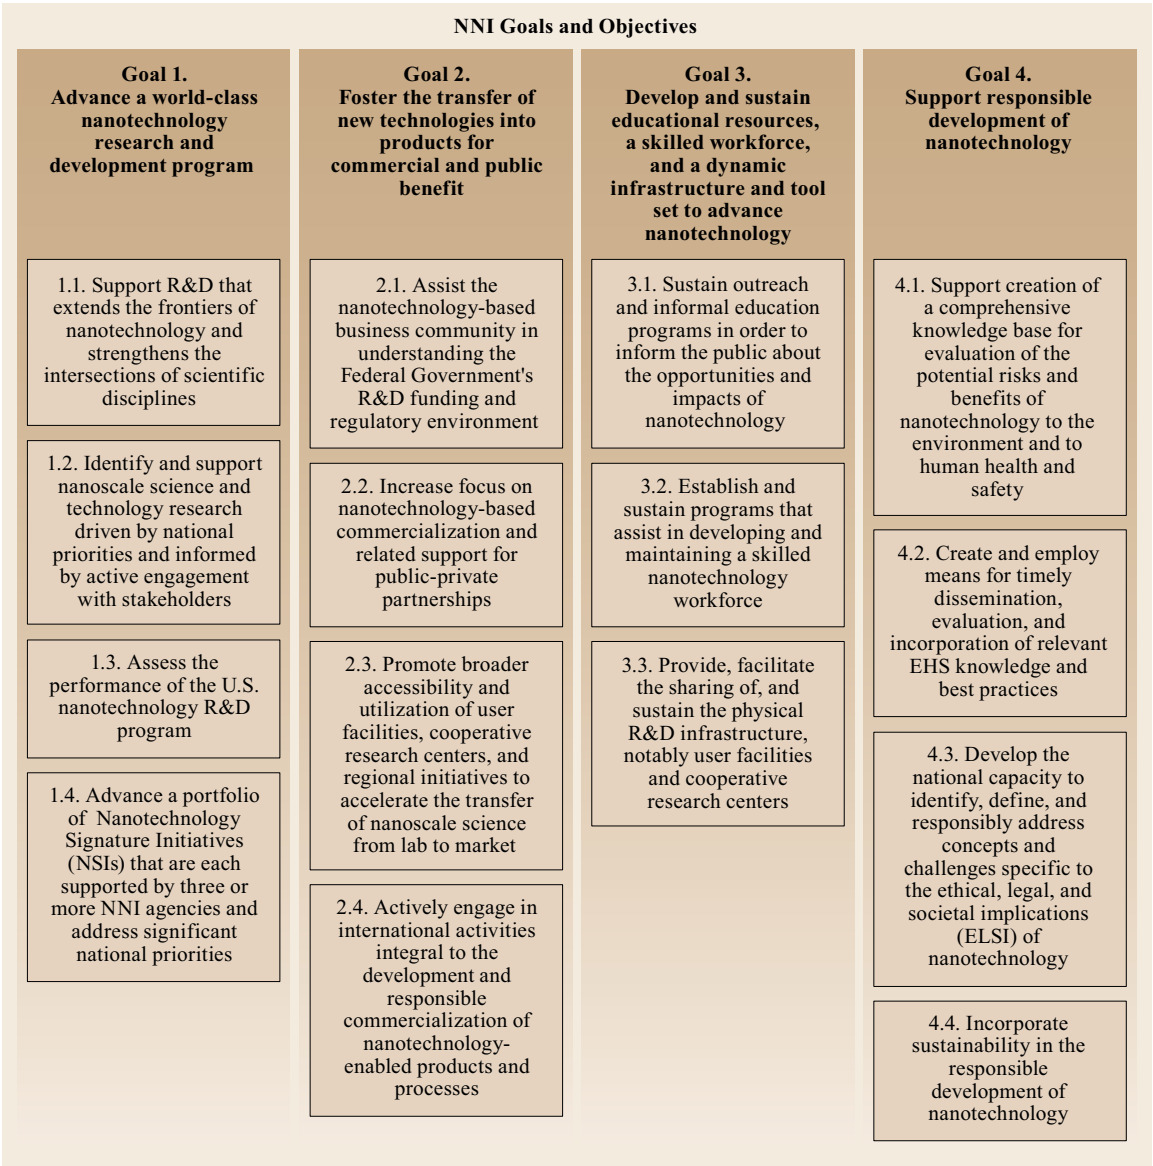

Fig. 1.3 A summary of NNI goals and objectives from the 2014 NNI Strategic Plan (after [1.14])

proliferation of nanotechnology. In 1999, the IWGN was elevated to the Subcommittee on Nanoscale Science, Engineering, & Technology (NSET). In a January 2000 speech also at the California Institute of Technology, President William J. Clinton talked about the exciting promise of nanotechnology and the importance of expanding research in nanoscale science and technology more broadly. Later that month in his State of the Union Address, he announced an ambitious $497 million federal, multiagency National Nanotechnology Initiative (NNI) in the FY (fiscal year) 2001 budget, and made the NNI a top science and technology priority [1.2]. The objective of this initiative was to form a broad-based coalition in which academia, the private sector, and local, state, and federal governments work together to push the envelope of nanoscience and nanoengineering to reap nanotechnology's potential social and economic benefits.

In Jan. 2003, following the creation of the NNI, the US Senate in the 108th Congress introduced a bill to establish a National Nanotechnology Program. On 3 Dec. 2003, President George W. Bush signed into law the 21st Century Nanotechnology Research and Development Act (NRDA) (Public Law 108–153). The legislation put into law programs and activities supported by the NNI. The bill gave nanotechnology a permanent home in the federal government and authorized $3.7 billion to be spent in the four year period beginning in October 2005. This allocation was for nanotechnology initiatives at six federal agencies: National Science Foundation (NSF), Department of Defense (DOD), Department of Energy (DOE), National Aeronautics and Space Administration (NASA), National Institute of Standards and Technology (NIST), and the National Institutes of Health (NIH). The funds were used to provide grants to researchers, coordinate R&D across the six agencies, establish interdisciplinary research centers, and accelerate technology transfer into the private sector.

Nanotechnology R&D is directed towards understanding and controlling matter at the nanoscale. NNI has four goals [1.14]:

1. Advance world-class nanotechnology research and development
2. Foster the transfer of new technologies into products for commercial and public benefit
3. Develop and sustain educational resources, a skilled workforce, and the supporting infrastructure and tools to advance nanotechnology; and
4. Support the responsible development of nanotechnology.

Further details are presented in Fig. 1.3.

Regarding international activities in early stages, in 2002, the European Union (EU) made nanosciences and nanotechnologies a priority in the Sixth Framework Program (FP6) for the period of 2003–2006. They had also dedicated small funds in the FP4 and FP5 programs before. FP6 was tailored to help better structure European research and to cope with the strategic objectives set out in the Lisbon Strategy Development Plan of 2000. Japan identified nanotechnology as one of its main research priorities in 2001. The funding levels increased from $400 million in 2001 to around $950 million in 2004. In 2003, South Korea embarked upon a ten-year program with around $2 billion in public funding, and Taiwan had committed around $600 million in public funding over six years. Russia, Singapore, and China also started to invest on a large scale.

1.3 Governance of the National Nanotechnology Initiative

In 2001, OSTP established a National Nanotechnology Coordination Office (NNCO), which was funded by NSET. The NNCO serves as a central point of contact for Federal nanotechnology R&D activities, and provides public outreach on behalf of the NNI. The NNCO Director and Deputy Director are appointed by the White House Co-Chair of the NSTC Committee on Technology. The NNCO coordinates the preparation and publication of interagency planning, budget, and various documents, such as the NNI supplement to the President's budget. The 21st Century Nanotechnology Research and Development Act called for a National Nanotechnology Advisory Panel (NNAP), to review the NNI triennially. In 2004, PCAST was designated as that panel. In addition, the Act had called for a triennial review by the National Academies.

NNI investments are guided by an annual strategic plan published by the OSTP. Figure 1.4 shows the organizational structure for management of NNI and OSTP coordination and assessment of NNI efforts. The NNI reporting requirements overseen by OSTP include:

1. The triennial strategic plan (Year 1)
2. The triennial assessment by PCAST (Year 2)
3. The triennial assessment of the program by the National Academies (Year 3); and
4. The annual supplemental report submitted with the President's budget.

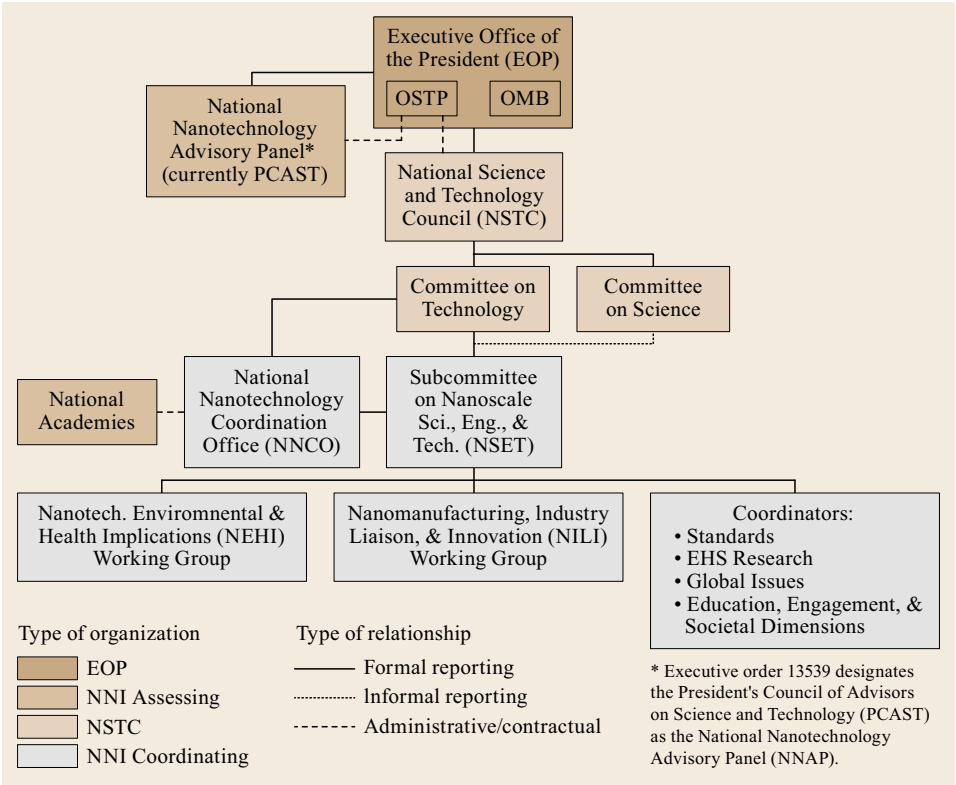

Fig. 1.4 Organizational structure for management of NNI (after [1.14])

It should be noted that since the enactment of the Nanotechnology Act on 3 Dec. 2003, it has not been reauthorized by US Congress. Reauthorization sets the policy for how funding should be spent by the various agencies that carry out the vision of the Nanotechnology Act. While the various funding agencies continue to fund under their current authority, no new direction for that funding has been set.

1.4 Nanotechnology R&D Funding Since 2001

Since 2001, the US Congress has appropriated about $20 billion for nanotechnology R&D through FY 2015, with about $1.5 billion spent in FY 2015 alone. Figure 1.5 shows NNI funding growth from FY 2001 through FY 2015. Twenty top-level federal agencies (27 including all subsidiary subagencies) fund NNI-related research, as shown in Table 1.2. Table 1.3 shows the breakdown of the NNI budget by agency for the period of FY 2001 to FY 2015. About 93% of the funding is spent by five agencies –NIH (28.7%), NSF (26.8%), DOE (22.3%), DOD (9.4%), and NIST (5.4%). US private sector R&D funding, presented in Table 1.4, is more than double that of federal and state funding with a focus on translating fundamental research into commercial products.

The NNI strategic plan for FY 2015 was published in February 2014 by OSTP [1.14]. In this plan, priorities for NNI funding by Program Component Area were:

1. Foundational Research (35% of NNI funding)
2. Applications, Devices, and Systems (24%)
3. Signature Initiatives (19%)
4. Infrastructure & Implementation (16%); and
5. Environment, Health, and Safety (EHS) (7%).

Five areas, called Nanotechnology Signature Initiatives (NSIs), were identified for targeted program-level interagency collaboration. These NSIs were intended to enable the rapid advancement of selected science and technology in the service of national security, economic, and environmental goals by focusing resources on critical challenges and R&D gaps [1.14, 16]. These areas were:

- *Nanotechnology for Solar Energy Collection and Conversion: Contributing to Energy Solutions for the Future*: This NSI will utilize the unique physical phenomena that occur on the nanoscale to help

overcome current performance barriers and substantially improve the collection and conversion of solar energy. Participating agencies include: DOE, NIST, NSF, DOD, Intelligence Community (IC), US Department of Agriculture (USDA), and the National Institute of Food and Agriculture (NIFA).

- *Sustainable Nanomanufacturing: Creating the Industries of the Future*: This NSI will establish manufacturing technologies for economical and sustainable integration of nanoscale building blocks into complex, large-scale systems by supporting product, tool, and process design informed by and adhering to the overall constraints of safety, sustainability, and scalability. Participating agencies include: NIST, NSF, DOE, Environmental Protection Agency (EPA), IC, NIH, National Institute for Occupational Safety and Health (NIOSH), Occupational Safety and Health Administration (OSHA), and USDA/Forestry Service (FS).
- *Nanoelectronics for 2020 and Beyond*: This NSI is aimed at discovering and using novel nanoscale fabrication processes and innovative concepts to produce revolutionary materials, devices, systems, and architectures to advance the field of nanoelectronics. Participating agencies include: NSF, DOD, NIST, DOE, and IC.
- *Nanotechnology Knowledge Infrastructure (NKI): Enabling National Leadership in Sustainable Design*: This NSI will coordinate the nanoscale science, engineering, and technology communities around the fundamental, interconnected elements of collaborative modeling, a cyber-toolbox, and data infrastructure that will capitalize on American strengths in innovation, shorten the time from research to new product development, and maintain US leadership in sustainable design of engineered nanoscale materials. Participating agencies include: Consumer Product Safety Commission (CPSC), DOD, DOE, EPA, Food and Drug Administration (FDA), NASA, NIOSH, NIST, NSF, OSHA.
- *Nanotechnology for Sensors and Sensors for Nanotechnology: Improving and Protecting Health, Safety, and the Environment*: This NSI has considerable potential for nanotechnology to open the door to the development of inexpensive, portable devices that can rapidly detect, identify, and quantify biological and chemical substances. Participating agencies include: CPSC, DOD, EPA, FDA, NASA, NIH, NIOSH, NIST, NSF, USDA.

In the international context, Federal investment in FY 2014 and 2015 by the US of about $1.5 B per year is slightly higher than that by the EU or Japan. In 2014, the EU launched Horizon 2020 (2014-2020) after the conclusion of the EU FP7, with a total budget of €77 B. In Horizon 2020, the EU identified six key areas: nanotechnology, advanced manufacturing, advanced materials, nanoelectronics, photonics, and biotechnology, and allocated €6.6 B for these areas over a six year period; about €1.1 B per year. An additional €5 B was planned for public-private partnerships. It should be noted that, in addition to EU expenditure, individual countries within the EU invest additional money on research. In 2014, Japan planned to spend ¥550 B over the following five year period on nanotechnology, which translates to about $1 B per year. Japanese companies are reported to invest about 90% of total R&D in nanotechnology.

1.5 Worldwide R&D Investments and Output

1.5.1 R&D Investments

Figure 1.6 shows Federal R&D funding from FY 1997 to FY 2009 for the US, EU, Japan, and others. The funding has steadily grown for all countries. The US and the EU have made comparable investments, followed by Japan, China, Korea, and Taiwan. A substantial change in global investment rate is observed around 2000 after introduction of the NNI and around 2006 due to the introduction of second-generation nanotechnology products. The figure also shows the specific Nano R&D 2008 in dollars per capita. The numbers for the US, EU, and Korea are comparable, with Japan being higher. Figure 1.7 shows industrial spending for various countries in 2012. The US spent far more than other countries. However, the rest of the world, particularly emerging economies such as China, have been increasing their funding both at the national government and industrial levels at a rapid rate.

1.5.2 Output

Limited current US data exists on the return on investment in nanotechnology as it relates to scientific output, the number of jobs created, and product revenues [1.17–22]). The European Commission Research Directorate General, Brussels, and the US Organization for Economic Cooperation and Development (OECD) have published some data on these subjects, though individual US federal agencies have not published much

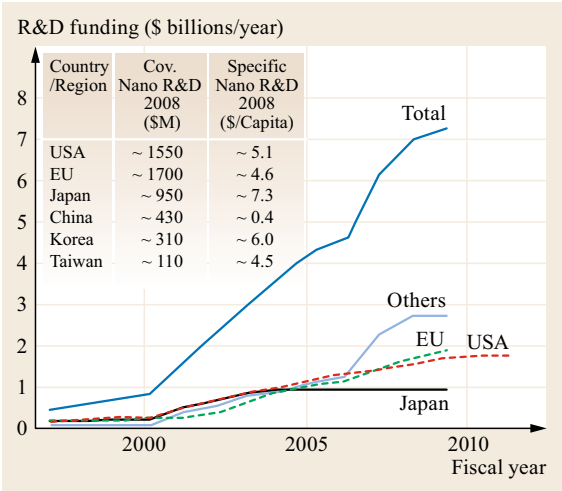

Fig. 1.6 FY 1997-2009 Federal/national government R&D funding. Specific nanotechnology R&D per capita is based on the national nanotechnology expenditures and effective expenditure for all other R&D programs (after [1.3, 17])

data themselves. These data are critical for tracking performance and for planning purposes. They are also critical for Congress to make educated decisions on reprioritization and total investments in nanotechnology R&D. In this section, we present an overview of the US data that exists in the public domain.

Figure 1.8a shows the number of nanotechnology publications in archival journals in the SCI (Science Citation Index) database between 1990 and 2013 for the US and other countries, and Fig. 1.8b,c shows the number of nanotechnology patents published for the US and other countries. There is a steady growth in the number of publications for each country, although unevenly distributed among the various countries. The metrics of patents published in three or more countries is a more representative indicator of significance compared to those patents published in just one or two countries. It should be noted that although the rate of patents published has decreased over the past decade, the cumulative growth has continued. Additional data are provided by *Roco* [1.17], and *Chen* et al. [1.19]. Figure 1.9 gives the breakdown of the number of patents issued by the US Patent and Trademark Office (USPTO) by technology area as of 31 December 2012, type of invention in 2012, and by country of residence of the first-named inventor taken from patent applications.

R&D funding breakdown and nanoenabled product revenues for various regions in 2012 are presented in Tables 1.4 and 1.5. In 2012, for the US alone, nanoenabled product revenues were $236 billion for a modest annual federal R&D investment of $1.5 billion, or a total public/private investment of $6.6 billion. This represents an impressive return on investment.

Table 1.6 presents a summary of six key indicators of nanotechnology R&D investment and output in the world and the US between 2000 and 2010. The key indicators include:

1. R&D funding (public and private)
2. Venture capital
3. SCI papers
4. Patent applications
5. People – primary workforce, and
6. Final products market.

A growth rate of the key nanotechnology indicators of 16–33% is observed. It is noted that the global market for nanomaterials has been reported to be tens of billions of dollars in FY 2015 with a rapid growth rate. The global revenues of nanoenabled products and nanomaterials are approaching $1 trillion.

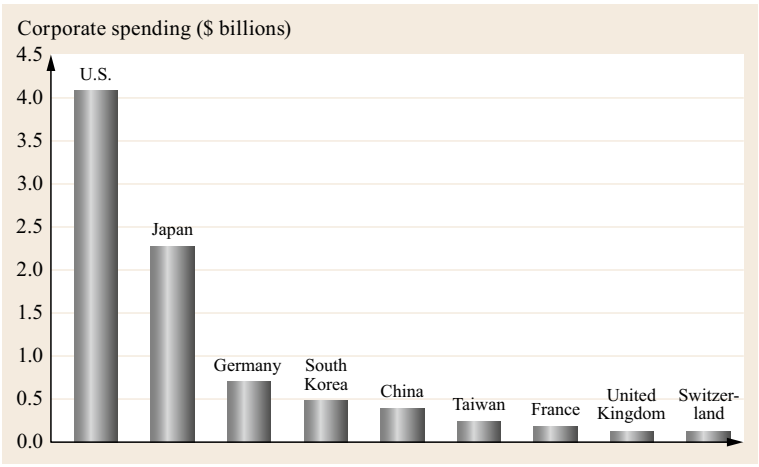

Fig. 1.7 Industrial R&D spending in 2012 for industry focused on applied R&D for first & second generations of nanotechnology products (after [1.3, 18])

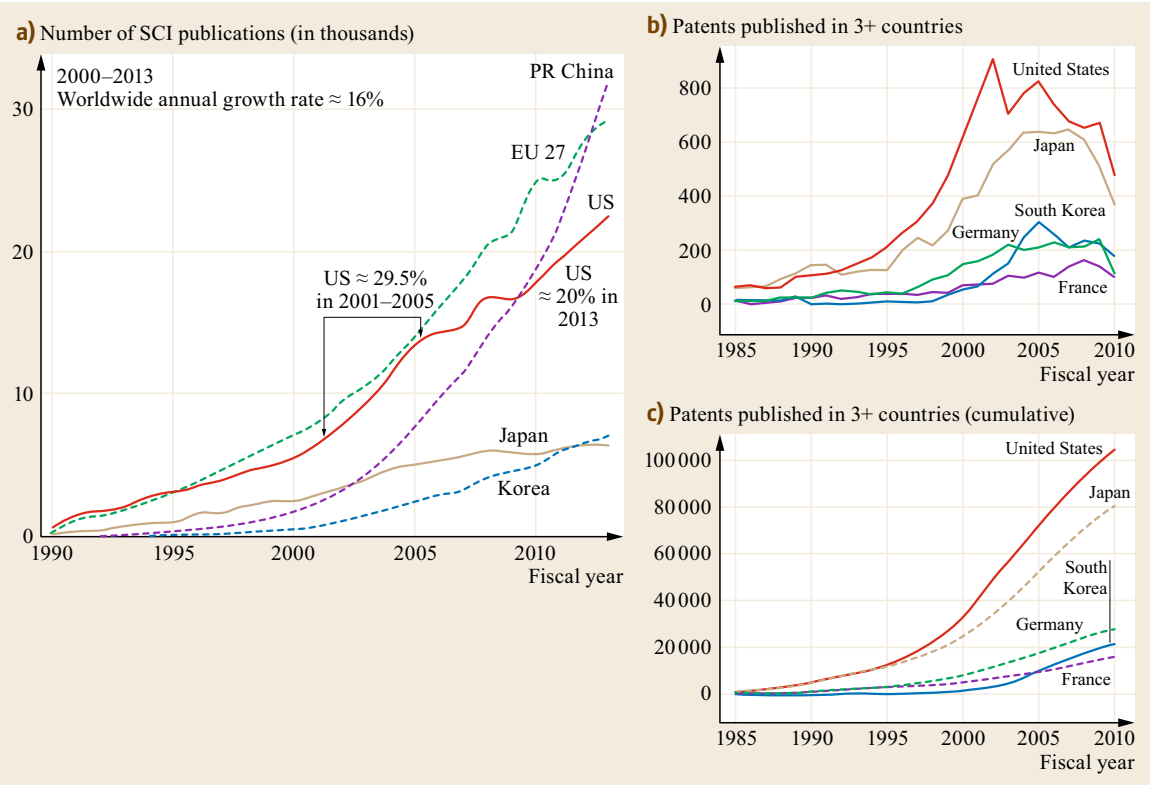

Fig. 1.8 **(a)** Number of nanotechnology SCI publications from 1990 to 2013. Data was generated from an online search in the Web of Science using a *title-abstract* search in the SCI database for nanotechnology by keywords (after [1.3, 18]). **(b,c)** Number of nanotechnology patents published from 1985 to 2010 for the US and other countries. The metrics of patents published in three or more countries is a more representative indicator of significance (after [1.3, 15])

Table 1.4 R&D funding data across all industrial sectors in various regions in 2012, data collected by Lux Research (after [1.3, 15, 21])

US	Federal and state	$ 2.1 billion
	Industry	$ 4.0 billion
	Venture capital investors	$ 0.5 billion
	Total	$ 6.6 billion
Worldwide	Federal, state, industry, and venture capital investors	$18.5 billion

Table 1.5 Nanoenabled Product Revenues data across all industrial sectors in various regions in 2012, data collected by Lux Research (after [1.3, 21])

US	$236 billion
Europe	$235 billion
Asia	$213 billion
Rest of the world	$ 47 billion
Total	$731 billion

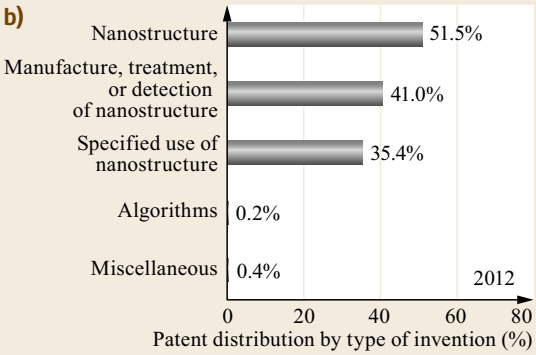

Table 1.6 Summary of six key indicators of nanotechnology R&D investment and output in the world and the US during 2000-2010 and projections for 2015 (after [1.3, 18]) (Venture Capital estimations were made by Lux Research)

World/US	R&D funding (public & private)	Venture capital	SCI papers	Patent applications	People – primary workforce	Final products market
2000	≈ $1.2 B/$0.37 B	≈ $0.21 B/$0.17 B	18 085/5342	1197/405	≈ 60 000/25 000	≈ $30 B/$13 B
2010	≈ $18 B/$4.1 B	≈ $1.3 B/$1.0 B	78 842/17 978	≈ 20 000/5000	≈ 600 000/ 220 000	≈ $300 B/$110 B
2000–2010 (aver. growth)	≈ 31%/ ≈ 27%	≈ 30%/ ≈ 35%	≈ 16%/ ≈ 13%	≈ 33%/ ≈ 28%	≈ 25%/ ≈ 23%	≈ 25%/ ≈ 24%
2015 (projected)					≈ 2 000 000/ 800 000	≈ $1000 B/ $400 B

a)

Area of technology	No. of Patents
Biotechnology and organic chemistry	1231
Chemical and materials engineering	2768
Computer architecture software and information security	28
Computer networking, network security, cryptography	5
Communications	259
Semiconductor, electrical, optical systems	3594
Transportation, construction, electronic commerce	66
Mechanical engineering, manufacturing and products	433
Total	8384

b)

c) Patent distribution by residence country (%)

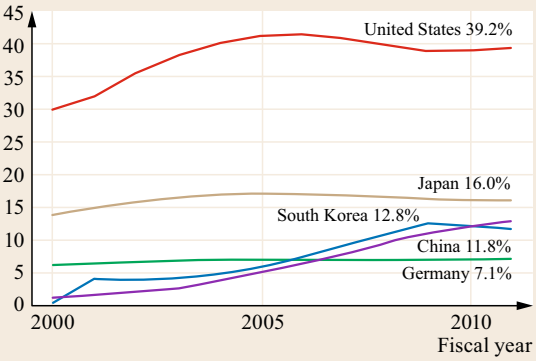

Fig. 1.9a–c The breakdown of the number of patents issued by the USPTO based on **(a)** technology area, as of December 31, 2012, **(b)** type of invention in 2012, and **(c)** residence – country of first-named inventor (after [1.3, 23])

Figure 1.10 shows the primary applications markets for nanoenabled products based on reviews gathered

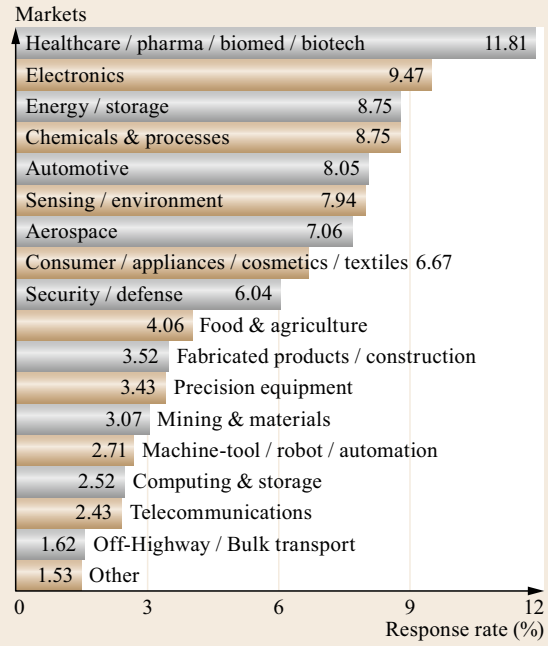

Fig. 1.10 Primary application markets in 2014 for nanoenabled products based on reviews as ranked in a survey (after [1.3, 24])

from 300 respondents in a 2014 survey project conducted by the National Center for Manufacturing Sciences (NCMS), Ann Arbor, Michigan. The data shows that some industries pursue simultaneous pathways for penetrating multiple markets and end users for their products. The largest application markets are listed below in decreasing order of response rate (percentage):

- Healthcare, pharmaceuticals, biomedical applications, and biotechnological applications
- Electronics
- Energy and energy storage
- Chemical and processes
- Automotive
- Sensing and environment, and
- Aerospace.

In summary, the US remains a global leader in both investments and output, as measured by the number of publications and patents, jobs, and nanoenabled product revenue. However, other countries are slowly catching up and competing with the US, including China which is rapidly increasing its share of investment.

1.6 Translation of Basic Research to Technology Commercialization

Research and some development occurs in academic labs, primarily funded by federal and state investments. Translational research is funded jointly by federal/state and private funding. Product launch is then carried out by startups and funded by venture capitalists or industry. Federal R&D agencies and public-private partnerships need to invest in technology transfer and developing research into a successful product. Technology transfer will drive the economy and facilitate in multiplying the investment in basic research. The move of US manufacturing to locations offshore and around the world has given rise to the idea that we *invent here and manufacture there*. This exists because the US economy is not able to provide the necessary investments and incentives for venture capitalists and industries to continue both development and manufacturing in the US [1.25].

Various concerns regarding the NNI have been raised in several reports on the mandated NNI Triennial Reviews; a recent one prepared by The National Academies on the Triennial Review in 2013 [1.26]. Major concerns include lack of information at the project level on who is performing research and its implications; poor planning, management, and coordination; lack of metrics for assessing progress; and lack of official data on return on investments. The Government Accountability Office (GAO) conducted a study and issued a report in 2014 entitled *Nanomanufacturing: Emergence and Implications for US Competitiveness, the Environment, and Human Health* [1.27]. It examined current issues related to nanotechnology and nanomanufacturing. This report also identified various concerns in regard to NNI implementation, including the valley of death – gaps in funding or support for technology development and manufacturing development (for a schematic, see Fig. 1.11). The report also stated that there is a lack of participation in setting standards for nanomanufacturing and nanotechnology, a lack of national vision for nanomanufacturing capability, and a need for an integrated framework to help assess and address the EHS implications.

The PCAST report on the Triennial Review issued in 2014 [1.15] reiterated many critiques advanced by the National Academies and GAO reviews. It stated that the NNI has reached a turning point. Although continued support of fundamental research in nanotechnology is critical, the transition toward commercialization is encouraged to translate the technologies and investments into commercial products and revenues. This may affect a range of technology areas, including drug delivery, energy technology, smart sensors, clean water, and quantum computing.

The report presented four general constraints on technology commercialization [1.15]. It stated that first-time academic entrepreneurs have little training or experience in moving a technical innovation out of the research lab and into a company. The second constraint has to do with a lack of marketing knowledge, i. e., how their innovation might address strategic goals of a company or could be translated into a successful product. Third, given that venture capitalists prefer to back experienced entrepreneurs, fund raising for newcomers becomes more difficult. Finally, an academic may not be allowed by the peer review process to pursue high-risk, high-return ideas. The report made recommendations to address all these constraints.

The report argued that the NSIs being used are shaped by coordination of three or more federal agencies around a topic. Instead, it recommends creation of *Grand Challenges*, which are large, outward-facing efforts with specific, measurable goals. A Grand Challenge has a well-defined technical goal and it addresses

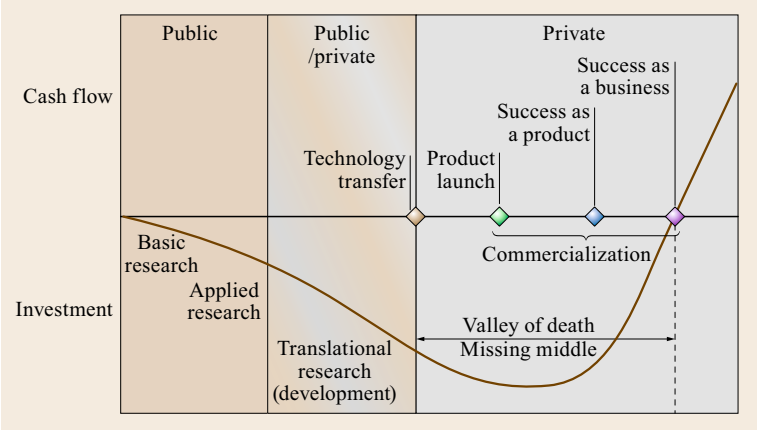

Fig. 1.11 Schematic showing the *valley of death* scenario (after [1.25])

an issue of significant societal impact. It has a measurable end-point with clear milestones en route.

There needs to be a focus on EHS as the use of nanotechnology products, particularly nanomaterials, is perceived to have potential EHS risks when exposed during manufacturing, use, or disposal. Established tools and techniques to study EHS risks do not exist for nanotechnology products. In addition, it is difficult to assess risks because nanomaterials may differ in size, shape, and surface chemistry. NIOSH is responsible for developing recommended exposure limits and necessary protective actions for nanomaterials [1.28–31].

1.7 Nanoscience and Nanotechnology Education

Education and training are essential to produce a new generation of scientists, engineers, and skilled workers with the flexible and interdisciplinary R&D approach necessary for rapid progress in nanosciences and nanotechnology. A trained nanotechnology workforce at both vocational and professional levels needs to be developed. This needs to be accomplished with both formal and informal education efforts, starting with the foundations in children and increasing in technical and specialized education through the university and continuing education levels.

Nanoscience and nanoetechnology education is concerned with five general topics related to this necessity: interdisciplinary education; K-12 education, excitement, and creativity; vocational, undergraduate, graduate, and continuing education programs; educator training; and informal science education [1.32].

1.7.1 Interdisciplinary Education

With decreasing numbers of people choosing to study science and engineering and with the rapid progress in nanoscience and nanotechnology demanding an increasing number of people, the problem of a trained workforce is expected to be acute. The question is being asked – is the traditional separation of academic disciplines into physics, chemistry, biology, and various engineering disciplines meaningful at the nanolevel? Arguably, nanoscience and nanoetechnology education should begin by covering the broad science topics in order to facilitate comprehensive understanding of foundational science. Generic skills and entrepreneurship are also needed to transfer scientific knowledge into products, increasing the importance and support for scientific education. Therefore, fundamental understanding of business, society, politics, and health and safety are required, with preparation to work in a global environment and solve global problems. Thus, nanoscience and nanoetechnology education should focus on a broad, interdisciplinary approach to science and engineering at the nanoscale.

1.7.2 K–12 Education, Excitement, and Creativity

To increase the pool of students interested in advanced education in science and technology, science needs to be conveyed as an exciting and creative endeavor from its first introduction. Innovative foundational education in traditional education environments, such as schools and supplementary instruction opportunities, can help to accomplish this goal. In order to encourage excitement and creativity in the fields of nanoscience and nanoetechnology, K-12 education needs to take a cross-disciplinary approach that includes combining arts and science.

To this end, since the mid-1990s, there has been a global push for science, technology, engineering, and mathematics (STEM) education, particularly in the K-12 arena. However, this curriculum, while rich in content, is lacking in critical and creative thinking and real-world application skills. However, since the early 2010s, there has been a drive, called STEAM, to include the arts in STEM education to encourage that creativity and critical thinking skills derived from arts-based education as well. To develop interdisciplinary curricula relevant for nanoscience and nanotechnology, a revamping of the STEAM education model for nanoscience, development of new courses and course material, and training of new instructors is required.

1.7.3 Vocational, Undergraduate, Graduate, and Continuing Education Programs

In the US, a strong example of vocational-level programs is the one-semester, 18 credit-hour *capstone* style program pioneered by Pennsylvania State University (Penn State), designed to complete a student's vocational degree at a *home* institution by integrating nanoscience into their foundational classes. In addition, Penn State developed a network to develop a standardized curriculum to assist vocational institutions in those foundations, as well as to train practitioners. Contin-

ually identified areas of improvement for vocational training include a best practices manual, creating nationwide programs that ensure appropriate education and training, but are sufficiently flexible to account for local and regional technical needs.

The current state of undergraduate nanoscience education is confined mostly to opportunities for undergraduate research. For example, the US NSF funds a Research Experience for Undergraduates, providing students with nanoscience-specific training and research education, as well as networking and professional development opportunities. However, there is a need to promote interdisciplinary cooperation and societal impacts in existing university programs to increase diversity in student populations.

There are also deficiencies in graduate training for nanoscience, including interdisciplinary education and diversity, but these programs will improve as the pipeline of students funneling into the programs have better foundational nanoscience knowledge due to strengthening of nanoscience education from kindergarten through undergraduate training.

Continuing education is necessary to educate and update practitioners on new technology and best practices. Presently, there is a wealth of information available at a variety of sources on nanoscience and nanotechnology, but there is a need to assemble the information into learning packages or short courses for targeted training, increasing accessibility and rapid dissemination.

1.7.4 Educator Training

In order to accomplish the above education goals and further nanoscience and nanotechnology education, including attraction and engagement, educator training is essential. Presently, educator training is focused broadly on STEM fields, without, perhaps, specific training in nanoscience and nanotechnology.

1.7.5 Informal Science Education

Education for the general public on the benefits of nanoscience and nanotechnology is an important part of furthering nanoscience and nanotechnology education goals. This means supporting and engaging community-based opportunities for science and education, and making them approachable, affordable, inclusive, and interesting. Currently, this is being done mostly by a mix of science museums [1.33] and university groups. In the US, these efforts are largely funded by the National Science Foundation. In Germany, efforts are supported by the Federal Ministry of Education and Research, who have a traveling exhibit that visits schools to supplement the formal science curriculum.

1.8 Summary and Outlook

Nanotechnology refers to any technology done on a nanoscale that has applications in the real world. The properties of matter at the nanoscale are different from those at a larger scale. The unique physical and chemical properties of nanomaterials can be exploited for commercial applications that benefit society. The discovery of novel materials, processes, and phenomena at the nanoscale and the development of new experimental and theoretical techniques for research at the end of the 20th century, provide fresh opportunities for the development of innovative nanosystems and nanomaterials. Nanotechnology represents a *megatrend*, and has become a *general purpose* technology.

The NNI was launched in the US in 2000 with a $497 million investment in the FY 2001 budget. In 2003, a 21st Century Nanotechnology R&D Act became law in the US, with $3.7 billion to be spent in the four year period beginning in October 2005 over six federal agencies. Through FY 2015, about $20 billion was spent by 20 federal agencies, with about $1.5 billion for FY 2015. Twenty top-level federal agencies (27 including all subsidiary and subagencies) fund NNI-related research with about 93% of the funding being spent by five agencies (NIH, NSF, DOE, DOD, and NIST). The US private sector R&D investment is estimated to be twice that of public funding, with a focus on translating fundamental research into commercial products.

NNI is governed by an intricate organizational structure overseen by OSTP. NNCO has the responsibility to coordinate R&D activities among various federal agencies. Congress mandates various Triennial Review reports, including an external triennial assessment by the National Academies and another by PCAST, which reports to OSTP. It should be noted that since the enactment of the Nanotechnology Act in 2003, it has not been reauthorized by US Congress.

The US and the rest of the world continue to make significant investments. As of FY 2015, the US and the EU have made comparable government investments, followed by Japan, China, Korea, and Taiwan. US private industry has spent far more than industry in other countries. However, the rest of the world,

particularly emerging economies such as China, are increasing funding at a rapid rate. On the basis of key indicators of nanotechnology development, which include R&D funding, venture capital, SCI papers, patent applications, primary workforce, and final product market, a significant growth rate in all of these indicators is observed worldwide. The revenue from nanoenabled products continues to grow, with over $200 billion in 2012 in the US alone. This represents an impressive return on R&D investment.

As an outlook, there appears to be a lack of investment in technology transfer. Since 2001, as expected, the major broad-based focus has been on foundational research. NNI is believed to have reached a turning point. One should assess the scientific progress made and its economic impact. On the basis of this detailed analysis, scientific focus may need to be on only a few areas of economic importance. In addition, the NNI needs to develop strategies for investment in translational research to facilitate commercialization, as well as research on EHS-related issues to protect public life and the environment. Finally, development of the nanotechnology workforce and curriculum development, and programs to educate the public of the benefits of nanotechnology and to change attitudes toward nanotechnology should be continued.

1.9 Organization of the Handbook

This handbook integrates knowledge of nanofabrication, materials, applications, and reliability. The organization of the handbook is straightforward. The handbook is divided into ten parts. The first two parts include an introduction to micro/nanofabrication techniques, nanomaterials, and nanostructures. The third and fourth parts introduce various MEMS/NEMS and BioMEMS/BioNEMS devices. The fifth part introduces various nanometrology techniques. The sixth part provides an overview of bio/nanotribology and bio/nanomechanics, which will prepare the reader to understand interface reliability in industrial applications. The seventh part provides an overview of molecularly thick films for lubrication. The eighth part focuses on the emerging field of biomimetics and bioinspired surfaces, in which one mimics nature to develop products and processes of interest. The ninth part focuses on industrial applications and micro/nanodevice reliability. The tenth part focuses on nanotechnology in the social context, environment, health and safety issues, and nanotechnology education.

2. Molecule-Based Devices

Françisco M. Raymo

The constituent components of conventional devices are carved out of larger materials relying on physical methods. This top-down approach to engineered building blocks becomes increasingly challenging as the dimensions of the target structures approach the nanoscale. Nature, on the other hand, assembles nanoscaled biomolecules relying on chemical strategies. Small molecular building blocks are joined to produce nanostructures with defined geometries and specific functions. It is becoming apparent that Nature's bottom-up approach to functional nanostructures can be mimicked to produce artificial molecules with nanoscaled dimensions and engineered properties. Indeed, examples of artificial nanohelices, nanotubes and molecular motors are starting to be developed. Some of these fascinating chemical systems have intriguing electrochemical and photochemical properties, which can be exploited to manipulate chemical, electrical and optical signals at the molecular level. This tremendous opportunity has led to the development of the molecular equivalent of conventional logic gates. Indeed, simple logic operations can be reproduced with collections of molecules operating in solution. Most of these chemical systems, however, rely on bulk addressing to execute combinational and sequential logic operations. It is essential to devise methods to reproduce these useful functions in solid-state configurations and, eventually, with single molecules. These challenging objectives are stimulating the design of clever devices that interface small assemblies of organic molecules with macroscaled and nanoscaled electrodes. These strategies have already produced rudimentary examples of diodes, switches and transistors based on functional molecular components. The rapid and continuous progress of this exploratory research will, hopefully, lead to an entire generation of molecule-based devices that might ultimately find useful applications in a variety of fields ranging from biomedical research to information technology.

2.1 Chemical Approaches to Nanostructured Materials

The fabrication of conventional devices relies on the assembly of macroscopic building blocks with specific configurations. The shapes of these components are carved out of larger materials by exploiting physical methods. This top-down approach to engineered building blocks is extremely powerful and can deliver effectively and reproducibly microscaled objects. However, this strategy becomes increasingly challenging as the dimensions of the target structures approach the nanoscale. Indeed, the physical fabrication of nanosized features with subnanometer precision is a formidable technological challenge.

2.1.1 From Molecular Building Blocks to Nanostructures

Nature efficiently builds nanostructures relying on chemical approaches. Tiny molecular building blocks are assembled with a remarkable degree of structural control in a variety of nanoscaled materials with defined shapes, properties and functions. In contrast to the top-down physical methods, small components are connected to produce larger objects in these bottom-up chemical strategies. It is becoming apparent that the limitations of the top-down approach to artificial nanostructures can be overcome by mimicking nature's bottom-up processes. Indeed, beautiful and ingenious examples of molecule-based strategies to chemically fabricate nanoscaled building blocks for functional materials and innovative devices are starting to emerge.

2.1.2 Nanoscaled Biomolecules: Nucleic Acids and Proteins

Nanoscaled macromolecules play a fundamental role in biological processes [2.1]. Nucleic acids, for example, ensure the transmission and expression of genetic information. These particular biomolecules are linear polymers incorporating nucleotide repeating units (Fig. 2.1a). Each nucleotide has a phosphate bridge and a sugar residue. Chemical bonds between the phosphate of one nucleotide and the sugar of the next ensures the propagation of a polynucleotide strand from the 5′ to the 3′ end. Along the sequence of alternating sugar and phosphate fragments, an extended chain of robust covalent bonds involving carbon, oxygen and phospho-

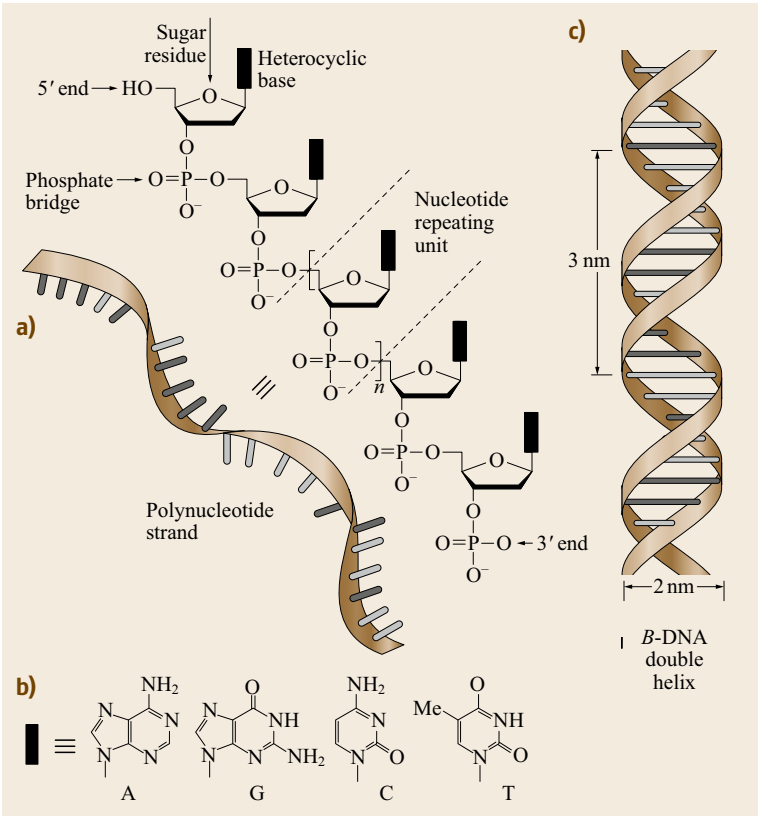

Fig. 2.1a–c A polynucleotide strand **(a)** incorporates alternating phosphate and sugar residues joined by covalent bonds. Each sugar carries one of four heterocyclic bases **(b)**. Noncovalent interactions between complementary bases in two independent polynucleotide strands encourage the formation of nanoscaled double helixes **(c)**

rous atoms forms the main backbone of the polymeric strand.

Every single nucleotide of a polynucleotide strand carries one of the four heterocyclic bases shown in Fig. 2.1b. For a strand incorporating 100 nucleotide repeating units, a total of 4^{100} unique polynucleotide sequences are possible. It follows that nature can fabricate a huge number of closely related nanostructures relying on four building blocks only. The heterocyclic bases appended to the main backbone of alternating phosphate and sugar units can sustain hydrogen bonding and $[\pi \cdots \pi]$ stacking interactions. Hydrogen bonds, formed between [N–H] donors and either N or O acceptors, encourage the pairing of adenine (A) with thymine (T) and of guanine (G) with cytosine (C). The stacking interactions involve attractive contacts between the extended π-surfaces of heterocyclic bases.

In the *B* conformation of deoxyribonucleic acid (DNA), the synergism of hydrogen bonds and $[\pi \cdots \pi]$ stacking glues pairs of complementary polynucleotide strands into fascinating double helical supermolecules (Fig. 2.1c) with precise structural control at the subnanometer level. The two polynucleotide strands wrap around a common axis to form a right-handed double helix with a diameter of ca. 2 nm. The hydrogen bonded and $[\pi \cdots \pi]$ stacked base pairs lie at the core of the helix with their π-planes perpendicular to the main axis of the helix. The alternating phosphate and sugar units define the outer surface of the double helix. In *B*-DNA, approximately ten base pairs define each helical turn corresponding to a rise per turn or helical pitch of ca. 3 nm. Considering that these molecules can incorporate up to approximately 10^{11} base pairs, extended end-to-end lengths spanning from only a few nanometers to hundreds of meters are possible.

Nature's operating principles to fabricate nanostructures are not limited to nucleic acids. Proteins are also built joining simple molecular building blocks, the amino acids, by strong covalent bonds [2.1]. More precisely, nature relies on twenty amino acids differing in their side chains to assemble linear polymers, called polypeptides, incorporating an extended backbone of robust [C–N] and [C–C] bonds (Fig. 2.2a). For a single polymer strand of 100 repeating amino acid units, a total of 20^{100} unique combinations of polypeptide sequences are possible. Considering that proteins can incorporate more than one polypeptide chain with over 4000 amino acid residues each, it is obvious that nature can assemble an enormous number of different biomolecules relying on the same fabrication strategy and a relatively small pool of building blocks.

The covalent backbones of the polypeptide strands form the main skeleton of a protein molecule. In addition, a myriad of secondary interactions, involving noncovalent contacts between portions of the amino acid residues, control the arrangement of the individual polypeptide chains. Intrastrand hydrogen bonds curl single polypeptide chains around a longitudinal axis in a helical fashion to form tubular nanostructures ca. 0.5 nm wide and ca. 2 nm long (Fig. 2.2b). Similarly, interstrand hydrogen bonds can align from 2 up to 15 parallel or antiparallel polypeptide chains to form nanoscaled sheets with average dimensions of 2×3 nm (Fig. 2.2c). Multiple nanohelices and/or nanosheets

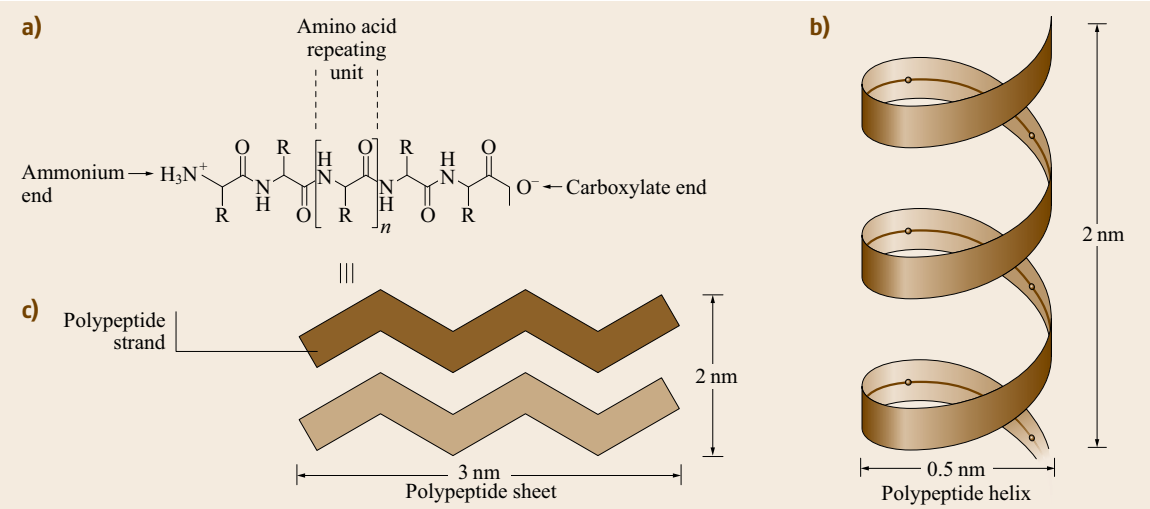

Fig. 2.2a–c A polypeptide strand **(a)** incorporates amino acid residues differing in their side chains and joined by covalent bonds. Hydrogen bonding interactions curl a single polypeptide strand into a helical arrangement **(b)** or lock pairs of strands into nanoscaled sheets **(c)**

combine into a unique three-dimensional arrangement dictating the overall shape and dimensions of a protein.

2.1.3 Chemical Synthesis of Artificial Nanostructures

Nature fabricates complex nanostructures relying on simple criteria and a relatively small pool of molecular building blocks. Robust chemical bonds join the basic components into covalent scaffolds. Noncovalent interactions determine the three-dimensional arrangement and overall shape of the resulting assemblies. The multitude of unique combinations possible for long sequences of chemically connected building blocks provides access to huge libraries of nanoscaled biomolecules.

Modern chemical synthesis has evolved considerably over the past few decades [2.2]. Experimental procedures to join molecular components with structural control at the picometer level are available. A multitude of synthetic schemes to encourage the formation of chemical bonds between selected atoms in reacting molecules have been developed. Furthermore, the tremendous progress of crystallographic and spectroscopic techniques has provided efficient and reliable tools to probe directly the structural features of artificial inorganic and organic compounds. It follows that designed molecules with engineered shapes and dimensions can be now prepared in a laboratory relying on the many tricks of chemical synthesis and the power of crystallographic and spectroscopic analyses.

The high degree of sophistication reached in this research area translates into the possibility of mimicking the strategies successfully employed by nature to chemically fabricate nanostructures [2.3]. Small molecular building blocks can be synthesized and covalently joined following routine laboratory procedures. It is even possible to design the stereoelectronic properties of the assembling components in order to shape the geometry of the final product with the assistance of noncovalent interactions. For example, five bipyridine building blocks (Fig. 2.3) can be connected in five synthetic steps to produce an oligobipyridine strand [2.4]. The five repeating units are bridged by [C–O] bonds and can chelate metal cations in the bay regions defined by their two nitrogen atoms. The spontaneous assembly of two organic strands in a double helical arrangement occurs in the presence of inorganic cations. In the resulting helicate, the two oligobipyridine strands wrap around an axis defined by five Cu(I) centers. Each inorganic cation coordinates two bipyridine units with a tetrahedral geometry imposing a diameter of ca. 0.6 nm on the nanoscaled helicate [2.5]. The overall length from one end of the helicate to the other is ca. 3 nm [2.6]. The analogy between this artificial double helix and the *B*-DNA double helix shown in Fig. 2.1c is obvious. In both instances, a supramolecular glue combines two independent molecular strands into nanostructures with defined shapes and dimensions.

The chemical synthesis of nanostructures can borrow Nature's design criteria as well as its molecular building blocks. Amino acids, which are the basic components of proteins, can be assembled into artificial macrocycles. In the example of Fig. 2.4, eight amino acid residues are joined through the formation of [C–N] bonds in multiple synthetic steps [2.7]. The resulting covalent backbone defines a circular cavity with a diameter of ca. 0.8 nm [2.8]. In analogy to the polypeptide chains of proteins, the amino acid residues of this artificial oligopeptide can sustain hydrogen bonding interactions. It follows that multiple macrocycles can pile on top of each other to form tubular nanostructures. The walls of the resulting nanotubes are maintained in

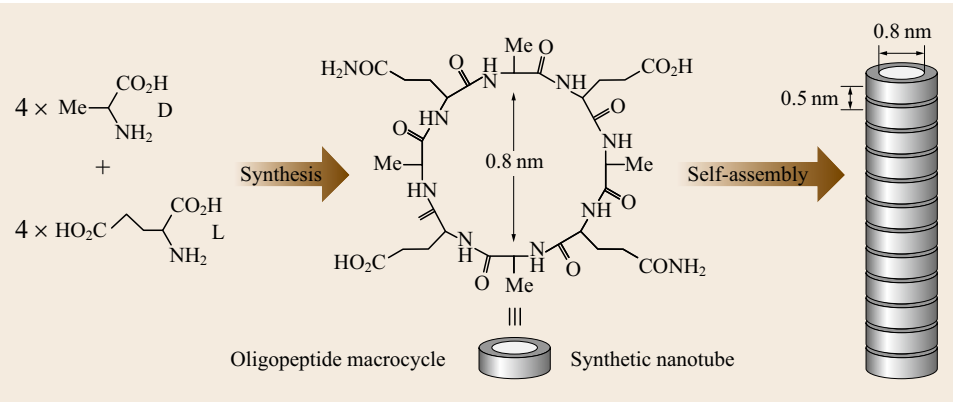

Fig. 2.4 Cyclic oligopeptides can be synthesized joining eight amino acid residues by covalent bonds. The resulting macrocycles self-assemble into nanoscaled tube-like arrays

position by the cooperative action of at least eight primary hydrogen bonding contacts per macrocycle. These noncovalent interactions maintain the mean planes of independent macrocycles in an approximately parallel arrangement with a plane-to-plane separation of ca. 0.5 nm.

2.1.4 From Structural Control to Designed Properties and Functions

The examples in Figs. 2.3 and 2.4 demonstrate that modular building blocks can be assembled into target compounds with precise structural control at the picometer level through programmed sequences of synthetic steps. Indeed, modern chemical synthesis offers access to complex molecules with nanoscaled dimensions and, thus, provides cost-effective strategies for the production and characterization of billions of engineered nanostructures in parallel. Furthermore, the high degree of structural control is accompanied by the possibility of designing specific properties into the target nanostructures. Electroactive and photoactive components can be integrated chemically into functional molecular machines [2.9]. Extensive electrochemical investigations have demonstrated that inorganic and organic compounds can exchange electrons with macroscopic electrodes [2.10]. These studies have unraveled the processes responsible for the oxidation and reduction of numerous functional groups and indicated viable design criteria to adjust the ability of molecules to accept or donate electrons [2.11]. Similarly, detailed photochemical and photophysical investigations have elucidated the mechanisms responsible for the absorption and emission of photons at the molecular level [2.12]. The vast knowledge established on the interactions between light and molecules offers the opportunity to engineer chromophoric and fluorophoric functional groups with defined absorption and emission properties [2.13].

The power of chemical synthesis to deliver functional molecules is, perhaps, better illustrated by the molecular motor shown in Fig. 2.5. The preparation of this [2]rotaxane requires twelve synthetic steps starting from known precursors [2.14]. This complex molecule incorporates a Ru(II)-trisbipyridine stopper bridged to a linear tetracationic fragment by a rigid triaryl spacer. The other end of the tetracationic portion is terminated by a bulky tetraarylmethane stopper. The bipyridinium unit of this dumbbell-shaped compound is encircled by a macrocyclic polyether. No covalent bonds join the macrocyclic and linear components. Rather, hydrogen bonding and $[\pi \cdots \pi]$ stacking interactions maintain the macrocyclic polyether around the bipyridinium unit. In addition, mechanical constraints associated with the bulk of the two terminal stoppers prevent the macrocycle to slip off the thread. The approximate end-to-end distance for this [2]rotaxane is ca. 5 nm.

The bipyridinium and the 3,3′-dimethyl bipyridinium units within the dumbbell-shaped component undergo two consecutive and reversible monoelectronic reductions [2.14]. The two methyl substituents on the 3,3′-dimethyl bipyridinium dication make this electroactive unit more difficult to reduce. In acetonitrile, its redox potential is ca. 0.29 V more negative than that of the unsubstituted bipyridinium dication. Under irradiation at 436 nm in degassed acetonitrile, the excitation of the Ru(II)-trisbipyridine stopper is followed by electron transfer to the unsubstituted bipyridinium unit. In the presence of a sacrificial electron donor (triethanolamine) in solution, the photogenerated hole in the photoactive stopper is filled and the undesired back electron transfer is suppressed. The permanent and light-induced reduction of the dicationic bipyridinium unit to a radical cation depresses significantly the magnitude of the noncovalent interactions holding the macrocyclic polyether in position. As a result, the macrocycle shuttles from the reduced unit to the adjacent dicationic 3,3′-dimethyl bipyridinium. After

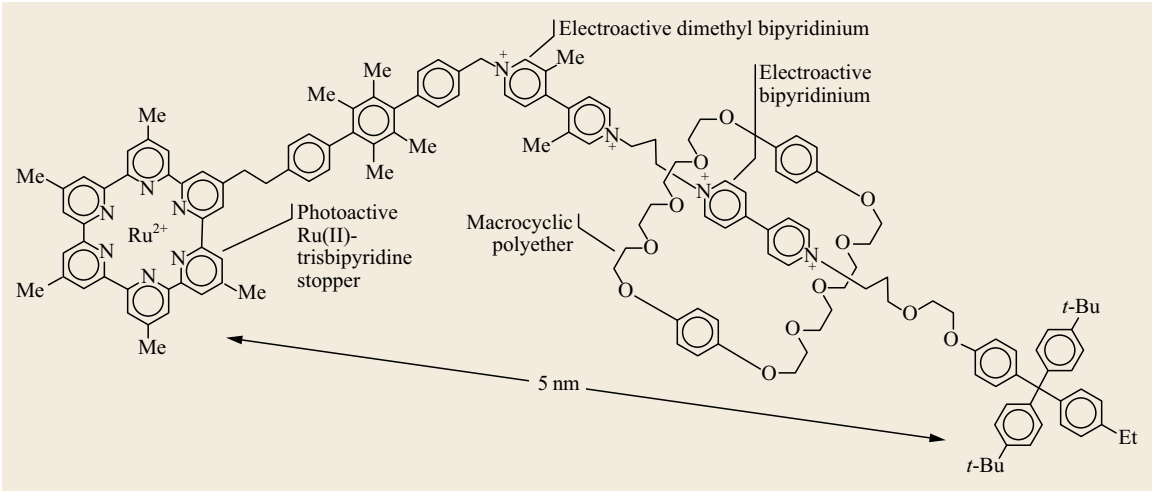

Fig. 2.5 This nanoscaled [2]rotaxane incorporates a photoactive Ru(II)-trisbipyridine stopper and two electroactive bipyridinium units. Photoinduced electron transfer from the photoactive stopper to the encircled electroactive unit forces the macrocyclic polyether to shuttle to the adjacent bipyridinium dication

the diffusion of molecular oxygen into the acetonitrile solution, oxidation occurs restoring the dicationic form of the bipyridinium unit and its ability to sustain strong noncovalent bonds. As a result, the macrocyclic polyether shuttles back to its original position. This amazing example of a molecular shuttle reveals that dynamic processes can be controlled reversibly at the molecular level relying on the clever integration of electroactive and photoactive fragments into functional and nanoscaled molecules.

2.2 Molecular Switches and Logic Gates

2.2.1 From Macroscopic to Molecular Switches

Everyday, we routinely perform dozens of switching operations. We turn our personal computers, cellular phones, CD players, radios or simple light bulbs off and on at a click of a button. Every single time, our finger exerts a mechanical stimulation on a control device, namely a switch. The external stimulus changes the physical state of the switch, closing or opening an electric circuit and enabling or preventing the passage of electrons. Overall, the switch transduces a mechanical input into an electrical output.

The use of switching devices is certainly not limited to electric circuits. For example, a switch at the junction of a railroad can divert trains from one track to another. Similarly, a faucet in a lavatory pipe can block or release the flow of water. Of course, the nature of the control stimulations and the character of the final outcome vary significantly from case to case, but the operating principle behind each switching device is the same. In all cases, input stimulations reach the switch changing its physical state and producing a specific output.

The development of nanoscaled counterparts to conventional switches is expected to have fundamental scientific and technological implications. Indeed, practical applications for ultraminiaturized switches can be easily envisaged in a diversity of areas ranging from biomedical research to information technology. The major challenge in the quest for nanoswitches, however, is the identification of reliable design criteria and operating principles for these devices. Chemical approaches to implement molecule-sized switches appear to be extremely promising. The intrinsically small dimensions of organic molecules coupled to the power of chemical synthesis are the main driving forces behind these exploratory investigations.

Certain organic molecules adjust their structural and electronic properties when stimulated with chemical, electrical or optical inputs. Generally, the change is accompanied by an electrochemical or spectroscopic response. Overall, these nanostructures transduce input stimulations into detectable outputs and, appropriately, are called molecular switches [2.15, 16]. The chemical transformations associated with these switching processes are often reversible. The chemical system returns

to the original state when the input signal is turned off. The interconverting states of a molecular switch can be isomers, an acid and its conjugated base, the oxidized and reduced forms of a redox active molecule or even the complexed and uncomplexed forms of a receptor [2.9, 15, 16]. The output of a molecular switch can be a chemical, electrical and/or optical signal that varies in intensity with the interconversion process. For example, changes in absorbance, fluorescence, pH or redox potential can accompany the reversible transformation of a molecular switch.

2.2.2 Digital Processing and Molecular Logic Gates

In present computer networks, data are electronically elaborated by microprocessor systems [2.17] and are exchanged optically between remote locations [2.18]. Data processing and communication require the encoding of information in electrical and optical signals in the form of binary digits. Using arbitrary assumptions, logic thresholds can be established for each signal and, then, 0 and 1 digits can be encoded following simple conventions. Sequences of electronic devices manipulate the encoded bits executing logic functions as a result of basic switching operations.

The three basic AND, NOT and OR operators combine binary inputs into binary outputs following precise logic protocols [2.17]. The NOT operator converts an input signal into an output signal. When the input is 0, the output is 1. When the input is 1, the output is 0. Because of the inverse relationship between the input and output values, the NOT gate is often called inverter [2.19]. The OR operator combines two input signals into a single output signal. When one or both inputs are 1, the output is 1. When both inputs are 0, the output is 0. The AND gate also combines two input signals into one output signal. In this instance, however, the output is 1 only when both inputs are 1. When at least one input is 0, the output is 0.

The output of one gate can be connected to one of the inputs of another operator. A NAND gate, for example, is assembled connecting the output of an AND operator to the input of a NOT gate. Now, the two input signals are converted into the final output after two consecutive logic operations. In a similar fashion, a NOR gate can be assembled connecting the output of an OR operator to the input of a NOT gate. Once again, two consecutive logic operations determine the relation between two input signals and a single output. The NAND and NOR operations are termed universal functions because any conceivable logic operation can be implemented relying on one of these two gates only [2.17]. In fact, digital circuits are fabricated routinely, interconnecting exclusively NAND or exclusively NOR operators [2.19].

The logic gates of conventional microprocessors are assembled interconnecting transistors and their input and output signals are electrical [2.19]. However, the concepts of binary logic can be extended to chemical, mechanical, optical, pneumatic or any other type of signal. First, it is necessary to design devices that can respond to these stimulations in the same way transistors respond to electrical signals. Molecular switches respond to a variety of input stimulations producing specific outputs and can, therefore, be exploited to implement logic functions [2.20, 21].

2.2.3 Molecular AND, NOT and OR Gates

More than a decade ago, a potential strategy to execute logic operations at the molecular level was proposed [2.22]. Later, the analogy between molecular switches and logic gates was recognized in a seminal article [2.23]. There, it is demonstrated that AND, NOT and OR operations can be reproduced with fluorescent molecules. The pyrazole derivative **1** (Fig. 2.6) is a molecular NOT gate. It imposes an inverse relation between a chemical input (concentration of H^+) and an optical output (emission intensity). In a mixture of methanol and water, the fluorescence quantum yield of **1** is 0.13 in the presence of only 0.1 equivalents of H^+ [2.23]. The quantum yield drops to 0.003 when the equivalents of H^+ are 1000. Photoinduced electron transfer from the central pyrazoline unit to the pendant benzoic acid quenches the fluorescence of the protonated form. Thus, a change in H^+ concentration (**I**) from a low to a high value switches the emission intensity (**O**) from a high to a low value. The inverse relationship between the chemical input **I** and the optical output **O** translates into the truth table of a NOT operation if a positive logic convention (low = 0, high = 1) is applied to both signals. The emission intensity is high ($\mathbf{O} = 1$) when the concentration of H^+ is low ($\mathbf{I} = 0$). The emission intensity is low ($\mathbf{O} = 0$) when the concentration of H^+ is high ($\mathbf{I} = 1$).

The anthracene derivative **2** (Fig. 2.6) is a molecular OR gate. It transduces two chemical inputs (concentrations of Na^+ and K^+) into an optical output (emission intensity). In methanol, the fluorescence quantum yield is only 0.003 in the absence of metal cations [2.23]. Photoinduced electron transfer from the nitrogen atom of the azacrown fragment to the anthracene fluorophore quenches the emission. After the addition of 1000 equivalents of either Na^+ or K^+, the quantum yield raises to 0.053 and 0.14, respectively. Similarly, the quantum yield is 0.14 when both metal cations are present in solution. The complexation of one of the

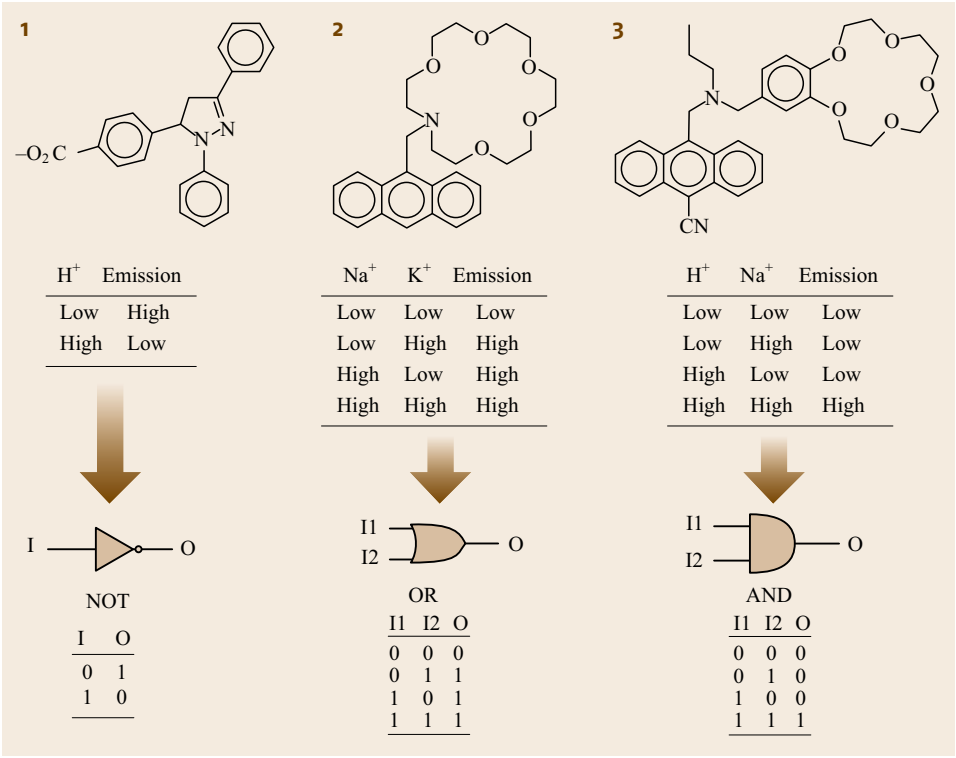

Fig. 2.6 The fluorescence intensity of the pyrazoline derivative **1** is high when the concentration of H^+ is low and vice versa. The fluorescence intensity of the anthracene derivative **2** is high when the concentration of Na^+ and/or K^+ is high. The emission is low when both concentrations are low. The fluorescence intensity of the anthracene **3** is high only when the concentrations of H^+ and Na^+ are high. The emission is low in the other three cases. The signal transductions of the molecular switches **1**, **2** and **3** translate into the truth tables of NOT, OR and AND gates, respectively, if a positive logic convention is applied to all inputs and outputs (low = 0, high = 1)

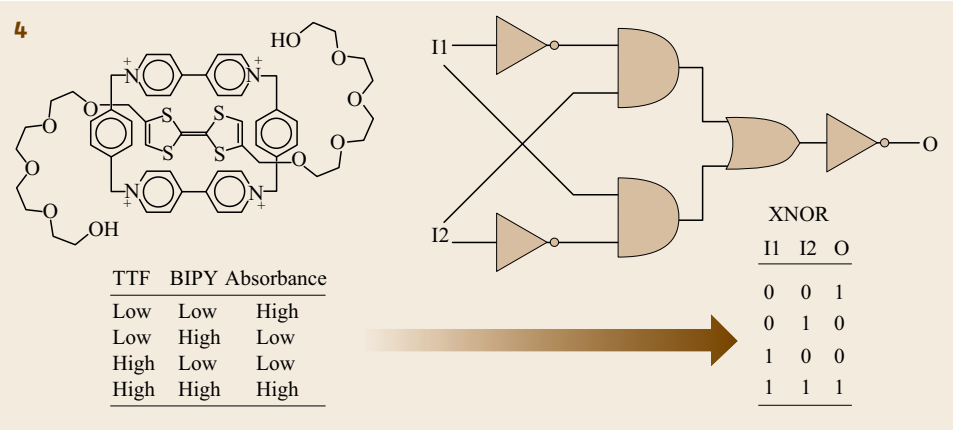
two metal cations inside the azacrown receptor depresses the efficiency of the photoinduced electron transfer enhancing the fluorescence. Thus, changes in the concentrations of Na^+ (**I1**) and/or K^+ (**I2**) from low to high values switch the emission intensity (**O**) from a low to a high value. The relationship between the chemical inputs **I1** and **I2** and the optical output **O** translates into the truth table of an OR operation if a positive logic convention (low = 0, high = 1) is applied to all signals. The emission intensity is low (**O** = 0) only when the concentration of Na^+ and K^+ are low (**I1** = 0, **I2** = 0). The emission intensity is high (**O** = 1) for the other three input combinations.

The anthracene derivative **3** (Fig. 2.6) is a molecular AND gate. It transduces two chemical inputs (concentrations of H^+ and Na^+) into an optical output (emission intensity). In a mixture of methanol and *iso*-propanol, the fluorescence quantum yield is only 0.011 in the absence of H^+ or Na^+ [2.23]. Photoinduced electron transfer from either the tertiary amino group or the catechol fragment to the anthracene fluorophore quenches the emission. After the addition of either 100 equivalents of H^+ or 1000 equivalents of Na^+, a modest change of the quantum yield to 0.020 and 0.011, respectively, is observed. Instead, the quantum yield increases to 0.068 when both species are present in solution. The protonation of the amino group and the insertion of the metal cation in the benzocrown ether receptor depress the efficiency of the photoinduced electron transfer processes enhancing the fluorescence. Thus, changes in the concentrations of H^+ (**I1**) and Na^+ (**I2**) from low to high values switch the emission intensity (**O**) from a low to a high value. The relationship between the chemical inputs **I1** and **I2** and the optical output **O** translates into the truth table of an AND operation if a positive logic convention (low = 0, high = 1) is applied to all signals. The emission intensity is high (**O** = 1) only when the concentration of H^+ and Na^+ are high (**I1** = 1, **I2** = 1). The emission intensity is low (**O** = 0) for the other three input combinations.



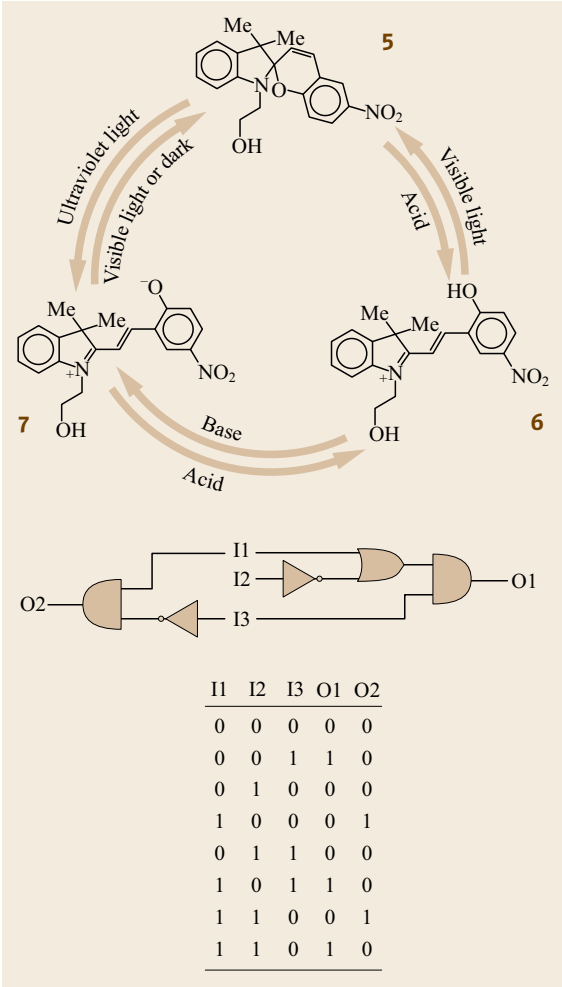


Fig. 2.7 The charge-transfer absorbance of complex **4** is high when the voltage input addressing the tetrathiafulvalene (TTF) unit is low and stimulating the bipyridinium (BIPY) units is high, and vice versa. If a positive logic convention is applied to the TTF input and to the absorbance output (low = 0, high = 1) while a negative logic convention is applied to the BIPY input (low = 0, high = 1), the signal transduction of **4** translates into the truth table of a XNOR circuit

2.2.4 Combinational Logic at the Molecular Level

The fascinating molecular AND, NOT and OR gates illustrated in Fig. 2.6 have stimulated the design of related chemical systems able to execute the three basic logic operations and simple combinations of them [2.20, 21]. Most of these molecular switches convert chemical inputs into optical outputs. However, the implementation of logic operations at the molecular level is not limited to the use of chemical inputs. For example, electrical signals and reversible redox processes can be exploited to modulate the output of a molecular switch [2.24]. The supramolecular assembly **4** (Fig. 2.7) executes a XNOR function relying on these operating principles. The π-electron-rich tetrathiafulvalene (TTF) guest threads the cavity of a π-electron deficient bipyridinium (BIPY) host. In acetonitrile, an absorption band associated with the charge-transfer interactions between the complementary π-surfaces is observed at 830 nm. Electrical stimulations alter the redox state of either the TTF or the BIPY units encouraging the separation of the two components of the complex and the disappearance of the charge-transfer band. Electrolysis at a potential of +0.5 V oxidizes the neutral TTF unit to a monocationic state. The now cationic guest is expelled from the cavity of the tetracationic host as a result of electrostatic repulsion. Consistently, the absorption band at 830 nm disappears. The charge-transfer band, however, is restored after the exhaustive back reduction of the TTF unit at a potential of 0 V. Similar changes in the absorption properties can be induced addressing the BIPY units. Electrolysis at −0.3 V reduces the dicationic BIPY units to their monocationic forms encouraging the separation of the two components of the complex and the disappearance of the absorption band. The original absorption spectrum is restored after the exhaustive back oxidation of the BIPY units at a potential of 0 V. Thus, this supramolecular system responds to electrical stimulations producing an optical output. One of the electrical inputs (**I1**) controls the redox state of the TTF unit switching between 0 and +0.5 V. The other (**I2**) determines the redox state of the bipyridinium units switching between −0.3 and 0 V. The optical output (**O**) is the absorbance of the charge-transfer band. A positive logic convention (low = 0, high = 1) can be applied to the input **I1** and output **O**. A negative logic convention (low = 1, high = 0) can be applied to the input **I2**. The resulting truth table corresponds to that of a XNOR circuit (Fig. 2.7). The charge-transfer absorbance is high (**O** = 1) only when one voltage input is low and the other is high (**I1** = 0, **I2** = 0) or vice versa (**I1** = 1, **I2** = 1). It is important to note that the input string with both **I1** and **I2** equal to 1 implies that input potentials of +0.5 and −0.3 V are applied simultaneously to a solution containing the supramolecular assembly **4** and not to an individual complex. Of course, the concomitant oxidation of the TTF guest and reduction of the BIPY units in the very same complex would be unrealistic. In bulk solution, instead, some complexes are oxidized while other are reduced, leaving the average solution composition unaffected. Thus, the XNOR operation executed by this supramolecular system is a consequence of bulk properties and not a result of unimolecular signal transduction.

Optical inputs can be employed to operate the three-state molecular switch of Fig. 2.8 in acetonitrile

Fig. 2.8 Ultraviolet light (**I1**), visible light (**I2**) and H^+ (**I3**) inputs induce the interconversion between the three states **5**, **6** and **7**. The colorless state **5** does not absorb in the visible region. The yellow-green state **6** absorbs at 401 nm (**O1**). The purple state **7** absorbs at 563 nm (**O2**). The truth table illustrates the conversion of input strings of three binary digits (**I1**, **I2** and **I3**) into output strings of two binary digits (**O1** and **O2**) operated by this three-state molecular switch. A combinational logic circuit incorporating nine AND, NOT and OR operators correspond to this particular truth table

solution [2.25]. This chemical system responds to three inputs producing two outputs. The three input stimulations are ultraviolet light (**I1**), visible light (**I2**) and the concentration of H^+ (**I3**). One of the two optical outputs is the absorbance at 401 nm (**O1**), which is high when the molecular switch is in the yellow-green state **6** and low in the other two cases. The other optical output is the absorbance at 563 nm (**O2**), which is high when the molecular switch is in the purple state **7** and low in the other two cases. The colorless spiropyran state **5** switches to the merocyanine form **7** upon irradiation with ultraviolet light. It switches to the protonated merocyanine from **6** when treated with H^+. The colored state **7** isomerizes back to **5** in the dark or upon irradiation with visible light. Alternatively, **7** switches to **6** when treated with H^+. The colored state **6** switches to **5**, when irradiated with visible light, and to **7**, after the removal of H^+. In summary, this three-state molecular switch responds to two optical inputs (**I1** and **I2**) and one chemical input (**I3**) producing two optical outputs (**O1** and **O2**). Binary digits can be encoded on each signal applying positive logic conventions (low = 0, high = 1). It follows that the three-state molecular switch converts input strings of three binary digits into output strings of two binary digits. The corresponding truth table (Fig. 2.8) reveals that the optical output **O1** is high (**O1** = 1) when only the input **I3** is applied (**I1** = 0, **I2** = 0, **I3** = 1), when only the input **I2** is not applied (**I1** = 1, **I2** = 0, **I3** = 1) or when all three inputs are applied (**I1** = 1, **I2** = 1, **I3** = 1). The optical output **O2** is high (**O2** = 1) when only the input **I1** is applied (**I1** = 1, **I2** = 0, **I3** = 0) or when only the input **I3** is not applied (**I1** = 1, **I2** = 1, **I3** = 0). The combinational logic circuit (Fig. 2.8) equivalent to this truth table shows that all three inputs determine the output **O1**, while only **I1** and **I3** control the value of **O2**.

2.2.5 Intermolecular Communication

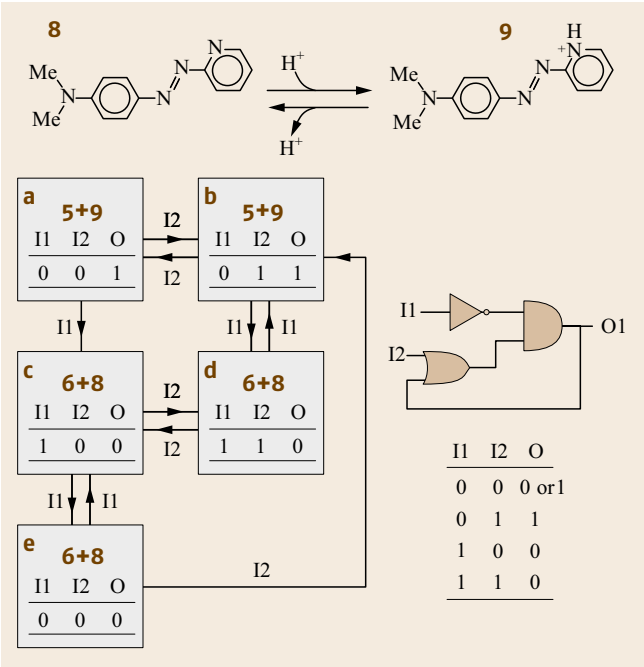
The combinational logic circuits in Figs. 2.7 and 2.8 are arrays of interconnected AND, NOT and OR operators. The digital communication between these basic logic elements ensures the execution of a sequence of simple logic operations that results in the complex logic function processed by the entire circuit. It follows that the logic function of a given circuit can be adjusted altering the number and type of basic gates and their interconnection protocol [2.17]. This modular approach to combinational logic circuits is extremely powerful. Any logic function can be implemented connecting the appropriate combination of simple AND, NOT and OR gates.

The strategies followed so far to implement complex logic functions with molecular switches is based on the careful design of the chemical system and on the judicious choice of the inputs and outputs [2.20, 21]. A specific sequence of AND, NOT and OR operations is programmed in a single molecular switch. No digital communication between distinct gates is needed since they are built in the same molecular entity. Though extremely elegant, this strategy does not have the same versatility of a modular approach. A different molecule

has to be designed, synthesized and analyzed every single time a different logic function has to be realized. In addition, the degree of complexity that can be achieved with only one molecular switch is fairly limited. The connection of the input and output terminals of independent molecular AND, NOT and OR operators, instead, would offer the possibility of assembling any combinational logic circuit from three basic building blocks.

In digital electronics, the communication between two logic gates can be realized connecting their terminals with a wire [2.19]. Methods to transmit binary data between distinct molecular switches are not so obvious and must be identified. Recently, we developed two strategies to communicate signals between compatible molecular components. In one instance, a chemical signal is communicated between two distinct molecular switches [2.26]. They are the three-state switch illustrated in Fig. 2.8 and the two-state switch of Fig. 2.9. The merocyanine form **7** is a photogenerated base. Its *p*-nitrophenolate fragment, produced upon irradiation of the colorless state **5** with ultraviolet light, can abstract a proton from an acid present in the same solution. The resulting protonated form **6** is a photoacid. It releases a proton upon irradiation with visible light and can protonate a base codissolved in the same medium. The orange azopyridine **8** switches to the red-purple azopyridinium **9** upon protonation. This process is reversible and the addition of a base restores the orange state **8**. It follows that photoinduced proton transfer can be exploited to communicate a chemical signal from **6** to **8** and from **9** to **7**. The two colored states **8** and **9** have different absorption properties in the visible region. In acetonitrile, the orange state **8** absorbs at 422 nm and the red-purple state **9** absorbs at 556 nm. The changes in absorbance of these two bands can be exploited to monitor the photoinduced exchange of protons between the two communicating molecular switches.

The three-state molecular switch and the two-state molecular switch can be operated sequentially when dissolved in the same acetonitrile solution. In the presence of one equivalent of H^+, the two-state molecular switch is in state **9** and the absorbance at 556 nm is high (**O** = 1). Upon irradiation with ultraviolet light (**I1** = 1), **5** switches to **7**. The photogenerated base deprotonates **9** producing **8** and **6**. As a result, the absorbance at 556 nm decreases (**O** = 0). Upon irradiation with visible light (**I2** = 1), **6** switches to **5** releasing H^+. The result is the protonation of **8** to form **9** and restore the high absorbance at 556 nm (**O** = 1). In summary, the three-state molecular switch transduces two optical inputs (**I1** = ultraviolet light, **I2** = visible light) into a chemical signal (proton transfer) that is communicated to the two-state molecular switch and converted into a final optical output (**O** = absorbance at 556 nm).



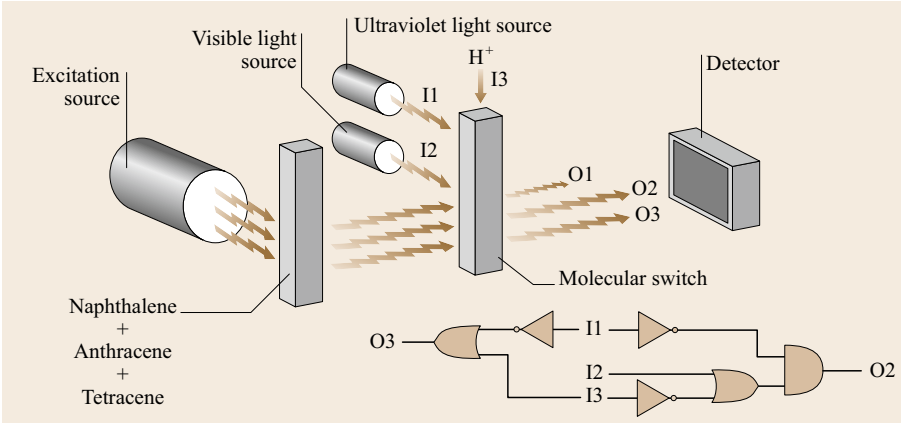


Fig. 2.9 The concentration of H^+ controls the reversible interconversion between the two states **8** and **9**. In response to ultraviolet (**I1**) and visible (**I2**) inputs, the three-state molecular switch in Fig. 2.7 modulates the ratio between these two forms and the absorbance (**O**) of **9** through photoinduced proton transfer. The truth table and sequential logic circuit illustrate the signal transduction behavior of the two communicating molecular switches. The interconversion between the five three-digit strings of input (**I1** and **I2**) and output (**O**) data is achieved varying the input values in steps

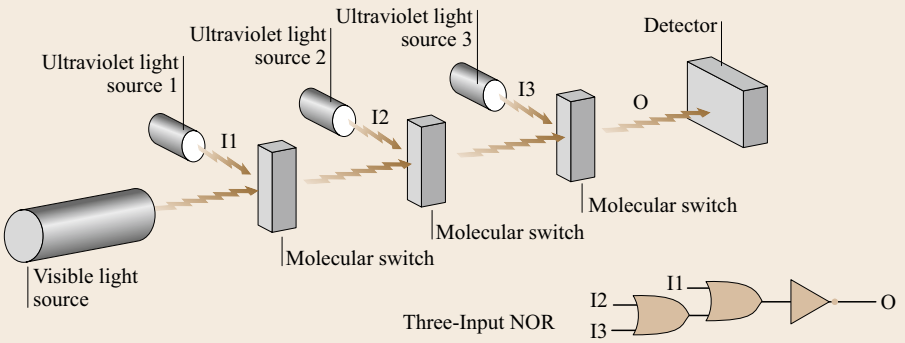
The logic behavior of the two communicating molecular switches is significantly different from those of the chemical systems illustrated in Figs. 2.6–2.8 [2.26]. The truth table in Fig. 2.9 lists the four possible combinations of two-digit input strings and the corresponding one-digit output. The output digit **O** for the input strings 01, 10 and 11 can take only one value. In fact, the input string 01 is transduced into a 1 and the input strings 10 and 11 are converted into 0. Instead, the output digit **O** for the input string 00 can be either 0 or 1. The sequence of events leading to the input string 00 determines the value of the output. The boxes a–e in Fig. 2.9 illustrates this effect. They correspond to the five three-digit input/output strings. The transformation of one box into any of the other four is achieved in one or two steps changing the values of **I1** and/or **I2**. In two instances (a and b), the two-state molecular switch is in state **9** and the output signal is high (**O** = 1). In the other three cases (c, d and e), the two-state molecular switch is in state **8** and the output signal is low (**O** = 0). The strings 000 (e) and 001 (a) correspond to the first



entry of the truth table. They share the same input digits, but differ in the output value. The string 000 (e) can be obtained only from the string 100 (c) varying the value of **I1**. Similarly, the string 001 (a) can be accessed only from the string 011 (b) varying the value of **I2**. In both transformations, the output digit remains unchanged. Thus, the value of **O1** in the parent string is memorized and maintained in the daughter string when both inputs become 0. This memory effect is the fundamental operating principle of sequential logic circuits [2.17], which are used extensively to assemble the memory elements of modern microprocessors. The sequential logic circuit equivalent to the truth table of the two communicating molecular switches is also shown in Fig. 2.9. In this circuit, the input data **I1** and **I2** are combined through NOT, OR and AND operators. The output of the AND gate **O** is also an input of the OR gate and controls, together with **I1** and **I2**, the signal transduction behavior.

The other strategy for digital transmission between molecules is based on the communication of optical signals between the three-state molecular switch (Fig. 2.8) and fluorescent compounds [2.25, 27, 28]. In the optical network of Fig. 2.10, three optical signals travel from an excitation source to a detector after passing through two quartz cells. The first cell contains an equimolar acetonitrile solution of naphthalene, anthracene and tetracene. The second cell contains an acetonitrile solution of the three-state molecular switch. The excitation source sends three consecutive monochromatic light beams to the first cell stimulating the emission of the three fluorophores. The light emitted in the direction perpendicular to the exciting beam reaches the second cell. When the molecular switch is in state **5**, the naphthalene emission at 335 nm is absorbed and a low intensity output (**O1**) reaches the detector. Instead, the anthracene and tetracene emissions at 401 and 544 nm, respectively, pass unaffected and high intensity outputs (**O2** and **O3**) reach the detector. When the molecular switch is in state **6**, the naphthalene and anthracene emissions are absorbed and only the tetracene emission reaches the detector (**O1** = 0, **O2** = 0, **O3** = 1). When the molecular switch is state **7**, the emission of all three fluorophores is absorbed (**O1** = 0, **O2** = 0, **O3** = 0). The interconversion of the molecular switch between the three states is induced addressing the second cell with ultraviolet (**I1**), visible (**I2**) and H^+ (**I3**) inputs. Thus, three independent optical outputs (**O1**, **O2** and **O3**) can be modulated stimulating the molecular switch with two optical and one chemical input. The truth table in Fig. 2.10 illustrates the relation between the three inputs (**I1**, **I2** and **I3**) and the three outputs (**O1**, **O2** and **O3**), when positive logic conventions are applied to all signals. The equivalent logic circuit shows that all three inputs control the anthracene channel **O2**, but only **I1** and **I3** influence the tetracene channel **O3**. Instead, the intensity of the naphthalene channel **O1** is always low and it is not affected by the three inputs.

Fig. 2.10 The excitation source sends three monochromatic light beams (275, 357 and 441 nm) to a quartz cell containing an equimolar acetonitrile solution of naphthalene, anthracene and tetracene. The three fluorophores absorb the exciting beams and reemit at 305, 401 and 544 nm, respectively. The light emitted in the direction perpendicular to the exciting beams passes through another quartz cell containing an acetonitrile solution of the three-state molecular switch shown in Fig. 2.7. Ultraviolet (**I1**), visible (**I2**) and H^+ (**I3**) inputs control the interconversion between the three states of the molecular switch. They determine the intensity of the optical outputs reaching the detector and correspond to the naphthalene (**O1**), anthracene (**O2**) and tetracene (**O3**) emissions. The truth table and equivalent combinational logic illustrate the relation between the three inputs and the three outputs. The output **O1** is always 0 and it is not influenced by the three inputs. Only two inputs determine the value of **O3**, while all of them control the output **O2**

Fig. 2.11 The visible source sends a monochromatic beam (563 nm) to the detector. The traveling light is forced to pass through three quartz cells containing the molecular switch illustrated in Fig. 2.7. The three switching elements are operated by independent ultraviolet inputs. When at least one of them is on, the associated molecular switch is in the purple form **7**, which can absorb and block the traveling light. The truth table and equivalent logic circuit illustrate the relation between the three inputs **I1**, **I2** and **I3** and the optical output **O**

The operating principles of the optical network in Fig. 2.10 can be simplified to implement all-optical logic gates. The chemical input inducing the formation of the protonated form **6** of the molecular switch can be eliminated. The interconversion between the remaining two states **5** and **7** can be controlled relying exclusively on ultraviolet inputs. Indeed, ultraviolet irradiation induces the isomerization of the colorless form **5** to the colored species **7**, which reisomerizes to the original state in the dark. Thus, a single ultraviolet source is sufficient to control the switching from **5** to **7** and vice versa. On the basis of these considerations, all-optical NAND, NOR and NOT gates can be implemented operating sequentially or in parallel from one to three independent switching elements [2.29]. For example, the all-optical network illustrated in Fig. 2.11 is a three-input NOR gate. A monochromatic optical signal travels from a visible source to a detector. Three switching elements are aligned along the path of the traveling light. They are quartz cells containing an acetonitrile solution of the molecular switch shown in Fig. 2.8. The interconversion of the colorless form **5** into the purple isomer **7** is induced stimulating the cell with an ultraviolet input. The reisomerization from **7** to **5** occurs spontaneously, as the ultraviolet source is turned off. Using three distinct ultraviolet sources, the three switching elements can be controlled independently.

The colorless form **5** does not absorb in the visible region, while the purple isomer **7** has a strong absorption band at 563 nm. Thus, a 563 nm optical signal leaving the visible source can reach the detector unaffected only if all three switching elements are in the nonabsorbing state **5**. If one of the three ultraviolet inputs **I1**, **I2** or **I3** is turned on, the intensity of the optical output **O** drops to 3–4% of its original value. If two or three ultraviolet inputs are turned on simultaneously, the optical output drops to 0%. Indeed, the photogenerated state **7** absorbs and blocks the traveling light. Applying positive logic conventions to all signals, binary digits can be encoded in the three optical inputs and in the optical output. The resulting truth table is illustrated in Fig. 2.11. The output **O** is 1 only if all three inputs **I1**, **I2** or **I3** are 0. The output **O** is 0 if at least one of the three inputs **I1**, **I2** or **I3** is 1. This signal transduction corresponds to that executed by a three-input NOR gate, which is a combination of one NOT and two OR operators.

2.3 Solid-State Devices

2.3.1 From Functional Solutions to Electroactive and Photoactive Solids

The fascinating chemical systems illustrated in Figs. 2.6–2.11 demonstrate that logic functions can be implemented relying on the interplay between designed molecules and chemical, electrical and/or optical signals [2.20, 21]. These molecular switches, however, are operated exclusively in solution and remain far from potential applications in information technology at this stage. The integration of liquid components and volatile organic solvents in practical digital devices is hard to

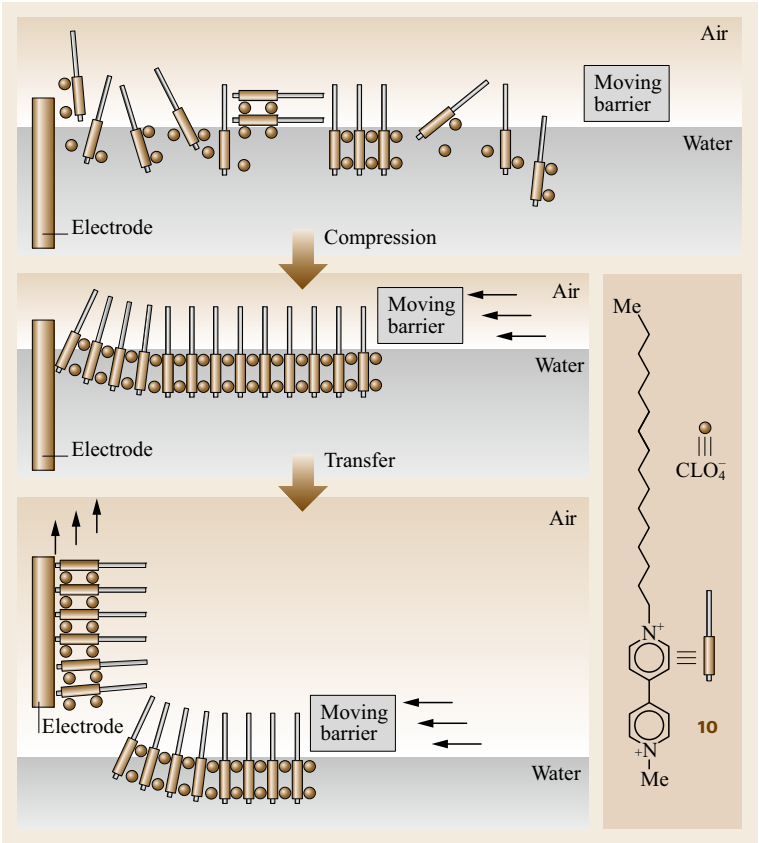

Fig. 2.12 The compression of the amphiphilic dication **10** with a moving barrier results in the formation of a packed monolayer at the air–water interface. The lifting of an electrode preimmersed in the aqueous subphase encourages the transfer of part of the monolayer on the solid support

envisage. Furthermore, the logic operations executed by these chemical systems rely on bulk addressing. Although the individual molecular components have nanoscaled dimensions, macroscopic collections of them are employed for digital processing. In some instances, the operating principles cannot even be scaled down to the unimolecular level. Often, bulk properties are responsible for signal transduction. For example, a single fluorescent compound **2** cannot execute an OR operation. Its azacrown appendage can accommodate only one metal cation. As a result, an individual molecular switch can respond to only one of the two chemical inputs. It is a collection of numerous molecular switches dissolved in an organic solvent that responds to both inputs enabling an OR operation.

The development of miniaturized molecule-based devices requires the identification of methods to transfer the switching mechanisms developed in solution to the solid state [2.30]. Borrowing designs and fabrication strategies from conventional electronics, the integration of molecular components into functional circuits and devices is starting to be explored [2.31–34]. Generally, these strategies combine lithography and surface chemistry to assemble nanometer-thick organic films on the surfaces of microscaled or nanoscaled electrodes. Two main approaches for the deposition of organized molecular arrays on inorganic supports have emerged so far. In one instance, amphiphilic molecular building blocks are compressed into organized monolayers at air–water interfaces. The resulting films can be transferred on supporting solids employing the Langmuir–Blodgett technique [2.35]. Alternatively, certain molecules can be designed to adsorb spontaneously on the surfaces of compatible solids from liquid or vapor phases. The result is the self-assembly of organic layers on inorganic supports [2.36].

2.3.2 Langmuir–Blodgett Films

Films of amphiphilic molecules can be deposited on a variety of solid supports employing the Langmuir–Blodgett technique [2.35]. This method can be extended to electroactive compounds incorporating hydrophilic and hydrophobic groups. For example, the amphiphile **10** (Fig. 2.12) has a hydrophobic hexadecyl tail attached to a hydrophilic bipyridinium dication [2.37, 38]. This compound dissolves in mixtures of chloroform and

methanol, but it is not soluble in moderately concentrated aqueous solutions of sodium perchlorate. Thus, the spreading of an organic solution of **10** on an aqueous sodium perchlorate subphase affords a collection of disorganized amphiphiles floating on the water surface (Fig. 2.12), after the evaporation of the organic solvent. The molecular building blocks can be compressed into a monolayer with the aid of a moving barrier. The hydrophobic tails align away from the aqueous phase. The hydrophilic dicationic heads and the accompanying perchlorate counterions pack to form an organized monolayer at the air–water interface. The compression process can be monitored by recording the surface pressure (π)–area per molecule (A) isotherm, which indicates a limiting molecular area of ca. 50 Å^2. This value is larger than the projected area of an oligomethylene chain. However, it correlates reasonably with the overall area of a bipyridinium dication plus two perchlorate anions.

The monolayer prepared at the air–water interface (Fig. 2.12) can be transferred on the surface of an indium-tin oxide electrode preimmersed in the aqueous phase. The slow lifting of the solid support drags the monolayer away from the aqueous subphase. The final result is the coating of the electrode with an organic film containing electroactive bipyridinium building blocks. The modified electrode can be integrated in a conventional electrochemical cell to probe the redox response of the electroactive layer. The resulting cyclic voltammograms reveal the characteristic waves for the first reduction process of the bipyridinium dications, confirming the successful transfer of the electroactive amphiphiles from the air–water interface to the electrode surface. The integration of the redox waves indicates a surface coverage of ca. 4×10^{-10} mol cm^{-2}. This value corresponds to a molecular area of ca. 40 Å^2 and is in excellent agreement with the limiting molecular area of the π–A isotherm.

These seminal experiments demonstrate that electroactive amphiphiles can be organized into uniform monolayers at the air–water interface and then transferred efficiently on the surface of appropriate substrates to produce electrode–monolayer junctions. The resulting electroactive materials can become the functional components of molecule-based devices. For example, bipyridinium-based photodiodes can be fabricated following this approach [2.39, 40]. Their operating principles rely on photoinduced electron transfer from chromophoric units to bipyridinium acceptors. The electroactive and photoactive amphiphile **11** (Fig. 2.13) incorporates hydrophobic ferrocene and pyrene tails and a hydrophilic bipyridinium head. Chloroform solutions of **11** containing ten equivalents of arachidic acid can be spread on an aqueous calcium chloride subphase in a Langmuir trough. The amphiphiles can be compressed into a mixed monolayer, after the evaporation of the organic solvent. Pronounced steps in the corresponding π–A isotherm suggest that the bulky ferrocene and pyrene groups are squeezed away from the water surface. In the final arrangement, both photoactive groups align above the hydrophobic dication.

A mixed monolayer of **11** and arachidic acid can be transferred from the air–water interface to the surface of a transparent gold electrode following the methodology illustrated for the system in Fig. 2.12. The coated electrode can be integrated in a conventional electrochemical cell. Upon irradiation at 330 nm under an inert atmosphere, an anodic photocurrent of ca. 2 nA develops at a potential of 0 V relative to a saturated calomel electrode. Indeed, the illumination of the electroactive monolayer induces the electron transfer from the pyrene appendage to the bipyridinium acceptor and then from the reduced acceptor to the electrode. A second intramolecular electron transfer from the ferrocene donor to the oxidized pyrene fills its photogenerated hole. Overall, a unidirectional flow of electrons across the monolayer–electrode junction is established under the influence of light.

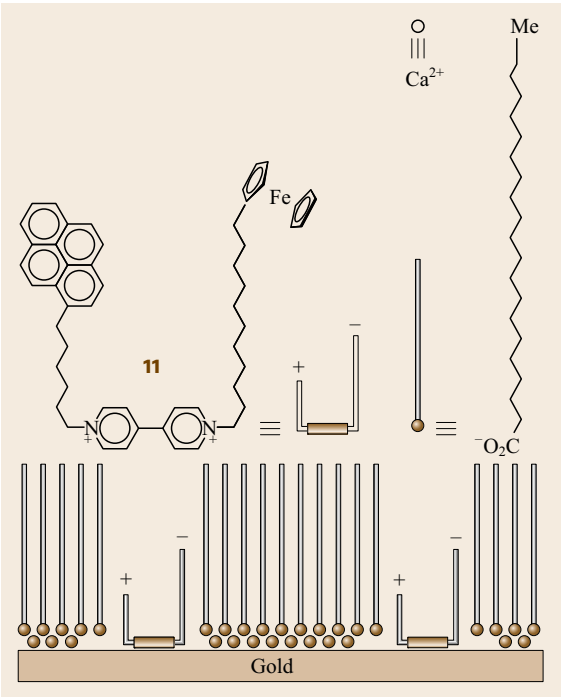

Fig. 2.13 Mixed monolayers of the amphiphile **11** and arachidic acid can be transferred from the air–water interface to the surface of an electrode to generate a molecule-based photodiode

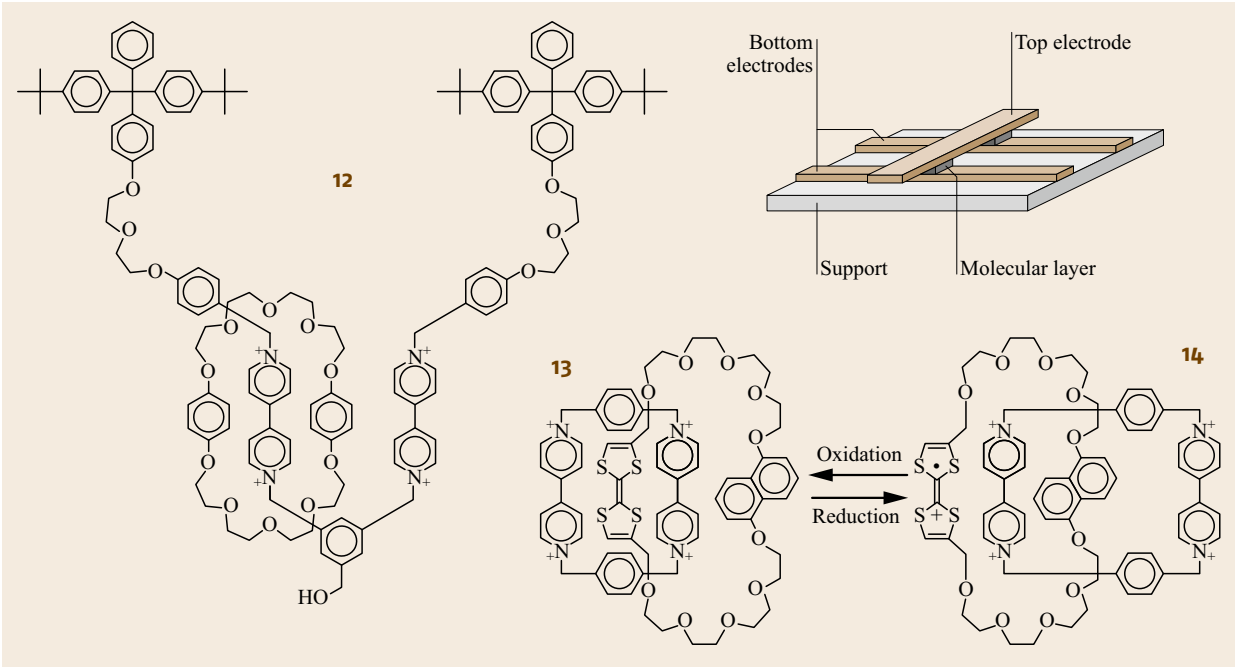

Fig. 2.14 The [2]rotaxane **12** and the [2]catenane **13** can be compressed into organized monolayers at air–water interfaces. The resulting monolayers can be transferred on the bottom electrodes of a patterned silicon support. After the deposition of a top electrode, electrode–monolayer–electrode junctions can be assembled. Note that only the portion of the monolayer sandwiched between the top and bottom electrodes is shown in the diagram. The oxidation of the tetrathiafulvalene unit of the [2]catenane **13** is followed by the circumrotation of the macrocyclic polyether to afford the [2]catenane **14**. The process is reversible and the reduction of the cationic tetrathiafulvalene unit restores the original state

The ability to transfer electroactive monolayers from air–water interfaces to electrode surfaces can be exploited to fabricate molecule-based electronic devices. In particular, arrays of interconnected electrode–monolayer–electrode tunneling junctions can be assembled combining the Langmuir–Blodgett technique with electron beam evaporation [2.33]. A schematic representation of the resulting devices is illustrated in Fig. 2.14. Initially, parallel fingers are patterned on a silicon wafer with a silicon dioxide overlayer by electron beam evaporation. The bottom electrodes deposited on the support can be either aluminum wires covered by an aluminum oxide or n-doped silicon lines with silicon dioxide overlayers. Their widths are ca. 6 or 7 μm, respectively. The patterned silicon chip is immersed in the aqueous subphase of a Langmuir trough prior to monolayer formation. After the compression of electroactive amphiphiles at the air–water interface, the substrate is pulled out of the aqueous phase to encourage the transfer of the molecular layer on the parallel bottom electrodes as well as on the gaps between them. Then, a second set of electrodes orthogonal to the first is deposited through a mask by electron beam evaporation. They consist of a titanium underlayer plus an aluminum overlayer. Their thicknesses are ca. 0.05 and 1 μm, respectively, and their width is ca. 10 μm. In the final assembly, portions of the molecular layer become sandwiched between the bottom and top electrodes. The active areas of these electrode–monolayer–electrode junctions are ca. 60–70 μm^2 and correspond to ca. 10^6 molecules.

The [2]rotaxane **12** (Fig. 2.14) incorporates a macrocyclic polyether threaded onto a bipyridinium-based backbone [2.41, 42]. The two bipyridinium dications are bridged by a *m*-phenylene spacer and terminated by tetraarylmethane appendages. These two bulky groups mechanically trap the macrocycle preventing its dissociation from the tetracationic backbone. In addition, their hydrophobicity complements the hydrophilicity of the two bipyridinium dications imposing amphiphilic character on the overall molecular assembly. This compound does not dissolve in aqueous solutions and can be compressed into organized monolayers at air-water interfaces. The corresponding π–A isotherm reveals a limiting molecular area of ca. 130 $Å^2$. This large value is a consequence of the bulk associated with the hydrophobic tetraarylmethane tails and the macrocycle encircling the tetracationic backbone.

Monolayers of the [2]rotaxane **12** can be transferred from the air–water interface to the surfaces of the bottom aluminum/aluminum oxide electrodes of a patterned silicon chip with the hydrophobic tetraarylmethane groups pointing away from the supporting substrate. The subsequent assembly of a top titanium/aluminum electrode affords electrode–monolayer–electrode junctions. Their current–voltage signature can be recorded by grounding the top electrode and scanning the potential of the bottom electrode. A pronounced increase in current is observed when the potential is lowered below −0.7 V. Under these conditions, the bipyridinium-centered lowest unoccupied molecular orbitals (LUMOs) mediate the tunneling of electrons from the bottom to the top electrode leading to a current enhancement. A similar current profile is observed if the potential is returned to 0 and then back to −2 V. Instead, a modest increase in current in the opposite direction is observed when the potential is raised above +0.7 V. Presumably, this trend is a result of the participation of the phenoxy-centered highest occupied molecular orbitals (HOMOs) in the tunneling process. After a single positive voltage pulse, however, no current can be detected if the potential is returned to negative values. In summary, the positive potential scan irreversibly suppresses the conducting ability of the electrode–molecule–electrode junction. The behavior of this device correlates with the redox response of the [2]rotaxane **12** in solution. Cyclic voltammograms reveal reversible monoelectronic reductions of the bipyridinium dications. However, they also show two irreversible oxidations associated, presumably, to the phenoxy rings of the macrocycle and tetraarylmethane groups. These observations suggest that a positive voltage pulse applied to the electrode–monolayer–electrode junction oxidizes irreversibly the sandwiched molecules suppressing their ability to mediate the transfer of electrons from the bottom to the top electrode under a negative bias.

The device incorporating the [2]rotaxane **13** can be exploited to implement simple logic operations [2.41]. The two bottom electrodes can be stimulated with voltage inputs (**I1** and **I2**) while measuring a current output (**O**) at the common top electrode. When at least one of the two inputs is high (0 V), the output is low (< 0.7 nA). When both inputs are low (−2 V), the output is high (ca. 4 nA). If a negative logic convention is applied to the voltage inputs (low = 1, high = 0) and a positive logic convention is applied to the current output (low = 0, high = 1), the signal transduction behavior translates into the truth table of an AND gate. The output **O** is 1 only when both inputs are 1. Instead, an OR operation can be executed if the logarithm of the current is considered as the output. The logarithm of the current is −12 when both voltage inputs are 0 V. It raises to ca. −9 when one or both voltage inputs are lowered to −2 V. This signal transduction behavior translates into the truth table of an OR gate if a negative logic convention is applied to the voltage inputs (low = 1, high = 0) and a positive logic convention is applied to the current output (low = 0, high = 1). The output **O** is 1 when at least one of the two inputs is 1.

The [2]catenane **13** (Fig. 2.14) incorporates a macrocyclic polyether interlocked with a tetracationic cyclophane [2.43, 44]. Organic solutions of the hexafluorophosphate salt of this [2]catenane and six equivalents of the sodium salt of dimyristoylphosphatidic acid can be cospread on the water surface of a Langmuir trough [2.45]. The sodium hexafluorophosphate formed dissolves in the supporting aqueous phase, while the hydrophilic bipyridinium cations and the amphiphilic anions remain at the interface. Upon compression, the anions align their hydrophobic tails away from the water surface forming a compact monolayer above the cationic bipyridinium derivatives. The corresponding π–A isotherm indicates limiting molecular areas of ca. 125 Å^2. This large value is a consequence of the bulk associated with the two interlocking macrocycles.

Monolayers of the [2]catenane **13** can be transferred from the air–water interface to the surfaces of the bottom n-doped silicon/silicon dioxide electrodes of a patterned silicon chip with the hydrophobic tails of the amphiphilic anions pointing away from the supporting substrate [2.46, 47]. The subsequent assembly of a top titanium/aluminum electrode affords electrode–monolayer–electrode arrays. Their junction resistance can be probed grounding the top electrode and maintaining the potential of the bottom electrode at +0.1 V. If a voltage pulse of +2 V is applied to the bottom electrode before the measurement, the junction resistance probed is ca. 0.7 GΩ. After a pulse of −2 V applied to the bottom electrode, the junction resistance probed at +0.1 V drops ca. 0.3 GΩ. Thus, alternating positive and negative voltage pulses can switch reversibly the junction resistance between high and low values. This intriguing behavior is a result of the redox and dynamic properties of the [2]catenane **13**.

Extensive spectroscopic and crystallographic studies [2.43, 44] demonstrated that the tetrathiafulvalene unit resides preferentially inside the cavity of the tetracationic cyclophane of the [2]catenane **13** (Fig. 2.14). Attractive [$\pi \cdots \pi$] stacking interactions between the neutral tetrathiafulvalene and the bipyridinium dications are responsible for this coconformation. Oxidation of the tetrathiafulvalene generates a cationic form that is expelled from the cavity of the tetracationic cyclophane. After the circumrotation of the macrocyclic polyether, the oxidized tetrathiafulvalene is exchanged

with the neutral 1,5-dioxynaphthalene producing the [2]catenane **14** (Fig. 2.14). The reduction of the tetrathiafulvalene back to its neutral state is followed by the circumrotation of the macrocyclic polyether, which restores the original state **14**. The voltage pulses applied to the bottom electrode of the electrode–monolayer–junction oxidize and reduce the tetrathiafulvalene unit inducing the interconversion between the forms **13** and **14**. The difference in the stereoelectronic properties of these two states translates into distinct current–voltage signatures. Indeed, their ability to mediate the tunneling of electrons across the junction differs significantly. As a result, the junction resistance probed at a low voltage after an oxidizing pulse is significantly different from that determined under the same conditions after a reducing pulse.

2.3.3 Self-Assembled Monolayers

In the examples illustrated in Figs. 2.12–2.15, monolayers of amphiphilic and electroactive derivatives are assembled at air–water interfaces and then transferred on the surfaces of appropriate substrates. An alternative strategy to coat electrodes with molecular layers relies on the ability of certain compounds to adsorb spontaneously on solid supports from liquid or vapor phases [2.36]. In particular, the affinity of certain sulfurated functional groups for gold can be exploited to encourage the self-assembly of organic molecules on microscaled and nanoscaled electrodes.

The electrode–monolayer–electrode junction in Fig. 2.15 incorporates a molecular layer between two gold electrodes mounted on a silicon nitride support. This device can be fabricated combining chemical vapor deposition, lithography, anisotropic etching and self-assembly [2.48]. Initially, a silicon wafer is coated with a 50 nm thick layer of silicon nitride by low pressure chemical vapor deposition. Then, a square of $400 \times 400\,\mu m$ is patterned on one side of the coated wafer by optical lithography and reactive ion etching. Anisotropic etching of the exposed silicon up to the other side of the wafer leaves a suspended silicon nitride membrane of $40 \times 40\,\mu m$. Electron beam lithography and reactive ion etching can be used to carve a bowl-shaped hole (diameter = 30–50 nm) in the membrane. Evaporation of gold on the membrane fills the pore producing a bowl-shaped electrode. Immersion of the substrate in a solution of the thiol **15** results in the self-assembly of a molecular layer on the narrow part of the bowl-shaped electrode. The subsequent evaporation of a gold film on the organic monolayer produces an electrode–monolayer–electrode junction (Fig. 2.15) with a contact area of less than $2000\,nm^2$ and approximately 1000 molecules.

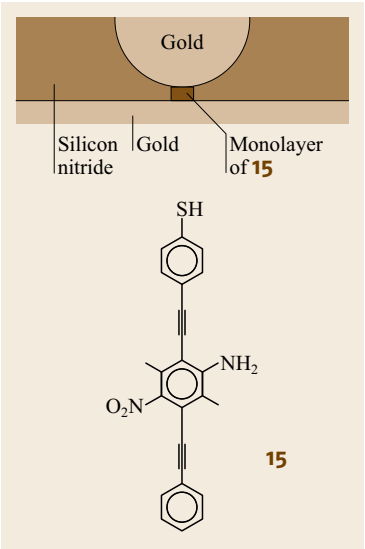

Fig. 2.15 A monolayer of the thiol **15** is embedded between two gold electrodes maintained in position by a silicon nitride support

Under the influence of voltage pulses applied to one of the two gold electrodes in Fig. 2.15, the conductivity of the sandwiched monolayer switches reversibly between low and high values [2.49]. In the initial state, the monolayer is in a low conducting mode. A current output of only 30 pA is detected, when a probing voltage of +0.25 V is applied to the bowl-shaped electrode. If the same electrode is stimulated with a short voltage pulse of +5 V, the monolayer switches to a high conducting mode. Now a current output of 150 pA is measured at the same probing voltage of +0.25 V. Repeated probing of the current output at various intervals of time indicates that the high conducting state is memorized by the molecule-based device and it is retained for more than 15 min. The low conducting mode is restored after either a relatively long period of time or the stimulation of the bowl-shaped electrode with a reverse voltage pulse of −5 V. Thus the current output switches from a low to a high value, if a high voltage input is applied. It switches from a high to a low value, under the influence of a low voltage pulse. This behavior offers the opportunity to store and erase binary data in analogy to a conventional random access memory [2.17]. Binary digits can be encoded on the current output of the molecule-based device applying a positive logic convention (low = 0, high = 1). It follows that a binary 1 can be stored in the molecule-based device applying a high voltage input and it can be erased applying a low voltage input [2.49].

The ability of thiols to self-assemble on the surface of gold can be exploited to fabricate nanocomposite materials integrating organic and inorganic components. For example, the bisthiol **16** forms monolayers (Fig. 2.16a) on gold electrodes with surface coverages

of ca. 4.1×10^{-10} mol cm^2 [2.50, 51]. The formation of a thiolate–gold bond at one of the two thiol ends of **16** is responsible for adsorption. The remaining thiol group points away from the supporting surface and can be exploited for further functionalization. Gold nanoparticles adsorb on the molecular layer (Fig. 2.16b), once again, as a result of thiolate–gold bond formation. The immersion of the resulting material in a methanol solution of **16** encourages the adsorption of an additional organic layer (Fig. 2.16c) on the composite material. Following these procedures, up to ten alternating organic and inorganic layers can be deposited on the electrode surface. The resulting assembly can mediate the unidirectional electron transfer from the supporting electrode to the redox active species in solution. For example, the cyclic voltammogram of the $[Ru(NH_3)_6]^{3+/2+}$ couple recorded with a bare gold electrode reveals a reversible reduction process. In the presence of ten alternating molecular and nanoparticle layers on the electrode surface, the reduction potential shifts by ca. −0.2 V and the back oxidation wave disappears. The pronounced potential shift indicates that $[Ru(NH_3)_6]^{3+}$ accepts electrons only after the surface-confined bipyridinium dications have been reduced. The lack of reversibility indicates that the back oxidation to the bipyridinium dications inhibits the transfer of electrons from the $[Ru(NH_3)_6]^{2+}$ to the electrode. Thus, the electroactive multilayer allows the flow of electrons in one direction only in analogy to conventional diodes.

The current–voltage behavior of individual nanoparticles in Fig. 2.16b can be probed by scanning tunneling spectroscopy in an aqueous electrolyte under an inert atmosphere [2.52]. The platinum-iridium tip of a scanning tunneling microscope is positioned above one of the gold particles. The voltage of the gold substrate relative to the tip is maintained at −0.2 V, while that relative to a reference electrode immersed in the same electrolyte is varied to control the redox state of the electroactive units. Indeed, the bipyridinium dications in the molecular layer can be reduced to a monocationic state reversibly. The resulting monocations can be reduced further and, once again, reversibly to a neutral form. Finally, the current flowing from the gold support to the tip of the scanning tunneling microscope is monitored as the tip–particle distance increases. From the distance dependence of the current, inverse length decays of ca. 16 and 7 nm^{-1} for the dicationic and monocationic states, respectively, of the molecular spacer can be determined. The dramatic decrease indicates that the reduction of the electroactive unit facilitates the tunneling of electrons through the gold–molecule–nanoparticle–tip junction. In summary, a change in the redox state of the bipyridinium components can be exploited to reversibly gate the current flowing through this nanoscaled device.

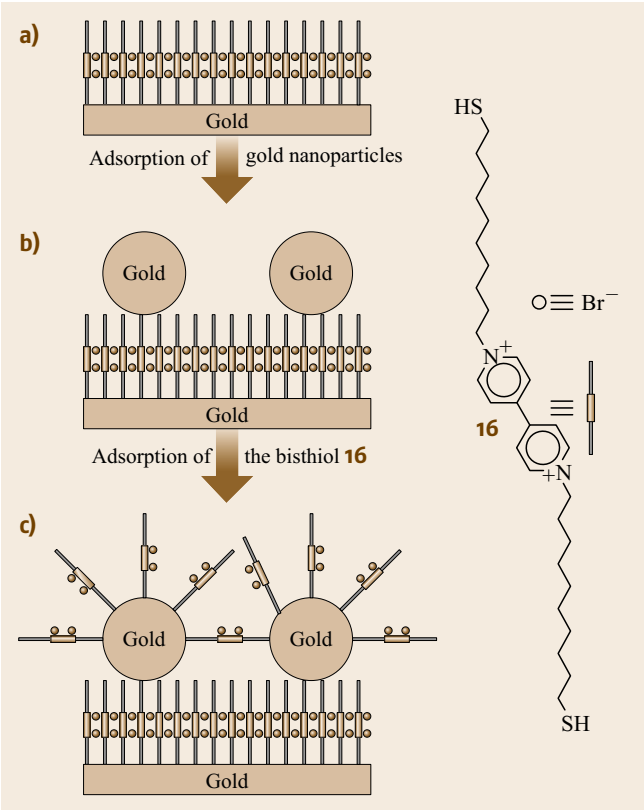

Fig. 2.16 **(a)** The bisthiol **16** self-assembles on gold electrodes as a result of thiolate–gold bond formation. **(b)** Gold nanoparticles adsorb spontaneously on the molecular layer. **(c)** Exposure of the composite assembly to a solution of **16** results in the formation of an additional molecular layer on the surface of the gold nanoparticles

Similar nanostructured materials, combining molecular and nanoparticle layers, can be prepared on layers of indium-tin oxide electrodes following multistep procedures [2.53]. The hydroxylated surfaces of indium-tin oxide supports can be functionalized with 3-ammoniumpropylsilyl groups and then exposed to gold nanoparticles having a diameter of ca. 13 nm [2.54, 55]. Electrostatic interactions promote the adsorption of the nanoparticles on the organic layer (Fig. 2.17a). The treatment of the composite film with the bipyridinium cyclophane **17** produces an organic layer on the gold nanoparticles (Fig. 2.18b). Following this approach, alternating layers of inorganic nanoparticles and organic building blocks can be assembled on the indium-tin oxide support. Cyclic voltammograms of the resulting materials show the oxidation of the gold nanoparticles and the reduction

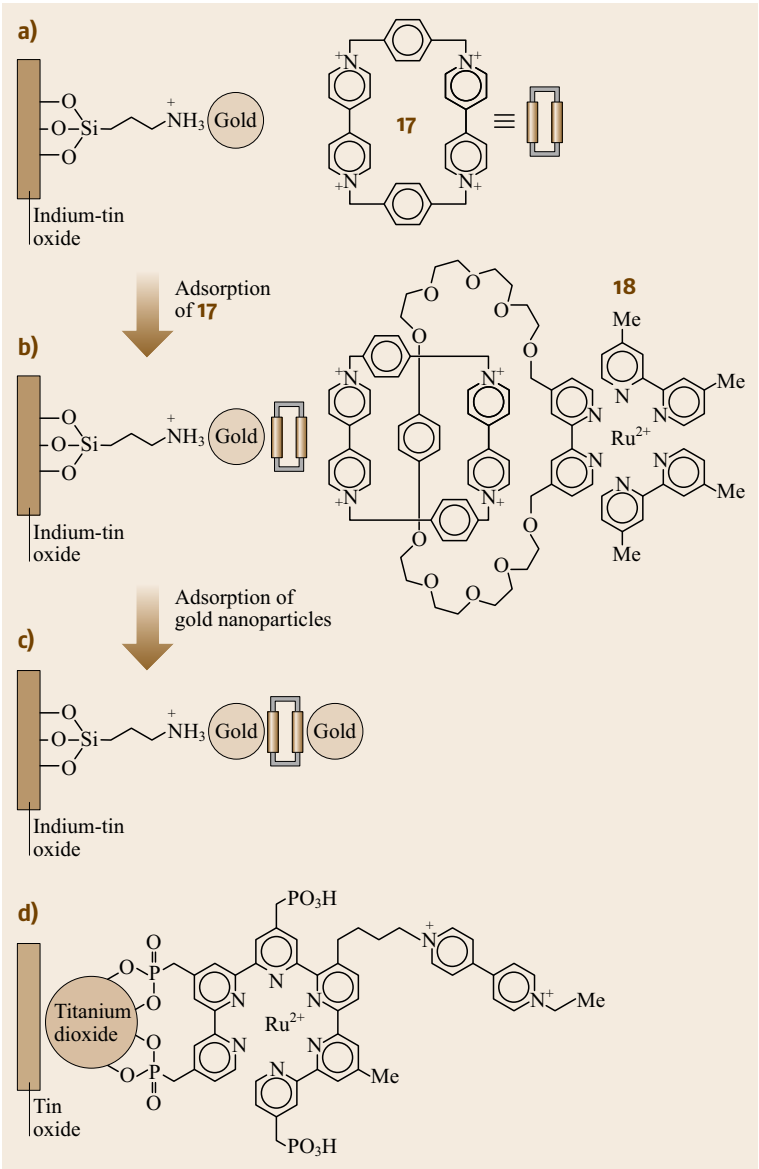

Fig. 2.17 **(a)** Gold nanoparticles assemble spontaneously on prefunctionalized indium-tin oxide electrodes. **(b)** Electrostatic interactions encourage the adsorption of the tetracationic cyclophane **17** on the surface-confined nanoparticles. **(c)** An additional layer of nanoparticles assembles on the cationic organic coating. Similar composite films can be prepared using the tetracationic [2]catenane **18** instead of the cyclophane **17**. **(d)** Phosphonate groups can be used to anchor molecular building blocks to titanium dioxide nanoparticles

of the bipyridinium units. The peak current for both processes increases with the number of alternating layers. Comparison of these values indicates that the ratio between the number of tetracationic cyclophanes and that of the nanoparticles is ca. 100:1.

The tetracationic cyclophane **17** binds dioxyarenes in solution [2.56, 57]. Attractive supramolecular forces between the electron deficient bipyridinium units and the electron-rich guests are responsible for complexation. This recognition motif can be exploited to probe the ability of the composite films in Fig. 2.17b,c to sense electron-rich analytes. In particular, hydroquinone is expected to enter the electron deficient cavities of the surface-confined cyclophanes. Consistently, cyclic voltammograms reveal the redox waves associated with the reversible oxidation of hydroquinone even when very small amounts of the guest (ca. 1×10^{-5} M) are added to the electrolyte solution [2.54, 55]. No redox response can be detected with a bare indium-tin oxide electrode under otherwise identical conditions. The supramolecular association of the guest and the surface-confined cyclophanes increases the local concentration of hydroquinone at the electrode–solution interface enabling its electrochemical detection.

Following a related strategy, the [2]catenane **18** (Fig. 2.17) can be incorporated into similar composite

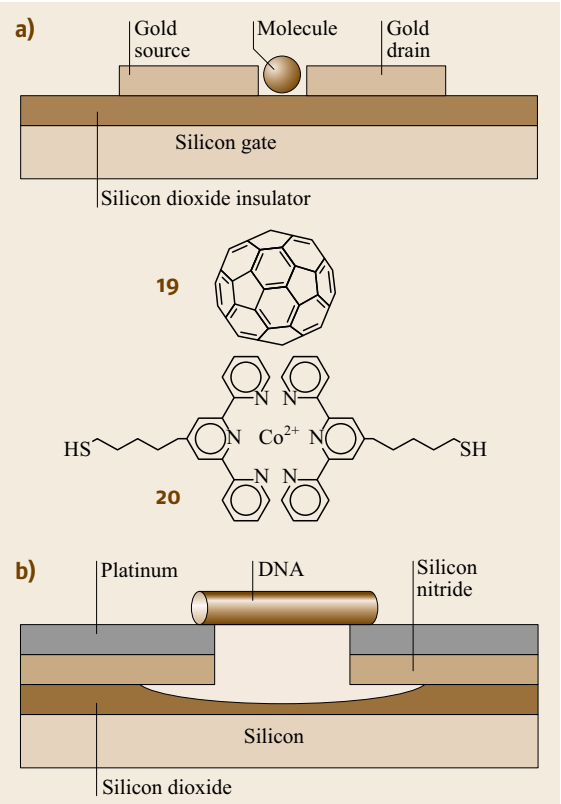

Fig. 2.18 **(a)** Nanoscaled transistors can be fabricated by inserting a single molecule (**19** or **20**) between source and drain electrodes mounted on a silicon/silicon dioxide support. **(b)** A DNA nanowire can bridge nanoelectrodes suspended above a silicon dioxide support

arrays [2.58, 59]. This interlocked molecule incorporates a Ru(II)/trisbipyridine sensitizer and two bipyridinium acceptors. Upon irradiation of the composite material at 440 nm, photoinduced electron transfer from the sensitizer to the appended acceptors occurs. The photogenerated hole in the sensitizer is filled after the transfer of an electron from a sacrificial electron donor present in the electrolyte solution. Under a positive voltage bias applied to the supporting electrode, an electron flow from the bipyridinium acceptors to the indium-tin oxide support is established. The resulting current switches between high and low values as the light source is turned off and on.

Another photoresponsive device, which is assembled combining inorganic nanoparticles with molecular building blocks, is illustrated in Fig. 2.17d. Phosphonate groups can be used to anchor a Ru(II)/trisbipyridine complex with an appended bipyridinium dication to titanium dioxide nanoparticles deposited on a doped tin oxide electrode [2.60, 61]. The resulting composite array can be integrated in a conventional electrochemical cell filled with an aqueous electrolyte containing triethanolamine. Under a bias voltage of −0.45 V and irradiation at 532 nm, 95% of the excited ruthenium centers transfer electrons to the titanium dioxide nanoparticles. The other 5% donate electrons to the bipyridinium dications. All the electrons transferred to the bipyridinium acceptors return to the ruthenium centers, while only 80% of those accepted by the nanoparticles return to the transition metal complexes. The remaining 15% reach the bipyridinium acceptors, while electron transfer from sacrificial triethanolamine donors fills the photogenerated holes left in the ruthenium sensitizers. The photoinduced reduction of the bipyridinium dication is accompanied by the appearance of the characteristic band of the radical cation in the absorption spectrum. This band persists for hours under open circuit conditions. However, it fades in ca. 15 s under a voltage bias of +1 V, as the radical cation is oxidized back to the dicationic form. In summary, an optical stimulation accompanied by a negative voltage bias reduces the bipyridinium building block. The state of the photogenerated form can be read optically, recording the absorption spectrum in the visible region, and erased electrically, applying a positive voltage pulse.

2.3.4 Nanogaps and Nanowires

The operating principles of the electroactive and photoactive devices illustrated in Figs. 2.12–2.17 exploit the ability of small collections of molecular components to manipulate electrons and photons. Designed molecules are deposited on relatively large electrodes and can be addressed electrically and/or optically by controlling the voltage of the support and/or illuminating its surface. The transition from devices relying on collections of molecules to unimolecular devices requires the identification of practical methods to contact single molecules. This fascinating objective demands the rather challenging miniaturization of contacting electrodes to the nanoscale.

A promising approach to unimolecular devices relies on the fabrication of nanometer-sized gaps in metallic features followed by the insertion of individual molecules between the terminals of the gap. This strategy permits the assembly of nanoscaled three-terminal devices equivalent to conventional transistors [2.62–64]. A remarkable example is illustrated in Fig. 2.18a [2.62]. It incorporates a single molecule in the nanogap generated between two gold electrodes. Initially, electron beam lithography is used to pattern a gold wire on a doped silicon wafer covered by an insulating silicon dioxide layer. Then, the gold feature is broken by electromigration to generate the nanogap.

The lateral size of the separated electrodes is ca. 100 nm and their thickness is ca. 15 nm. Scanning electron microcopy indicates that the facing surfaces of the separated electrodes are not uniform and that tiny gaps between their protrusions are formed. Current–voltage measurements suggest that the size of the smallest nanogap is ca. 1 nm. When the breakage of the gold feature is preceded by the deposition of a dilute toluene solution of C_{60} (**19**), junctions with enhanced conduction are obtained. This particular molecule has a diameter of ca. 0.7 nm and can insert in the nanogap, facilitating the flow of electrons across the junction.

The unique configuration of the molecule-based device in Fig. 2.18a can reproduce the functions of a conventional transistor [2.19] at the nanoscale. The two gold terminals of the junction are the drain and source of this nanotransistor and the underlying silicon wafer is the gate. At a temperature of 1.5 K, the junction conductance is very small, when the gate bias is low, and increases in steps at higher voltages [2.62]. The conductance gap is a consequence of the finite energy that is required to oxidize/reduce the single C_{60} positioned in the junction. Interestingly, the zero-conductance window also changes with the gate voltage and can be opened and closed reversibly adjusting the gate bias.

A similar strategy can be employed to fabricate a nanoscaled transistor incorporating the Co(II) complex **20** shown in Fig. 2.18 [2.64]. In this instance, a silicon dioxide layer with a thickness of ca. 30 nm is grown thermally on a doped silicon substrate. Then, a gold wire with a width of ca. 200 nm and a thickness of ca. 10−15 nm is patterned on the silicon dioxide overlayer by electron beam lithography. After extensive washing of the substrate with acetone and methylene chloride and cleaning with oxygen plasma, the gold wire is exposed to a solution of the bisthiol **20**. The formation of thiolate–gold bonds promotes the self-assembly of the molecular building block on the gold surface. At this point, electromigration-induced breakage produces a gap of 1−2 nm in the gold wire. The surface-confined bisthiol **20** is only 0.24 nm long and, therefore, it can insert in the nanogap producing an electrode–molecule–electrode junction.

The cobalt center in **20** can be oxidized/reduced reversibly between Co(II) and Co(III) states [2.64]. When this electroactive molecule is inserted in a nanogap (Fig. 2.18a), its ability to accept and donate electrons dictates the current–voltage profile of the resulting electrode–molecule–electrode junction. More precisely, no current flows across the junction below a certain voltage threshold. As the source voltage is raised above this particular value, the drain current increases in steps. Interestingly, the threshold associated with the source voltage varies in magnitude with the gate voltage. This intriguing behavior is a consequence of the finite energy necessary to oxidize/reduce the cobalt center and of a change in the relative stabilities of the oxidized and reduced forms Co(II) and Co(III) with the gate voltage. In summary, the conduction of the electrode–molecule–electrode junction can be tuned adjusting the voltage of the silicon support. The behavior of this molecule-based nanoelectronic device is equivalent to that of a conventional transistor [2.19]. In both instances, the gate voltage regulates the current flowing from the source to the drain.

The electromigration-induced breakage of preformed metallic features successfully produces nanogaps by moving apart two fragments of the same wire. Alternatively, nanogaps can be fabricated reducing the separation of the two terminals of much larger gaps. For example, gold electrodes separated by a distance of 20−80 nm can be patterned on a silicon/silicon dioxide substrate by electron beam lithography [2.65]. The relatively large gap between them can be reduced significantly by the electrochemical deposition of gold on the surfaces of both electrodes. The final result is the fabrication of two nanoelectrodes separated by ca. 1 nm and with a radius of curvature of 5−15 nm. The two terminals of this nanogap can be *contacted* by organic nanowires grown between them [2.66]. In particular, the electropolymerization of aniline produces polyaniline bridges between the gold nanoelectrodes. The conductance of the resulting junction can be probed immersing the overall assembly in an electrolyte solution. Employing a bipotentiostat, the bias voltage of the two terminals of the junction can be maintained at 20 mV, while their potentials are scanned relative to that of a silver/silver chloride reference electrode. Below ca. 0.15 V, the polymer wire is in an insulating state and the current flowing across the junction is less than 0.05 nA. At this voltage threshold, however, the current rises abruptly to ca. 30 nA. This value corresponds to a conductivity for the polymer nanojunction of 10−100 S cm^{-1}. When the potential is lowered again below the threshold, the current returns back to very low values. Interestingly, the abrupt decrease in current in the backward scan is observed at a potential that is slightly more negative than that causing the abrupt current increase in the forward scan. In summary, the conductance of this nanoscaled junction switches off and on as a potential input is switched above and below a voltage threshold.

It is interesting to note that the influence of organic bridges on the junction conductance can be exploited for chemical sensing. Nanogaps fabricated following a similar strategy, but lacking the polyaniline bridge, alter their conduction after exposure to dilute solutions of small organic molecules [2.67]. Indeed, the organic

analytes dock into the nanogaps producing a marked decrease in the junction conductance. The magnitude of the conductance drop happens to be proportional to the analyte–nanoelectrode binding strength. Thus, the presence of the analyte in solution can be detected probing the current–voltage characteristics of the nanogaps.

Nanogaps between electrodes patterned on silicon/silicon dioxide supports can be bridged also by DNA double strands [2.68, 69]. The device in Fig. 2.18b has a 10.4 nm long poly(G)–poly(C) DNA oligomer suspended between two nanoelectrodes. It can be fabricated patterning a 30 nm wide slit in a silicon nitride overlayer covering a silicon/silicon dioxide support by electron beam evaporation. Underetching the silicon dioxide layer leaves a silicon nitride finger, which can be sputtered with a platinum layer and chopped to leave a nanogap of 8 nm. At this point, a microdroplet of a dilute solution of DNA is deposited on the device and a bias of 5 V is applied between the two electrodes. Electrostatic forces encourage the deposition of a single DNA wire on top of the nanogap. As soon as the nanowire is in position, current starts to flow across the junction. The current–voltage signature of the electrode–DNA–electrode junction shows currents below 1 pA at low voltage biases. Under these conditions, the DNA nanowire is an insulator. Above a certain voltage threshold, however, the nanowire becomes conducting and currents up to 100 nA can flow across the junction through a single nanowire. Assuming that direct tunneling from electrode to electrode is extremely unlikely for a relatively large gap of 8 nm, the intriguing current–voltage behavior must be a consequence of the participation of the molecular states in the electron transport process. Two possible mechanisms can be envisaged. Sequential hopping of the electrons between states localized in the DNA base pairs can allow the current flow above a certain voltage threshold. However, this mechanism would presumably result in a Coulomb blockade voltage gap that is not observed experimentally. More likely, electronic states delocalized across the entire length of the DNA nanowire are producing a molecular conduction band. The off-set between the molecular conduction band and the Fermi levels of the electrodes is responsible for the insulating behavior at low biases. Above a certain voltage threshold, the molecular band and one of the Fermi levels align facilitating the passage of electrons across the junction.

Carbon nanotubes are extremely versatile building blocks for the assembly of nanoscaled electronic devices. They can be used to bridge nanogaps [2.70–73] and assemble nanoscaled cross junctions [2.74–76]. In Fig. 2.19a, a single-wall carbon nanotube crosses over another one in an orthogonal arrangement [2.74]. Both nanotubes have electrical contacts at their ends.

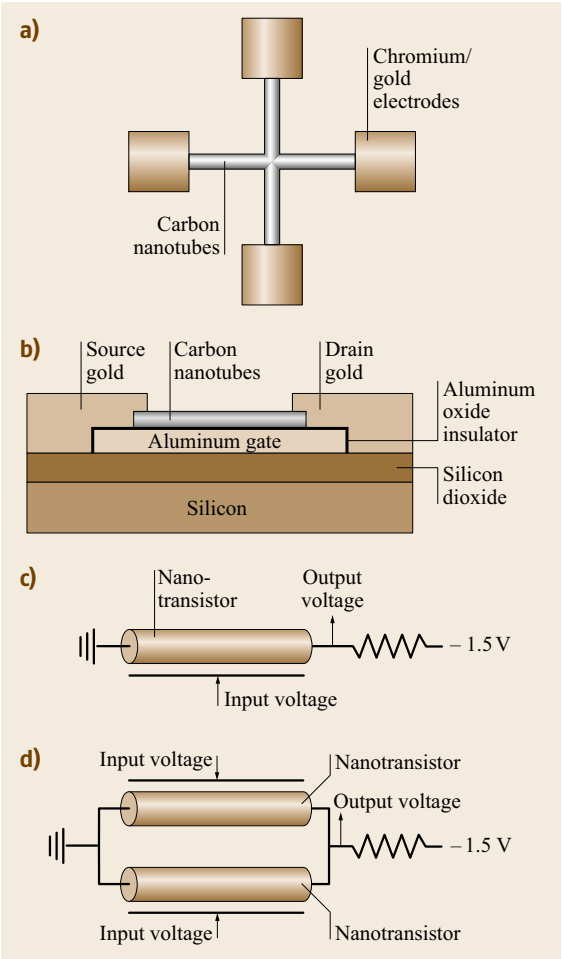

Fig. 2.19 **(a)** Nanoscaled junctions can be assembled on silicon/silicon dioxide supports crossing pairs of orthogonally arranged single-wall carbon nanotubes with chromium/gold electrical contacts at their ends. **(b)** Nanotransistors can be fabricated contacting the two ends of a single-wall carbon nanotube deposited on an aluminum/aluminum oxide gate with gold sources and drain. One or two nanotube transistors can be integrated into nanoscaled NOT **(c)** and NOR **(d)** logic gates

The fabrication of this device involves three main steps. First, alignment marks for the electrodes are patterned on a silicon/silicon dioxide support by electron beam lithography. Then, the substrate is exposed to a dichloromethane suspension of single-wall carbon nanotubes. After washing with isopropanol, crosses of carbon nanotubes in an appropriate alignment relative to the electrode marks are identified by tapping mode atomic force microscopy. Finally, chromium/gold electrodes are fabricated on top of the nanotube ends, again, by electron beam lithography. The conductance of in-

dividual nanotubes can be probed exploiting the two electric contacts at their ends. These two-terminal measurements reveal that certain nanotubes have metallic behavior, while others are semiconducting. It follows that three distinct types of cross junctions differing in the nature of their constituent nanotubes can be identified on the silicon/silicon dioxide support. Four terminal current–voltage measurements indicate that junctions formed by two metallic nanotubes have high conductance and ohmic behavior. Similarly, high junction conductance and ohmic behavior is observed when two semiconducting nanotubes cross. The current–voltage signature of junctions formed when a metallic nanotube crosses a semiconducting one are, instead, completely different. The metallic nanotube depletes the semiconducting one at the junction region producing a nanoscaled Schottky barrier with a pronounced rectifying behavior.

Similar fabrication strategies can be exploited to assemble nanoscaled counterparts of conventional transistors. The device in Fig. 2.19b is assembled patterning an aluminum finger on a silicon/silicon dioxide substrate by electron beam lithography [2.76]. After exposure to air, an insulating aluminum oxide layer forms on the aluminum finger. Then, a dichloromethane suspension of single-wall carbon nanotubes is deposited on the resulting substrate. Atomic force microscopy can be used to select carbon nanotubes with a diameter of ca. 1 nm that are positioned on the aluminum finger. After registering their coordinates relative to alignment markers, gold contacts can be evaporated on their ends by electron beam lithography. The final assembly is a nanoscaled three-terminal device equivalent to a conventional field effect transistor [2.19]. The two gold contacts are the source and drain terminals, while the underlying aluminum finger reproduces the function of the gate. At a source to drain bias of ca. −1.3 V, the drain current jumps from ca. 0 to ca. 50 nA when the gate voltage is lowered from −1.0 to −1.3 V. Thus, moderate changes in the gate voltage vary significantly the current flowing through the nanotube-based device in analogy to a conventional enhancement mode p-type field effect transistor [2.19].

The nanoscaled transistor in Fig.2.18a has a microscaled silicon gate that extends under the entire chip [2.62, 64]. The configuration in Fig. 2.19b, instead, has nanoscaled aluminum gates for every single carbon nanotube transistor fabricated on the same support [2.76]. It follows that multiple nanoscaled transistors can be fabricated on the same chip and operated independently following this strategy. This unique feature offers the possibility of fabricating nanoscaled digital circuits by interconnecting the terminals of independent nanotube transistors. The examples in Fig. 2.19c,d illustrate the configurations of nanoscaled NOT and NOR gates implemented using one or two nanotube transistors. In Fig. 2.19c, an off-chip bias resistor is connected to the drain terminal of a single transistor while the source is grounded. A voltage input applied to the gate modulates the nanotube conductance altering the voltage output probed at the drain terminal. In particular, a voltage input of −1.5 V lowers the nanotube resistance (26 MΩ) below that of the bias resistor (100 MΩ). As a result, the voltage output drops to 0 V. When the voltage input is raised to 0 V, the nanotube resistance increases above that of the bias resistor and the voltage output becomes −1.5 V. Thus, the output of this nanoelectronic device switches from a high (0 V) and to a low (−1.5 V) level as the input shifts from a low (−1.5 V) to a high (0 V) value. The inverse relation between input and output translates into a NOT operation if a negative logic convention (low = 1, high = 0) is applied to both signals.

In Fig. 2.15d, the source terminals of two independent nanotube transistors fabricated on the same chip are connected by a gold wire and grounded [2.76]. Similarly, the two drain terminals are connected by another gold wire and contacted to an off-chip bias resistor. The gate of each nanotube can be stimulated with a voltage input and the voltage output of the device can be probed at their interconnected drain terminals. When the resistance of at least one of the two nanotubes is below that of the resistor, the output is 0 V. When both nanotubes are in a nonconducting mode, the output voltage is −1.5 V. Thus, if a low voltage input −1.5 V is applied to one or both transistors, the output is high (0 V). When both voltage inputs are high (0 V), the output is low (−1.5 V). If a negative logic convention (low = 1, high = 0) is applied to all signals, the signal transduction behavior translates into a NOR operation.

2.4 Conclusions and Outlook

Nature builds nanostructured biomolecules relying on a highly modular approach [2.1]. Small building blocks are connected by robust chemical bonds to generate long strands of repeating units. The synergism of a multitude of attractive supramolecular forces determines the three-dimensional arrangement of the resulting polymeric chains and controls the association of independent strands into single and well-defined entities. Nucleic acids and proteins are two representative classes of biomolecules assembled with sub-

nanometer precision through the subtle interplay of covalent and noncovalent bonds starting from a relatively small pool of nucleotide and amino acid building blocks.

The power of chemical synthesis [2.2] offers the opportunity of mimicking nature's modular approach to nanostructured materials. Following established experimental protocols, small molecular building blocks can be joined together relying on the controlled formation of covalent bonds between designed functional groups. Thus, artificial molecules with nanoscaled dimensions can be assembled piece by piece with high structural control. Indeed, helical, tubular, interlocked and highly branched nanostructures have been prepared, and already exploit this general strategy and the synergism of covalent and noncovalent bonds [2.3].

The chemical construction of nanoscaled molecules from modular building blocks also offers the opportunity of engineering specific properties in the resulting assemblies. In particular, electroactive and photoactive fragments can be integrated into single molecules. The ability of these functional subunits to accept/donate electrons and photons can be exploited to design nanoscaled electronic and photonic devices. Indeed, molecules that respond to electrical and optical stimulations producing detectable outputs have been designed already [2.15]. These chemical systems can be employed to control the interplay of input and output signals at the molecular level. Their conceptual analogy with the signal transduction operated by conventional logic gates in digital circuits is evident. In fact, electroactive and photoactive molecules able to reproduce AND, NOT and OR operations as well as simple combinations of these basic logic functions, are already a reality [2.20, 21].

Most of the molecular switches for digital processing developed so far rely on bulk addressing. In general, relatively large collections of functional molecules are addressed simultaneously in solution. The realization of molecule-based devices with reduced dimensions as well as practical limitations associated with liquid phases in potential applications are encouraging a transition from the solution to the solid state. The general strategy followed so far relies on the deposition of functional molecules on the surfaces of appropriate electrodes following either the Langmuir–Blodgett methodology [2.77] or self-assembly processes [2.36]. The combination of these techniques with the nanofabrication of insulating, metallic and semiconducting features on appropriate supports has already allowed for the realization of fascinating molecule-based devices [2.31–34, 53]. The resulting assemblies integrate inorganic and organic components and, in some instances, even biomolecules to execute specific functions. They can convert optical stimulations into electrical signals. They can execute irreversible and reversible switching operations. They can sense qualitatively and quantitatively specific analytes. They can reproduce the functions of conventional rectifiers and transistors. They can be integrated within functioning nanoelectronic devices capable of simple logic operations.

The remarkable examples of molecule-based materials and devices already available are an obvious demonstration of the great potential and promise for this research area. At this stage, the only limit factor of designing functional molecules is the imagination of the synthetic chemist. All sorts of molecular building blocks with tailored dimensions, shapes and properties are more or less accessible with the assistance of modern chemical synthesis. Now the major challenges are (1) to master the operating principles of the molecule-based devices that have been and continue to be assembled, and (2) to expand and improve the fabrication strategies available to incorporate molecules into reliable device architectures. As we continue to gather further insights in these directions, design criteria for a wide diversity of molecule-based devices will emerge. It is not unrealistic to foresee the evolution of an entire generation of nanoscaled devices, based on engineered molecular components, which will find applications in a variety of fields ranging from biomedical research to information technology. Perhaps, Nature can once again illuminate our path teaching us not only how to synthesize nanostructured molecules but also how to use them. After all, Nature is full of examples of extremely sophisticated molecule-based devices. From tiny bacteria to higher animals, we are all a collection of molecule-based devices!

3. Introduction to Micro-/Nanofabrication

Gemma Rius, Antoni Baldi, Babak Ziaie, Massood Z. Atashbar

This chapter outlines and discusses important micro- and nanofabrication techniques. We focus on the most basic methods borrowed from the integrated circuit (IC) industry, such as thin-film deposition, lithography and etching, and then move on to look at microelectromechanical systems (MEMS) and nanofabrication technologies. We cover a broad range of dimensions, from the submillimeter to the nanometer scale. Although most of the current research is being geared towards the nanodomain, a good understanding of basic top-down methods for fabricating micron-sized objects can aid our understanding of this research. Due to space constraints, we focus here on the most important technologies; in the microdomain these include surface, bulk, and high-aspect-ratio micromachining; in the nanodomain we concentrate on e-beam lithography, epitaxial growth, scanning probe lithography, template manufacturing, and self-assembly. MEMS technology has matured rapidly, with some new technologies displacing older ones that have proven to be unsuited to manufacture on a commercial scale. However, due to limitations encountered on these methods used in the nanodomain, it appears that bottom-up methods or introduction of novel nanoforms and nanomaterials are the most feasible and promising solutions. Disruptive approaches are expected to have a major impact in a variety of application areas such as biology, medicine, environmental monitoring, and nanoelectronics.

References 82

Continuous efforts in the area of micro and nanofabrication have created a unique opportunity for manufacturing structures in the nm–mm range, particularly, utilizing the robust methods of semiconductor technology. The available six orders of magnitude dimensional span can be used to fabricate novel electronic, optical, magnetic, mechanical, and chemical/biological devices with applications ranging from sensors to computation and control. In this chapter, we will introduce major micro/nanofabrication techniques currently used to produce structures from the nm to several hundred μm range. We will mainly focus on the most important and widely used techniques and will not discuss specialized methods. After a brief introduction to basic microfabrication, we will discuss MEMS fabrication techniques used to build microstructures down to about 1 μm in dimensions. Following this, we will briefly discuss several top-down and bottom-up nanofabrication methods. As a comprehensive review of the diversity of nanofabrication techniques used nowadays is out of the scope of this chapter, we will refer to other dedicated chapters in this Handbook or provide relevant literature for the main ones.

3.1 Basic Microfabrication Techniques

Most micro/nanofabrication techniques have their roots in the standard fabrication methods developed for the semiconductor industry [3.1–3]. Therefore, a clear understanding of these techniques is necessary for anyone starting to embark on a research and development path in the micro/nano area. In this section, we will discuss the major microfabrication methods used most frequently in the manufacturing of micro/nanostructures. Some of these techniques such as thin-film deposition and etching are common between the micro/nano and very large-scale integration (VLSI) microchip fabrication disciplines. However, several other techniques which are more specific to the micro/nanofabrication area will also be discussed in this section. In essence, silicon technology is based on a combination or sequence of additive and substractive methods, such as ion implantation or sputtering and physical etching or resist development, respectively; typically applied together with a number of lithography or direct patterning steps.

3.1.1 Lithography

Lithography is the technique used to transfer a computer-generated pattern onto a substrate (silicon, glass, GaAs, etc.). This pattern is subsequently used to etch an underlying thin film (oxide, nitride, etc.) for various purposes (doping, etching, etc.). Although photolithography, i. e., lithography using an ultraviolet (UV) light source, is by far the most widely used lithography technique in the microelectronic fabrication, electron-beam (e-beam) and x-ray lithography are two other alternatives which have attracted considerable attention in the MEMS and nanofabrication areas. We will discuss photolithography in this section and postpone discussion of e-beam and x-ray techniques to subsequent sections dealing with MEMS and nanofabrication.

The starting point subsequent to the creation of the computer layout for a specific fabrication sequence is the generation of a photomask. This involves a sequence of photographic processes (using optical or e-beam pattern generators), which results in a glass plate having the desired pattern in the form of a thin ($\approx 100\,\mathrm{nm}$) chromium layer. Following the generation of the photomask, the lithography process can proceed as shown in Fig. 3.1. This sequence demonstrates the pattern transfer onto a Si substrate coated with silicon dioxide; however, the same technique is applicable to other materials. After depositing the desired material on the substrate, the photolithography process starts with spin-coating the substrate with a photoresist. This is a polymeric photosensitive material which can be spun onto the wafer in liquid from (usually an adhesion promoter such as hexamethyldisilazane (HMDS) is used prior to the application of the resist). The spinning speed and photoresist viscosity will determine the final resist thickness, which is typically in the range $0.5-2.5\,\mu\mathrm{m}$. Two different kinds of photoresist are available: positive and negative. With positive resist, UV-exposed areas will be dissolved in the subsequent development stage, whereas with negative photoresist, the exposed areas will remain intact after UV development. Due to its better performance with regard to process control in small geometries, positive resist is the most extensively used in the VLSI processes. After spinning the photoresist onto the wafer, the substrate is soft-baked ($5-30\,\mathrm{min}$ at $60-100\,^{\circ}\mathrm{C}$) in order to remove the solvents from the resist and improve adhesion. Subsequently, the mask is aligned to the wafer and the photoresist is, therefore, selectively exposed to a UV source.

Depending on the separation between the mask and the wafer three different exposure systems are available:

1. Contact
2. Proximity
3. Projection.

Fig. 3.1 Lithography process flow

Although contact printing gives better resolution compared with the proximity technique, the constant contact of the mask with the photoresist reduces the process yield and can damage the mask. Projection printing uses a dual-lens optical system to project the mask image onto the wafer. Since only one die at a time can be exposed, this requires a step-and-repeat system to cover the whole wafer area. Projection printing is by far the most widely used system in microfabrication and can yield superior resolutions compared with the contact and proximity methods. The exposure source for photolithography depends on the resolution (minimum feature size and pattern density). Above 0.25 μm minimum line width, a high-pressure mercury lamp is adequate (436 nm g-line and 365 nm i-line). However, between 0.25 and 0.13 μm, deep-UV sources such as excimer lasers (248 nm KrF and 193 nm ArF) are required. Although there has been extensive competition for the below-0.13 μm regime (including e-beam and x-ray), extreme UV (EUV) with wavelength of 10–14 nm seems to be the preferred technique, although major technical challenges still remain [3.4]. Immersion lithography (i. e., using a liquid in the space between the lens and substrate in order to increase the numerical aperture), a recent innovation, has allowed the minimum feature size to be reduced to 32 nm without the requirement for EUV sources [3.5].

After exposure, the photoresist is developed in a chemical process similar to the development of photographic films. The resist is subsequently hard-baked (20–30 min at 120–180 °C) in order to further improve adhesion. The hard-bake step concludes the photolithography sequence by creating the desired pattern on the wafer. Next, the underlying thin film is etched and the photoresist is stripped using acetone or other organic removal solvents. Figure 3.2 shows a schematic of the photolithography steps with a positive photoresist.

Schematic drawing of the photolithographic steps with a positive PR and pattern transfer. **(a)** Oxidation of silicon substrate. **(b)** Photoresist deposition and soft bake. **(c)** Photoresist exposure through mask. **(d)** Photoresist development and hard bake. **(e)** Silicon oxide etching. **(f)** Photoresist stripping

3.1.2 Thin-Film Deposition and Doping

Thin-film deposition and doping are extensively used in micro/nanofabrication technologies. Most fabricated micro/nanostructures contain materials other than that of the substrate, which are obtained by various deposition techniques or by modification of the substrate. Following is a list of a few typical applications for the deposited and/or doped materials used in micro/nanofabrication, which gives an idea of the required properties:

- Mechanical structure
- Electrical isolation
- Electrical connection
- Sensing or actuating
- Mask for etching and doping
- Support or mold during deposition of other materials (sacrificial materials)
- Passivation.

Most of the deposited thin films have properties different from those of their corresponding *bulk* forms (for example, metals shows higher resistivities in thin-film form). In addition, the techniques utilized to deposit these materials have a great impact on their final properties. For instance, internal stress (compressive or tensile) in a film is strongly process dependent. Ex-

cessive stress may crack or detach the film from the substrate and therefore must be minimized, although it may also be useful for certain applications. Adhesion is another important issue that needs to be taken into account when depositing thin films. In some cases such as the deposition of noble metals (e.g., gold) an intermediate layer (chromium or titanium) may be needed to improve adhesion. Finally, step coverage and conformality are two properties that can also influence the choice of one or another deposition technique. Figure 3.3 illustrates these concepts.

Oxidation

Oxidation of silicon is a process used to obtain a thin film of SiO_2 with excellent quality (very low density of defects) and thickness homogeneity. Although it is not properly a deposition (often referred indistinctively as growth), the result is the same; i. e., a thin layer of a new material covering the surface is produced. The oxidation process is typically carried out at temperatures in the range of 900–1200 °C in the presence of O_2 (dry oxidation) or H_2O (wet oxidation). The reactions for oxide formation are

$$Si_{(solid)} + O_{2\,(gas)} \rightarrow SiO_{2\,(solid)}$$

and

$$Si_{(solid)} + 2H_2O_{(steam)} \rightarrow SiO_{2\,(solid)} + 2H_{2\,(gas)} \,.$$

Although the rate of oxide growth is higher for wet oxidation, this is achieved at the expense of lower oxide quality (density). Since silicon atoms from the substrate participate in the reaction, the substrate is consumed as the oxide grows ($\approx 44\%$ of the total thickness lies above the line of the original silicon surface). The oxidation of silicon also occurs at room temperature, however a layer of about 20 Å (namely, native oxide) is enough to passivate the surface and prevent further oxidation. To grow thicker oxides, wafers are introduced into an electric resistance furnace such as that represented in Fig. 3.4. Tens of wafers can be processed in a single batch in such equipment. By strictly controlling the timing, temperature, and gas flow entering the quartz tube the desired thickness can be achieved with high accuracy. Thicknesses ranging from a few tens of Angstroms to 2 µm can be obtained in reasonable times. Despite the good quality of the SiO_2 obtained by silicon oxidation (also called *thermal oxide*), the use of this process is often limited to the early stages of the fabrication, since some of the materials added during the formation of structures may not withstand the high temperatures. The contamination of the furnace, when the substrates have been previously in contact with certain etchants such as KOH or when materials such as metals have been deposited, also poses limitations in most cases.

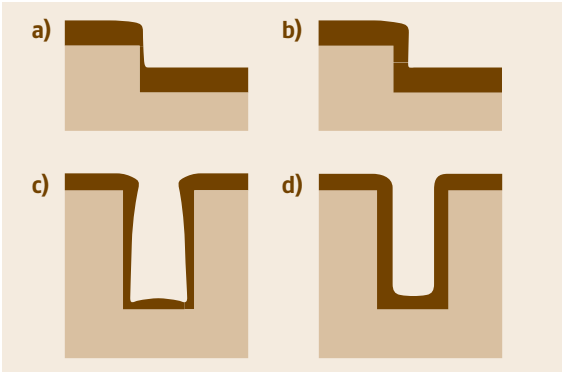

Fig. 3.3a–d Step coverage and conformality: **(a)** poor step coverage, **(b)** good step coverage, **(c)** nonconformal layer, and **(d)** conformal layer

Doping

The introduction of certain impurities in a semiconductor can change its electrical, chemical, and even mechanical properties. Typical impurities or *dopants* used in silicon include boron (to form p-type regions) and phosphorous or arsenic (to form n-type regions). Doping is the key process used in the microelectronic industry to fabricate major components such as diodes and transistors. In micro/nanofabrication technologies doping has additional applications such as the formation of piezoresistors for mechanical transducers or the creation of etch stop-layers. Two different techniques are used to introduce impurities into a semiconductor substrate: diffusion and ion implantation.

Diffusion is the process which became dominant in the initial years following the invention of the integrated circuit to form n- and p-type regions in the silicon. The diffusion of impurities into silicon occurs only at high temperature (above 800 °C). Furnaces used to carry out this process are similar to those used for oxidation. Dopants are introduced in the furnace gaseous atmosphere from liquid or solid sources. Figure 3.5 il-

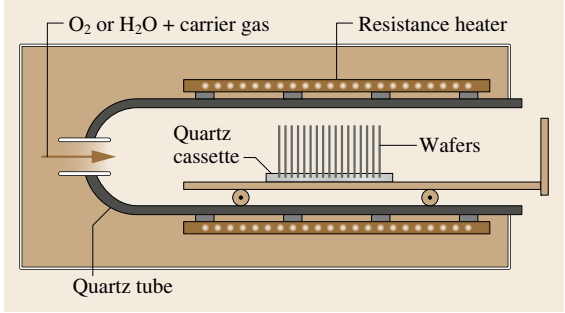

Fig. 3.4 Schematic representation of a typical oxidation furnace

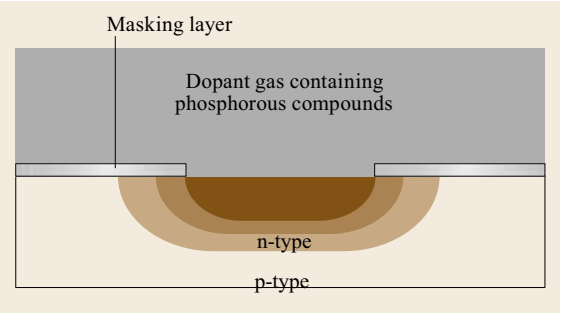

Fig. 3.5 Formation of an n-type region on a p-type silicon substrate by diffusion of phosphorous

lustrates the process of creating an n-type region by diffusion of phosphor from the surface into a p-type substrate. A masking material is previously deposited and patterned on the surface to define the areas to be doped. However, because diffusion is an isotropic process, the doped area will also extend underneath the mask. In microfabrication, diffusion is mainly used for the formation of very highly boron-doped regions (p^{++}), which are usually used as an etch stop in bulk micromachining.

Ion implantation allows more precise control of the dose (the total amount of impurities introduced per area unit) and the impurity profile (the concentration versus depth). In ion implantation the impurities are ionized and accelerated towards the semiconductor surface, at high energies. The penetration of impurities into the material follows a Gaussian distribution. After implantation, an annealing process is needed to activate the impurities and repair the damage in the crystal structure produced by ion collisions. A *drive-in* process to redistribute the impurities, done in a standard furnace such as those used for oxidation or diffusion, may be required as well.

Chemical Vapor Deposition and Epitaxy

As its name suggests, chemical vapor deposition (CVD) includes all deposition techniques using the reaction of chemicals in gas phase to form the deposited thin film. The energy needed for the chemical reaction to occur is usually supplied by maintaining the substrate at elevated temperature. Alternative energy sources such as plasma or optical excitation are also used, with the advantage of requiring a lower temperature at the substrate. The most common CVD processes in microfabrication are low-pressure CVD (LPCVD) and plasma-enhanced (PECVD).

The LPCVD process is typically carried out in electrically heated tubes, similar to oxidation tubes, equipped with pumping capabilities to achieve the low pressures required (0.1–1.0 Torr). Large numbers of wafers can be processed simultaneously where the material is deposited on both sides of the wafers. The process temperature depends on the material to be deposited, but generally is in the range 550–900 °C. As in oxidation, high temperatures and contamination issues can restrict the type of processes used previous to the LPCVD. Typical materials deposited by LPCVD include silicon oxide (e.g., $SiCl_2H_2 + 2N_2O \rightarrow SiO_2 + 2N_2 + 2HCl$ at 900 °C), silicon nitride (e.g., $3SiH_4 + 4NH_3 \rightarrow Si_3N_4 + 12H_2$ at 700–900 °C), and polysilicon (e.g., $SiH_4 \rightarrow Si + 2H_2$ at 600 °C). Due to its faster etch rate in HF, in situ phosphorous-doped LPCVD oxide (phosphosilicate glass, PSG) is extensively used in surface micromachining as the sacrificial layer. Conformality in this process is excellent, even for very high-aspect-ratio structures. Mechanical properties of LPCVD materials are good compared with others such as PECVD, and are often used as structural materials in microfabricated devices. Stress in the deposited layers depends on the material, deposition conditions, and subsequent thermal history (e.g., postdeposition annealing). Typical values are: 100–300 MPa (compressive) for oxide, ≈ 1 GPa (tensile) for stoichiometric nitride, and ≈ 200–300 MPa (tensile) for polysilicon. The stress in nitride layers can be reduced to nearly zero by using a silicon-rich composition. Since the stress values can vary over a wide range, one has to measure and characterize the internal stress of deposited thin films for any specific equipment and deposition conditions.

The PECVD process is performed in plasma systems such as that represented in Fig. 3.6. The use of radiofrequency (RF) energy to create highly reactive species in the plasma allows for the use of lower temperature at the substrate (150–350 °C). Parallel-plate plasma reactors normally used in microfabrication can

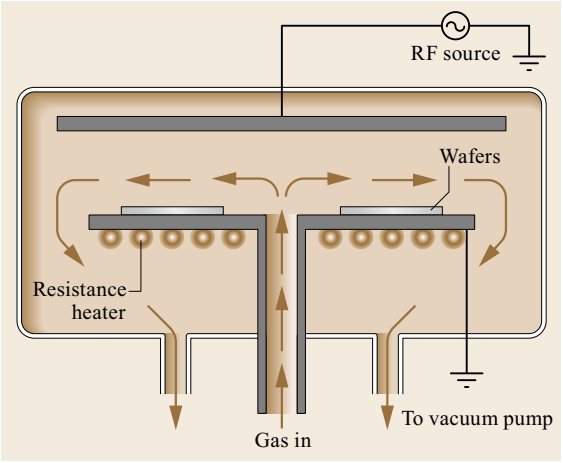

Fig. 3.6 Schematic representation of a typical PECVD system

only process a limited number of wafers per batch. The wafers are positioned horizontally on top of the lower electrode so only one side gets deposited. Typical materials deposited with PECVD include silicon oxide, nitride, and amorphous silicon. Conformality is good for low-aspect-ratio structures, but becomes very poor for deep trenches (20% of the surface thickness inside through-wafer holes with an aspect ratio of 10). Stress depends on deposition parameters and can be either compressive or tensile. PECVD nitrides are typically nonstoichiometric (Si_xN_y) and are much less resistant to etchants in masking applications.

Another interesting type of CVD is epitaxial growth. In this process, a single-crystalline material is grown as an extension of the crystal structure of the substrate. It is possible to grow dissimilar materials if the crystal structures are somehow similar (lattice matched; preferably mismatch below 8%). Silicon-on-sapphire (SoS) substrates and some heterostructures are fabricated in this way. However, most common in microfabrication is the growth of silicon on another silicon substrate. Of particular interest for the formation of microstructures is selective epitaxial growth. In this process the silicon crystal is allowed to grow only in windows patterned on a masking material. Many CVD techniques have been used to produce epitaxial growth. The most common for silicon is thermal chemical vapor deposition or vapor-phase epitaxy (VPE). Metalorganic chemical vapor deposition (MOCVD) and molecular-beam epitaxy (MBE) are the most common for growing high-quality III–V compound layers with nearly atomic abrupt interfaces. The former uses vapors of organic compounds with group III atoms such as trimethylgallium ($Ga(CH_3)_3$) and group V hydrides such as AsH_3 in a CVD chamber with fast gas switching capabilities. The latter typically uses molecular beams from thermally evaporated elemental sources aiming at the substrate in an ultrahigh-vacuum chamber. In this case, rapid on/off control of the beams is achieved by using shutters in front of the sources. Finally, it should be mentioned that many metals (molybdenum, tantalum, titanium, and tungsten) can also be deposited using LPCVD. These are attractive for their low resistivities and their ability to form silicides with silicon. Due to its application in new interconnect technologies, copper CVD is an active area of research.

Physical Vapor Deposition (Evaporation and Sputtering)

In physical deposition systems the material to be deposited is transported from a source to the wafers, both being in the same chamber. Two physical principles are used to do this: evaporation and sputtering.

In evaporation, the source is placed in a small container with tapered walls, called the crucible, and is heated up to a temperature where evaporation occurs. Various techniques are utilized to reach the high temperatures needed, including the induction of high currents with coils wound around the crucible and the bombardment of the material surface with an electron beam (e-beam evaporators). This process is mainly used to deposit metals, although dielectrics can also be evaporated. In a typical system the crucible is located at the bottom of a vacuum chamber whereas the wafers are placed lining the dome-shaped ceiling of the chamber (Fig. 3.7). The main characteristic of this process is very poor step coverage, including shadow effects as illustrated in Fig. 3.8. As will be explained in subsequent sections, some microfabrication techniques utilize these effects to pattern the deposited layer. One way to improve the step coverage is by rotating and/or heating the wafers during deposition.

In sputtering, a target of the material to be deposited is bombarded with high-energy inert ions (usually argon). The outcome of the bombardment is that

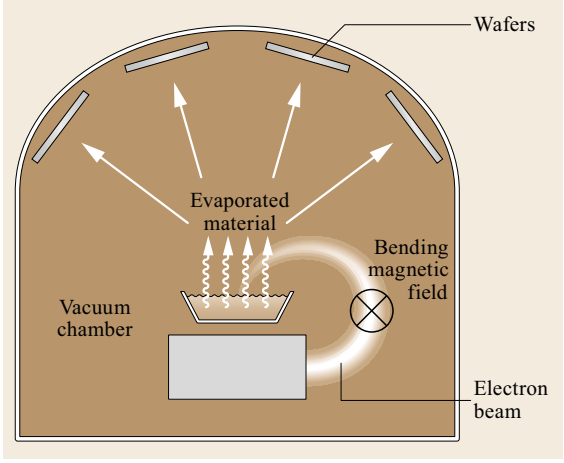

Fig. 3.7 Schematic representation of an e-beam deposition system

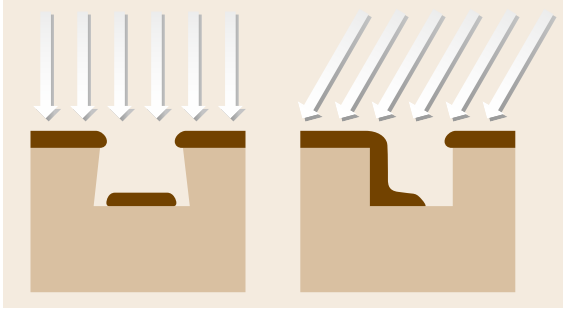

Fig. 3.8 Shadow effects observed in evaporated films. *Arrows* show the trajectory of the material atoms being deposited

individual atoms or clusters are removed from the surface and ejected towards the wafer. The physical nature and simplicity of this process allows its use with virtually any existing material. Examples of interesting materials for microfabrication that are frequently sputtered include metals, dielectrics, alloys (such as shape memory alloys), and all kinds of compounds (for example, piezoelectric lead zirconate titanate (PZT)). The inert ions bombarding the target are produced in direct-current (DC) or RF plasma. In a simple parallel-plate system the top electrode is the target and the wafers are placed horizontally on top of the bottom electrode. In spite of its lower deposition rate, step coverage in sputtering is much better than in evaporation. However, the films obtained with this deposition process are nonconformal. Figure 3.9 illustrates successive sputtering profiles in a trench.

Both evaporation and sputtering systems are often able to deposit more than one material simultaneously or sequentially. This capability is very useful to obtain alloys and multilayer films (e.g., multilayer magnetic recording heads are sputtered). For certain low-reactivity metals such as Au and Pt the previous deposition of a thin layer of another metal is needed to improve adhesion. Ti and Cr are two frequently used adhesion promoters. Stress in evaporated or sputtered layers is typically tensile. The deposition rates are much higher than for most CVD techniques. However, due to stress accumulation and cracking, thickness beyond 2 μm is rarely deposited with these processes. For thicker deposition a technique described in the next section is sometimes used.

Electroplating

Electroplating (or electrodeposition) is a process typically used to obtain thick (tens of μm) metal structures. The sample to be electroplated is introduced into a solution containing a reducible form of the ion of the desired metal and is maintained at a negative potential (cathode) relative to a counterelectrode (anode). The ions are reduced at the sample surface and the insoluble metal atoms are incorporated into the surface. As an example, copper electrodeposition is frequently done in copper sulfide-based solutions. The reaction taking place at the surface is $Cu^{2+} + 2e^- \rightarrow Cu_{(s)}$. Recommended current densities for electrodeposition processes are on the order of $5-100\,mA/cm^2$.

As can be deduced from the process mechanism, the surface to be electroplated has to be electrically conductive, and preferably of the same material as the deposited one if good adhesion is desired. In order to electrodeposit metals on top of an insulator (the most frequent case) a thin film of the same metal, called the seed layer, is previously deposited on the surface. Masking of the seed layer with a resist permits selective electroplating of the patterned areas. Figure 3.10 illustrates a typical sequence of the steps required to obtain isolated metal structures.

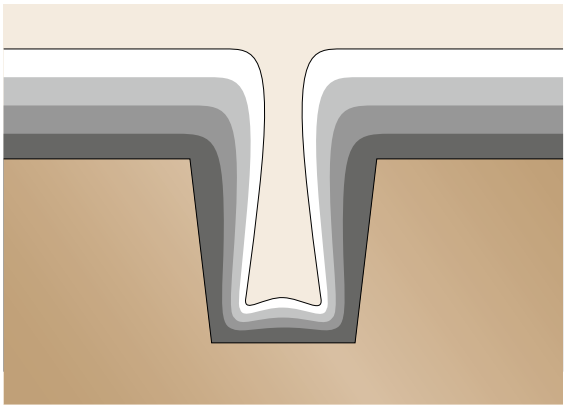

Fig. 3.9 Typical cross section evolution of a trench while being filled with sputter deposition

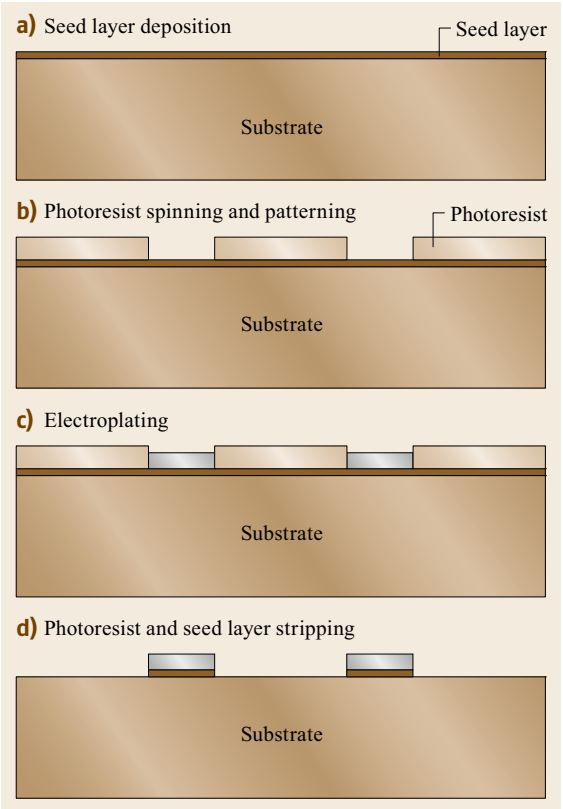

Fig. 3.10a–d Formation of isolated metal structures by electroplating through a mask: **(a)** seed layer deposition, **(b)** photoresist spinning and patterning, **(c)** electroplating, and **(d)** photoresist and seed layer stripping

Pulsed Laser Deposition and Atomic Layer Deposition

Pulsed laser and atomic layer deposition techniques have attracted a considerable amount of attention recently. These two techniques offer several unique advantages compared with other thin-film deposition methods that are particularly useful for next-generation nanoscale device fabrication. Pulsed laser deposition (PLD) is a simple technique that uses an intense (1 GW within 25 ns) UV laser (e.g., a KrF excimer) to ablate a target material [3.6]. Plasma is subsequently formed from the target and is deposited on the substrate. Multitarget systems with Auger and reflection high-energy electron diffraction (RHEED) spectroscopes are commercially available. Figure 3.11 shows a typical PLD deposition setup. The main advantages of the PLD are its simplicity and ability to deposit complex materials with preserved stoichiometry (so-called stoichiometry transfer). In addition, fine control over film thickness is also possible by controlling the number of pulses. The stoichiometry-transfer property of the PLD allows many complex targets such as ferroelectrics, superconductors, and magnetostrictives to be deposited. Other deposited materials include oxides, carbides, polymers, and metallic systems (e.g., FeNdB).

Atomic layer deposition (ALD) is a gas-phase self-limiting deposition method capable of depositing atomic layer thin films with excellent large-area uniformity and conformality [3.7]. It enables simple and accurate control over film composition and thickness at the atomic layer level (typical growth rates of a few Å/cycle). Although most of the attention recently has been directed towards depositing high-k dielectric materials (Al_2O_3, and HfO_2) for next-generation complementary metal–oxide–semiconductor (CMOS) electronics, other materials can also be deposited. These include transition metals (Cu, Co, Fe, and Ni), metal oxides, sulfides, nitrides, and fluorides. Atomic-level control over film thickness and composition are also attractive features for applications in MEMS such as conformal three-dimensional (3-D) packaging and air-gap structures. ALD is a modification of the CVD process and is based on two or more vapor-phase reactants that are introduced into the deposition chamber in a sequential manner. One growth cycle consists of four steps. First, a precursor vapor is introduced into the chamber, resulting in the deposition of a self-limiting monolayer on the surface of the substrate. Then, the extra unreacted vapor is pumped out and a vapor dose of a second reactant is introduced. This reacts with the precursor on the surface in a self-limiting fashion. Finally, the extra unreacted vapor is pumped out and the cycle is repeated.

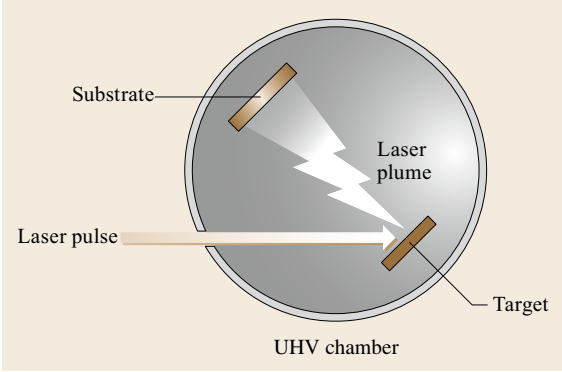

Fig. 3.11 A typical PLD deposition setup

3.1.3 Etching and Substrate Removal

Thin-film and bulk substrate etching is another fabrication step that is of fundamental importance to both VLSI processes and micro/nanofabrication. In the VLSI area, various conducting and dielectric thin films deposited for passivation or masking purposes need to be removed at some point or another. In micro/nanofabrication, in addition to thin-film etching, very often the substrate (silicon, glass, GaAs, etc.) also needs to be removed in order to create various mechanical micro/nanostructures (beams, plates, etc.). Two important figures of merit for any etching process are selectivity and directionality. Selectivity is the degree to which the etchant can differentiate between the masking layer and the layer to be etched. Directionality has to do with the etch profile under the mask. In an isotropic etch, the etchant attacks the material in all directions at the same rate, hence creating a semicircular profile under the mask (Fig. 3.12a). In contrast, in an anisotropic etch,

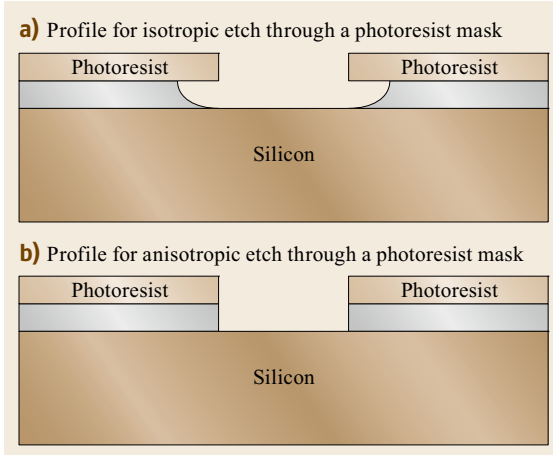

Fig. 3.12a,b Profile for (a) isotropic and (b) anisotropic etching through a photoresist mask

the dissolution rate depends on specific directions and one can obtain straight side-walls or other noncircular profiles (Fig. 3.12b). One can also divide the various etching techniques into wet and dry categories. In this chapter, we will use this classification and discuss different wet etchants first followed by dry etching techniques used most often in the micro/nanofabrication.

Wet Etching

Historically, wet etching techniques preceded the dry ones. These still constitute an important group of etchants for micro/nanofabrication in spite of their less frequent application in the VLSI processes. Wet etchants are by and large isotropic and show superior selectivity to the masking layer as compared with various dry techniques. In addition, due to the lateral undercut, the minimum feature size achievable with wet etchants is limited to $> 3\,\mu m$. Silicon dioxide is commonly etched in dilute (6 : 1, 10 : 1, or 20 : 1 by volume) or buffered HF (BHF: $HF + NH_4F$) solutions (etch rate of $\approx 1000\,Å/min$ in BHF). Photoresist and silicon nitride are the two most common masking materials for the wet oxide etch. The wet etchant for silicon nitride is hot (140–200 °C) phosphoric acid with silicon oxide as the masking material. Nitride wet etch is not very common (except for blanket etch) due to the masking difficulty and nonrepeatable etch rates. Metals can be etched using various combinations of acid and base solutions. There are also many commercially available etchant formulations for aluminum, chromium, and gold which can easily be used. A comprehensive table of various metal etchants can be found in [3.8].

Anisotropic and isotropic wet etching of crystalline (silicon and gallium arsenide) and noncrystalline (glass) substrates is an important topic in micro/nanofabrication [3.9–12]. In particular, the realization of the possibility of anisotropic wet etching of silicon is considered to mark the beginning of the micromachining and MEMS discipline. Isotropic etching of silicon using $HF/HNO_3/CH_3COOH$ (various different formulations have been used) dates back to the 1950s and is still frequently used to thin down the silicon wafer. The etch mechanism for this combination has been elucidated and is as follows: HNO_3 is used to oxidize the silicon, which is subsequently dissolved away in the HF. The acetic acid is used to prevent the dissociation of HNO_3 (the etch works as well without the acetic acid). For short etch times, silicon dioxide can be used as the masking material; however, one needs to use silicon nitride if a longer etch time is desired. This etch also shows dopant selectivity, with the etch rate dropping at lower doping concentrations ($< 10^{17}\,cm^{-3}$ n- or p-type). Although this effect can potentially be used as an etch-stop mechanism in order to fabricate microstructures, the difficulty in masking has prevented widespread application of this approach. Glass can also be isotropically etched using the HF/HNO_3 combination with the etch surfaces showing considerable roughness. This has been extensively used in fabricating microfluidic components (mainly channels). Although Cr/Au is usually used as the masking layer, long etch times require a more robust mask (bonded silicon has been used for this purpose).

Silicon anisotropic wet etch constitutes an important technique in bulk micromachining. The three most important silicon etchants in this category are potassium hydroxide (KOH), ethylenediamine pyrocatechol (EDP), and tetramethyl ammonium hydroxide (TMAH). These are all anisotropic etchants which attack silicon along preferred crystallographic directions. In addition, they all show marked reduction of the etch rate in heavily ($> 5 \times 10^{19}\,cm^{-3}$) boron-doped ($p^{++}$) regions. The chemistry behind the action of these etchants is not yet very clear but it seems that silicon atom oxidation at the surface and its reaction with hydroxyl ions (OH^-) is responsible for the formation of a soluble silicon complex ($SiO_2(OH)^{2-}$). The etch rate depends on the concentration and temperature and is usually around $1\,\mu m/min$ at temperatures of 85–115 °C. Common masking materials for anisotropic wet etchants are silicon dioxide and nitride, with the latter being superior for longer etch times. The crystallographic plane which shows the slowest etch rate is the (111) plane. Although the lower atomic concentration along these planes has been speculated to be the reason for this phenomena, the evidence is inconclusive and other factors must be included to account for this remarkable etch-stop property. The anisotropic behavior of these etchants with respect to the (111) planes has been extensively used to create beams, membranes, and other mechanical and structural components. Figure 3.13 shows the typical cross sections of (100) and (110) silicon wafers etched with an anisotropic wet etchant. As can be seen, the (111) slow planes are exposed in both situations, one creating 54.7° sloped side-walls in the (100) wafer and the other creating vertical side-walls in the (110) wafer. Depending on the dimensions of the mask opening, a V-groove or a trapezoidal trench is formed in the (100) wafer. A large enough opening will allow the silicon to be etched all the way through the wafer, thus creating a thin dielectric membrane on the other side. It should be mentioned that exposed convex corners have a higher etch rate than concave ones, resulting in an undercut which can be used to create dielectric (e.g., nitride) cantilever beams. Figure 3.14 shows a cantilever beam fabricated using the convex corner undercut on a (100) wafer.

The three above-mentioned etchants show different directional and dopant selectivities. KOH has the best (111) selectivity (400/1), followed by TMAH and EDP. However, EDP has the highest selectivity with respect to deep boron diffusion regions. Safety and CMOS compatibility are other important criteria for choosing a particular anisotropic etchant. Among the three mentioned etchants TMAH is the most benign, whereas EDP is extremely corrosive and carcinogenic. Silicon can be dissolved in TMAH in order to improve its selectivity with respect to aluminum. This property has made TMAH very appealing for post-CMOS micromachining where aluminum lines have to be protected. Finally, it should be mentioned that one can modulate the etch rate using a reversed-biased p–n junction (electrochemical etch stop). Figure 3.15 shows the setup commonly used to perform electrochemical etching. The silicon wafer under etch consists of an n-epi region on a p-type substrate. Upon the application of a reverse-bias voltage to the structure (p-substrate is in contact with the solution and n-epi is protected using a watertight fixture), the p-substrate is etched away. When the n-epi regions are exposed to the solution an oxide passivation layer is formed and etching is stopped. This technique can be used to fabricate single-crystalline silicon membranes for pressure sensors and other mechanical transducers.

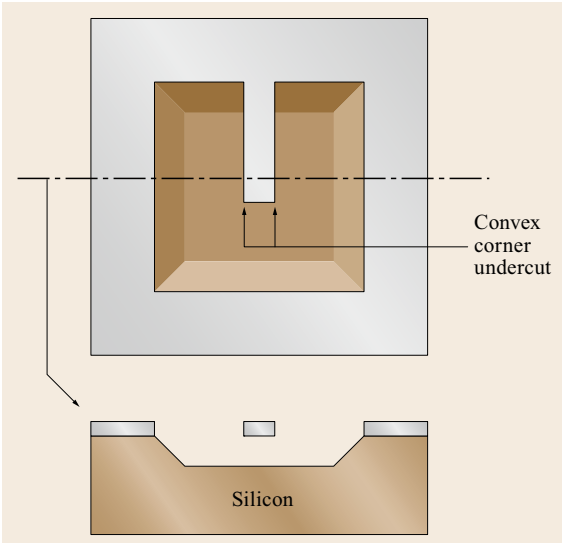

Fig. 3.14 Top view and cross section of a dielectric cantilever beam fabricated using convex corner undercut

Dry Etching

Most of the dry etching techniques are plasma based. They have several advantages when compared with wet etching. These include smaller undercut (allowing smaller lines to be patterned) and higher anisotropy (allowing high-aspect-ratio vertical structures), especially, as compared to some wet etching instances. However, the selectivity of dry etching techniques is lower than that of wet etchants, and one must take into account the finite etch rate of the masking materials. The three basic dry etching techniques, namely high-pressure plasma etching, reactive-ion etching (RIE), and ion milling, utilize different mechanisms to obtain directionality.

Ion milling is a purely physical process which utilizes accelerated inert ions (e.g., Ar^{+}) striking perpendicular to the surface to remove the material ($p \approx 10^{-4}$–10^{-3} Torr) (Fig. 3.16a). The main characteristics of this technique are very low etch rates (in the order of a few nm/min) and poor selectivity (close to 1 : 1 for most materials); hence it is generally used to etch very thin layers. In high-pressure (0.1–5 Torr) plasma etchers highly reactive species are created that react with

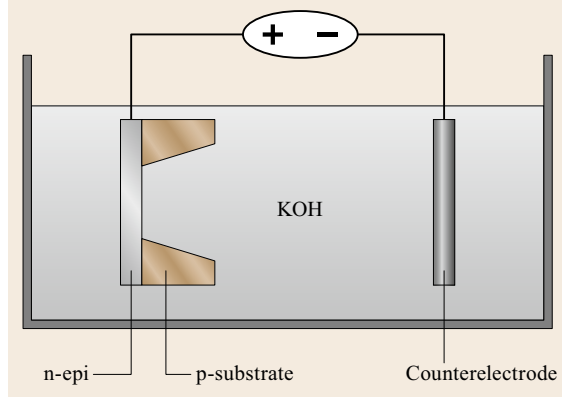

Fig. 3.15 Electrochemical etch setup

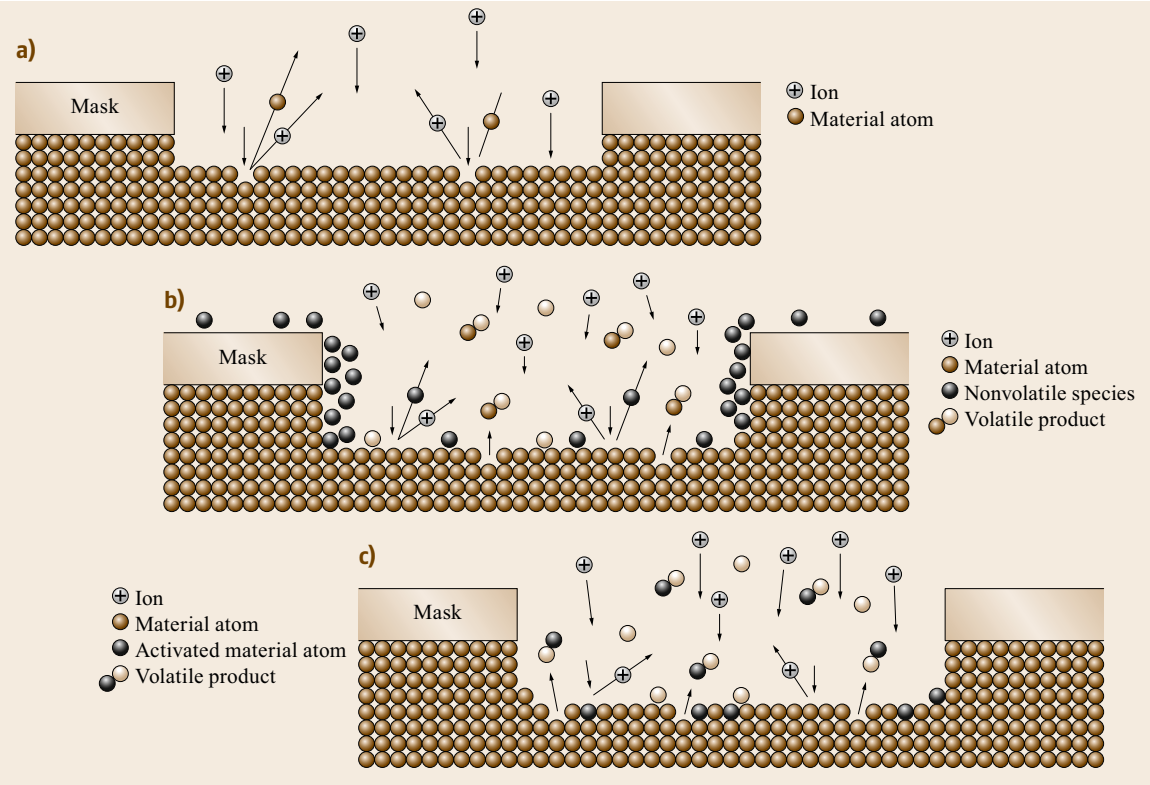

Fig. 3.16a–c Simplified representation of etching mechanisms for: **(a)** ion milling, **(b)** high-pressure plasma etching, and **(c)** RIE

the material to be etched. The products of the reaction are volatile so that they diffuse away and new material is exposed to the reactive species. Directionality can be achieved, if desired, with the side-wall passivation technique (Fig. 3.16b). In this technique nonvolatile species produced in the chamber deposit on and passivate the surfaces. The deposit can only be removed by physical collision with incident ions. Because the movement of the ions has a vertical directionality the deposit is removed mainly on horizontal surfaces, while vertical walls remain passivated. In this fashion, the vertical etch rate becomes much higher than the lateral one.

RIE etching, also called ion-assisted etching, is a combination of physical and chemical processes. In this technique the reactive species react with the material only when the surfaces are *activated* by the collision of incident ions from the plasma (e.g., by breaking bonds at the surface). As in the previous technique, the directionality of the ion's velocity produces much more collisions on the horizontal surfaces than on the walls, thus generating faster etching rates in the vertical direction (Fig. 3.16c). To increase the etch anisotropy further, in some cases side-wall passivation methods are also used. An interesting case is the deep reactive-ion etching (DRIE) technique, capable of achieving aspect ratios of 30 : 1 and silicon etching rates of 2–3 μm/min (through wafer etch is possible). In this technique, the passivation deposition and etching steps are performed sequentially in a two-step cycle, as shown in Fig. 3.17. In commercial silicon DRIE etchers SF_6/Ar is typically used for the etching step and a combination of Ar and a fluoropolymer (nCF_2) for the passivation step. A Teflon-like polymer about 50 nm thick is deposited during the latter step, covering only the side-walls (Ar^+ ion bombardment removes the Teflon on the horizontal surfaces). Due to the cyclic nature of this process, the side-walls of the etched features show a periodic *wave-shaped* roughness in the range of 50–400 nm. More recently, *Aimi* et al., reported on a similar method for deep etching of titanium. In this case titanium oxide was used as a side-wall passivation layer [3.13].

Dry etching can also be performed in nonplasma equipment if the etching gases are reactive enough. The so-called vapor-phase etching (VPE) processes can be carried out in a simple chamber with gas feeding and pumping capabilities. Two examples of VPE are xenon difluoride (XeF_2) etching of silicon and HF vapor

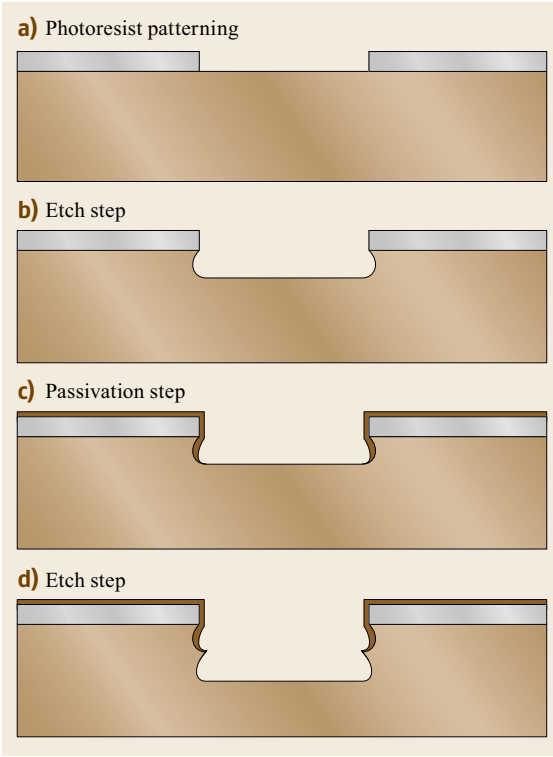

Fig. 3.17a–d DRIE cyclic process: **(a)** photoresist patterning, **(b)** etch step, **(c)** passivation step, and **(d)** etch step

etching of silicon dioxide. Due to its isotropic nature, these processes are typically used for etching sacrificial layers and releasing structures while avoiding stiction problems (Sects. 3.2.1 and 3.2.2).

Most important materials can be etched with the aforementioned techniques, and for each material a variety of chemistries are available. Table 3.1 lists some of the most common materials along with selected etch recipes [3.14]. For each chemistry the etch rate, directionality, and selectivity with respect to the mask materials depend on parameters such as the flow rates of the gases entering the chamber, the working pressure, and the RF power applied to the plasma.

Table 3.1 Typical dry etch chemistries

Si	CF_4/O_2, CF_2Cl_2, CF_3Cl, $SF_6/O_2/Cl_2$, $Cl_2/H_2/C_2F_6/CCl_4$, C_2ClF_5/O_2, Br_2, SiF_4/O_2, NF_3, ClF_3, CCl_4, $C_3Cl_3F_5$, C_2ClF_5/SF_6, C_2F_6/CF_3Cl, CF_3Cl/Br_2

Au	$C_2Cl_2F_4$, Cl_2, $CClF_3$

3.1.4 Substrate Bonding

Substrate (wafer) bonding (silicon–silicon, silicon–glass, and glass–glass) is among the most important fabrication techniques in microsystem technology [3.15, 16]. It is frequently used to fabricate complex 3-D structures both as a functional unit and as a part of the final microsystem package and encapsulation. The two most important bonding techniques are silicon–silicon fusion (or silicon direct bonding) and silicon–glass electrostatic (or anodic) bonding. In addition to these techniques, several other alternative methods which utilize an intermediate layer (eutectic, adhesive, and glass frit) have also been investigated. All these techniques can be used to bond the substrates at the wafer level. In the present Handbook edition, as an explanation of each of the mentioned main bonding techniques (Si direct bonding, anodic bonding and bonding with intermediate layers) cannot be included, we refer to the following relevant literature [3.16–19].

3.2 MEMS Fabrication Techniques

In this section, we will discuss various important MEMS fabrication techniques commonly used to build various microdevices (microsensors and microactuators) [3.9–12]. The dimensional spectrum of the microstructures that can be fabricated using these techniques spans from 1 mm to 1 μm. As mentioned in the introduction, we will mostly emphasize the more important techniques and will not discuss specialized methods. Nonetheless, currently there is a trend in manufacturing from MEMS towards nanoelectromechanical systems (NEMS), as they provide superior performance, e.g., operation at higher frequencies). Downscaling can be addressed by to distinctive approaches, as it will be briefly referred in the next section (Sect. 3.3). Following the methods described for MEMS is an evolutionary technology, where top-down fabrication of the mechanical element down to the nanoscale is achieved with further reduction of the feature

size, i. e., based on advanced lithography/patterning, thin film deposition or etching methods. Alternatively, a revolutionary route (disruptive in some cases) replaces the (monolithic) mechanical element by new entities, such as novel nanomaterials (e.g., graphene) of nanostructured objects (e.g., CVD Si nanowires (NWs)), which can be integrated, typically, by adaptations in the fabrication sequence of the same processing of conventional planar-technology. Detailed explanations on MEMS/NEMS concepts and applications can be found in Part C and D of this Handbook.

3.2.1 Bulk Micromachining

Bulk micromachining is the oldest MEMS technology and hence probably one of the more mature ones [3.20]. It is currently by far the most commercially successful one, helping to manufacture devices such as pressure sensors and inkjet printheads. Although there are many different variations, the basic concept behind bulk micromachining is selective removal of the substrate (silicon, glass, GaAs, etc.). This allows the creation of various micromechanical components such as beams, plates, and membranes which can be used to fabricate a variety of sensors and actuators. The most important microfabrication techniques used in bulk micromachining are wet and dry etching and substrate bonding. Although one can use various criteria to categorize bulk micromachining techniques, we will use a historical timeline for this purpose. Starting with the more traditional wet etching techniques, we will proceed to discuss the more recent ones using deep RIE and wafer bonding.

Bulk Micromachining Using Wet Etch and Wafer Bonding

The use of anisotropic wet etchants to remove silicon can be marked as the beginning of the micromachining era. Back-side etch was used to create movable structures such as beams, membranes, and plates (Fig. 3.18). Initially, etching was timed in order to create a specified thickness. However, this technique proved to be inadequate for the creation of (relatively) thin structures ($< 20\,\mu m$). Subsequent use of various etch-stop techniques allowed the creation of thinner membranes in a more controlled fashion. As was mentioned in *High-Aspect Ratio Micromachining*, heavily boron-doped regions and electrochemical bias can be used to slow down the etch process drastically and hence create controllable thickness microstructures. Figure 3.19a,b shows the cross section of two piezoresistive pressure sensors fabricated using electrochemical and p^{++} etch-stop techniques. The use of the p^{++} method requires epitaxial growth of a lightly doped region on top of a p^{++} etch-stop layer. This layer is subsequently used for the placement of piezoresistors. However, if no active component is required one can simply use the p^{++} region to create a thin membrane (Fig. 3.19c).

The p^{++} etch-stop technique can also be used to create isolated thin silicon structures through the dissolution of the entire lightly doped region [3.21]. This technique was successfully used to fabricate silicon recording and stimulating electrodes for biomedical applications. Figure 3.20 shows the cross section of

such a process which relies on deep (15–20 μm) and shallow boron (2–5 μm) diffusion steps to create microelectrodes with flexible connecting ribbon cables. An extension of this process which uses a combination of p^{++} etch-stop layers and silicon–glass anodic bonding has also been developed. This process is commonly known as the dissolved wafer process and has been used to fabricate a variety of microsensors and microactuators [3.22]. Figure 3.21 shows the cross section of this process. Figure 3.22 shows a scanning electron microscopy (SEM) photograph of a microaccelerometer fabricated using the dissolved wafer process.

Importantly, it is also possible to merge wet bulk micromachining and microelectronics fabrication processes to build micromechanical components on the same substrate as the integrated circuits (CMOS, bipolar, or bipolar complementary metal oxide semiconductor (BiCMOS)) [3.23]. This is very appealing since it allows the integration of interface and signal-processing circuitry with MEMS structures on a single chip. However, important fabrication issues such as process compatibility and yield have to be carefully considered. Among the most popular techniques in this category is postprocessing of CMOS integrated circuits by front-side etching in TMAH solutions. As was mentioned previously, silicon-rich TMAH does not attack aluminum and therefore can be used to undercut

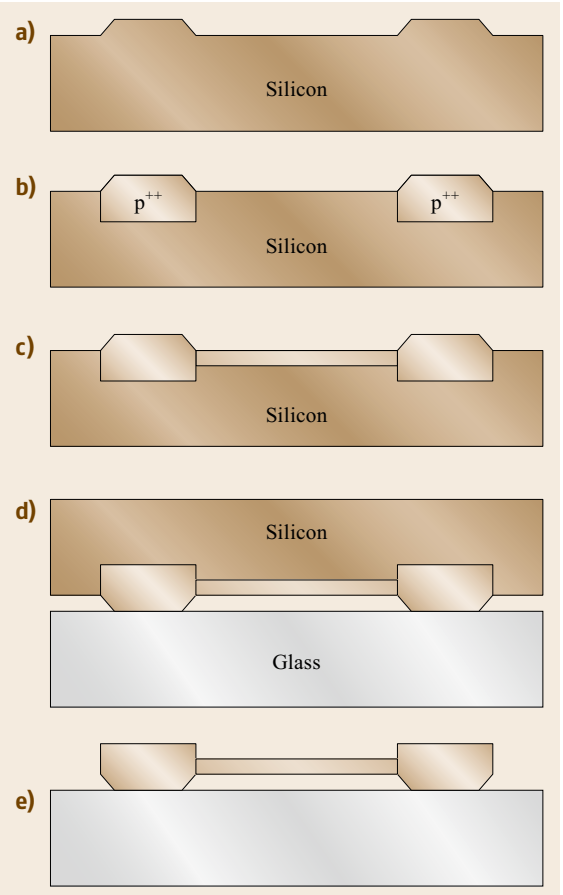

Fig. 3.21a–e Dissolved wafer process sequence: **(a)** KOH etch, **(b)** deep B diffusion, **(c)** shallow B diffusion, **(d)** silicon–glass anodic bond, and **(e)** release in EDP

microstructures in an already processed CMOS chip. Figure 3.23 shows a schematic of such a process in which a front-side wet etch and electrochemical etch stop are used to produce suspended beams. This technique has been extensively used to fabricate a variety of microsensors (e.g., humidity, gas, chemical, and pressure). Figure 3.24 shows a photograph of a post-CMOS-processed chemical sensor.

Bulk Micromachining Using Dry Etch

Bulk silicon micromachining using dry etching is a very attractive alternative to the wet techniques described in the previous section. These techniques were developed during the mid 1990s subsequent to successful efforts geared towards the development of processes for anisotropic dry silicon etch. More recent advances in deep silicon RIE and the availability of SOI wafers with a thick top silicon layer have increased the applicability of these techniques. These techniques allow the fabrica-

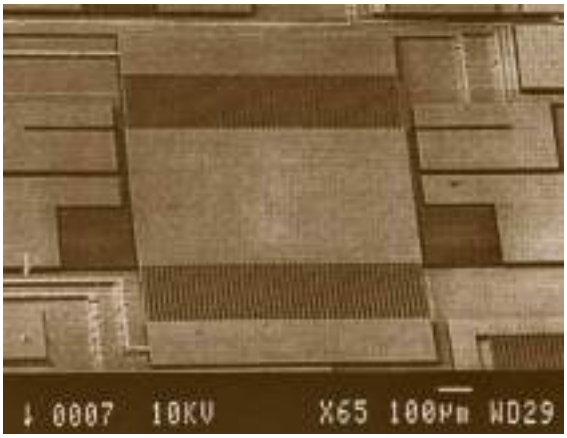

Fig. 3.22 SEM image of a microaccelerometer fabricated using the dissolved wafer process (after [3.22])

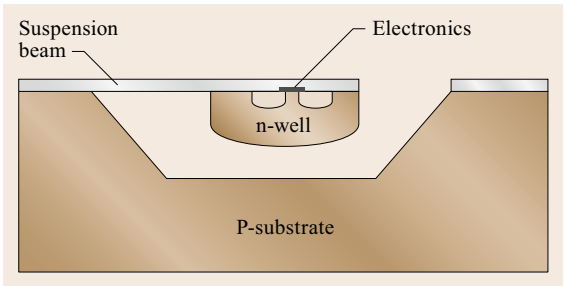

Fig. 3.23 Suspended island created on a prefabricated CMOS chip using front-side wet etch and electrochemical etch stop

tion of high-aspect-ratio vertical structures in isolation or along with on-chip electronics. Process compatibility with active microelectronics is less of a concern in dry methods since many of them do not damage the circuit or its interconnect.

The simplest dry bulk micromachining technique relies on front-side undercut of microstructures using a XeF_2 vapor-phase etch [3.24]. As was mentioned before, this, however, is an isotropic etch and therefore has limited applications. A combination of isotropic/anisotropic dry etch is more useful and can be used to create a variety of interesting structures. Two successful techniques using this combination are single-crystal reactive etching and metallization (SCREAM) [3.25] and post-CMOS dry release using aluminum/silicon dioxide laminate [3.26]. The first technique relies on the combination of isotropic/anisotropic dry etch to create single-crystalline suspended structures. Figure 3.25 shows the cross section of this process. If electrostatic actuation is desired, a metal can be sputtered to cover the top and side-wall of the microstructure and bottom of the cavity formed below it (Fig. 3.25f). Figure 3.26

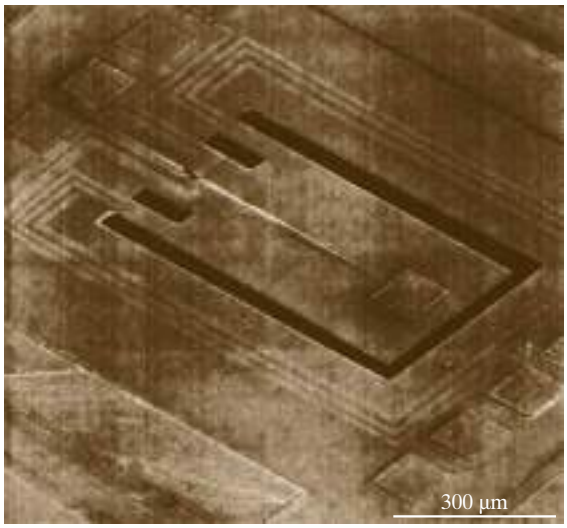

Fig. 3.24 Photograph of a post-CMOS-processed cantilever beam resonator for chemical sensing (after [3.23])

shows an SEM photograph of a comb-drive actuator fabricated using SCREAM technology.

The second dry release technique relies on the masking capability of aluminum interconnect lines in a CMOS integrated circuit to create suspended microstructures. Figure 3.27 shows a cross section of this process. As can be seen the third level Al of a prefabricated CMOS chip is used as a mask to etch the underlying oxide layers anisotropically all the way to the silicon (CHF_3/O_2) (Fig. 3.27b). This is followed by an anisotropic silicon etch to create a recess in the silicon, which will be used in the final step to facilitate the undercut and release (Fig. 3.27c). Finally, an isotropic silicon etch is used to undercut and release the structures (Fig. 3.27d). Figure 3.28 shows an SEM photograph of a comb-drive actuator fabricated using this technology.

In addition to the methods described above, recent advancements in the development of deep reactive-ion etching of silicon (DRIE) have created new opportunities for dry bulk micromachining techniques (Sect. 3.2.3). One of the most important ones uses thick silicon SOI wafers which are commercially available in various top silicon thicknesses [3.27]. Figure 3.29 shows a cross section of a typical process using DRIE and SOI wafers. The top silicon layer is patterned and etched all the way to the buried oxide (Fig. 3.29b). The oxide is subsequently removed in HF, hence releasing suspended single-crystalline microstructures (Fig. 3.29c). In a modification of this process, the substrate can also be removed from the back-side, allowing easy access from both sides (which allows easier release and prevents stiction) (Fig. 3.29d).

3.2.2 Surface Micromachining

Surface micromachining is another important MEMS microfabrication technique which can be used to create movable microstructures on top of a silicon substrate [3.30]. This technique relies on the deposition of structural thin films on a sacrificial layer which is subsequently etched away, resulting in movable micromechanical structures (beams, membranes, plate, etc.). The main advantage of surface micromachining is that extremely small sizes can be obtained. In addition, it is relatively easy to integrate the micromachined structures with on-chip electronics for increased functionality. However, due to the increased surface nonplanarity with any additional layer, there is a limit to the number of layers that can be deposited. Although one of the earliest reported MEMS structures was a surface-micromachined resonant gate transistor [3.31], material-related difficulties resulted in the termination of efforts in this area. In the mid 1980s, improvements in the field of thin-film deposition rekindled

interest in surface micromachining [3.32]. Later in the same decade polysilicon surface micromachining was introduced which opened the door to the fabrication of a variety of microsensors (accelerometers, gyroscopes, etc.) and microactuators (micromirrors, RF switches, etc.). In this section, we will concentrate on the key process steps involved in surface-micromachining fabrication and the various materials used. In addition, monolithic integration of CMOS with MEMS structures and 3-D surface micromachining are also discussed. For NEMS on CMOS integration, a review on cantilever beams fabrication can be found in [3.33].

Basic Surface-Micromachining Processes

The basic surface-micromachining process is illustrated in Fig. 3.30. The process begins with a silicon substrate, on top of which a sacrificial layer is grown and patterned (Fig. 3.30a). Subsequently, the structural material is deposited and patterned (Fig. 3.30b). As can be seen the structural material is anchored to the substrate through the openings created in the sacrificial layer during the previous step. Finally, the sacrificial layer is removed, resulting in the release of the microstructures (Fig. 3.31c). In wide structures, it is usually necessary to provide access holes in the structural layer for fast sacrificial layer removal. It is also possible to seal microcavities created by the surface-micromachining technique [3.11]. This can be done at the wafer level and is a big advantage in applications such as pressure sensors which require a sealed cavity. Figure 3.31 shows two different techniques that can be used for this purpose. In the first technique, following the etching of the sacrificial layer, a LPCVD dielectric layer (oxide or nitride) is deposited to cover and seal the etch holes in the structural material (Fig. 3.32a). Since the LPCVD deposition is performed at reduced pressures, a subatmospheric pillbox microcavity can be created. In the second technique, also called reactive sealing, the polysilicon structural material is oxidized following the sacrificial layer removal (Fig. 3.32b). If access holes are small enough the grown oxide can seal the cavity. Due to the consumption of oxygen during the growth process, in this case also the cavity is subatmospheric.

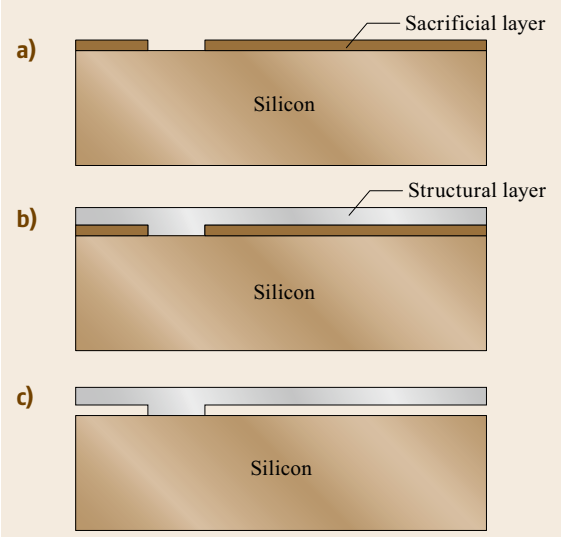

Fig. 3.30a–c Basic surface-micromachining fabrication process **(a)** silicon wafer with patterned sacrificial layer, **(b)** deposition and patterning of the structural layer, and **(c)** removal of the sacrificial layer

The most common sacrificial and structural materials are phosphosilicate glass (PSG) and polysilicon, respectively (low-temperature oxide, LTO, is also frequently used as the sacrificial layer). However, there are several other sacrificial/structural combinations that have been used to create a variety of surface-micromachined structures. Important design issues related to the choice of the sacrificial layer are:

1. Quality (pinholes, etc.)
2. Ease of deposition
3. Deposition rate
4. Deposition temperature
5. Etch difficulty and selectivity (sacrificial layer etchant should not attack the structural layer).

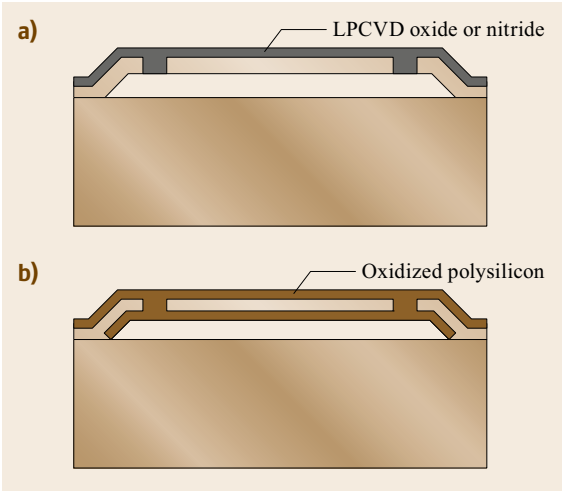

Fig. 3.31a,b Two sealing techniques for cavities created by surface micromachining

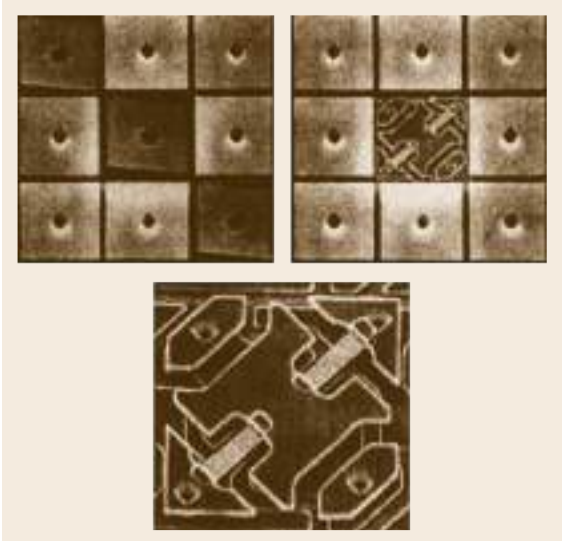

Fig. 3.32 SEM images of the Texas Instrument micromirror array (after [3.30])

The particular choice of material for the structural layer depends on the desired properties and specific application. Several important requirements are:

1. Ease of deposition
2. Deposition rate
3. Step coverage
4. Mechanical properties (internal stress, stress gradient, Young's moduli, fracture strength, and internal damping)
5. Etch selectivity
6. Thermal budget and history
7. Electrical conductivity
8. Optical reflectivity.

Two examples of commercially available surface-micromachined devices illustrate various successful sacrificial/structural combinations. The Texas Instruments (TI) deformable mirror display (DMD) spatial light modulator uses aluminum as the structural material (good optical reflectivity) and photoresist as the sacrificial layer (easy dry etch and low processing temperatures, allowing easy post-IC integration with CMOS) [3.34] (Fig. 3.32), whereas the Analog Devices microgyroscope uses polysilicon structural material and a PSG sacrificial layer (Fig. 3.33). Two additions to the collection of available structural layers

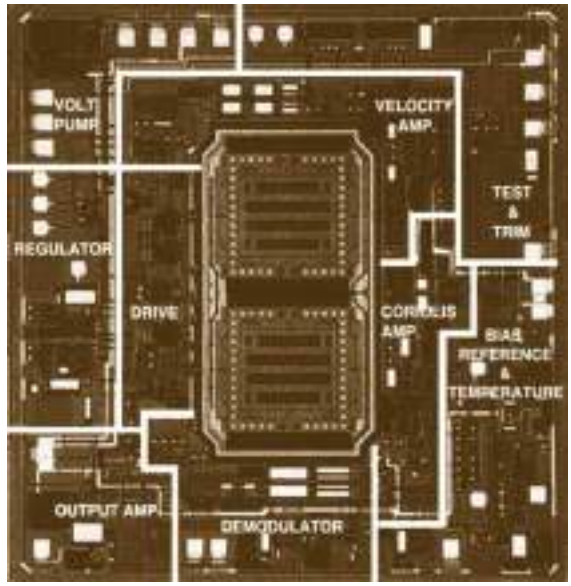

Fig. 3.33 SEM image of the Analog Devices gyroscope (after [3.35])

are polysilicon–germanium and polygermanium [3.36, 37]. These are intended as substitutes for polysilicon in applications where the high polysilicon deposition temperature (around 600 °C) is prohibitive (e.g., CMOS integration). Unlike in LPCVD of polysilicon, polygermanium (poly-Ge) and polysilicon–germanium (poly-$Si_{1-x}Ge_x$) can be deposited at temperatures as low as 350 °C (poly-Ge deposition temperature is usually lower than that for poly-SiGe). Table 3.2 summarizes important surface-micromachined sacrificial/structural combinations.

An important consideration in the design and processing of surface-micromachined structures is the issue of stiction [3.11, 38, 39], as the size of the mechanical element is reduced (NEMS) the risk is more accute. Stiction can happen during the release step if a wet etchant is used to remove the sacrificial layer or during the device lifetime. The reason for stiction during release is the surface tension of the liquid etchant, which can hold the microstructure down and cause stiction. This usually happens when the structure is compliant and does not possess enough spring constant to overcome the surface tension force of the rinsing liquid (i. e., water). There are several ways one can alleviate the release-related stiction problem. These include:

1. The use of dry or vapor phase etchant
2. The use of solvents with lower surface tension
3. Geometrical modifications
4. CO_2 critical drying
5. Freeze-drying
6. Self-assembled monolayer (SAM) or organic thin-film surface modification.

The first technique prevents stiction by not using a wet etchant, although in the case of vapor-phase release, condensation is still possible and can cause some stiction. The second method uses rinsing solvents such as methanol with a lower surface tension than water. This is usually followed by rapid evaporation of the solvent on a hot-plate. However, this technique is not optimum and many structures still stick. The third technique is geometrical, providing dimples in the structural layer in order to reduce the contact surface area and hence reduce the attractive force. The fourth and fifth techniques rely on phase change (in one case CO_2 and the other butyl alcohol) which avoids the liquid phase altogether by directly going to the gas phase. The last technique uses SAMs or organic thin films to coat the surfaces with a hydrophobic layer. The stiction that occurs during the operating lifetime of the device (in-use stiction) is due to condensation of moisture on the surfaces, electrostatic charge accumulation, or direct chemical bonding. Surface passivation using SAMs or organic thin films can be used to reduce the surface energy and reduce or eliminate capillary forces and direct chemical bonding. These organic coatings also reduce electrostatic forces if a thin layer is applied directly to the semiconductor (without an intervening oxide layer). Commonly used organic coatings include fluorinated fatty acids (TI aluminum micromirrors), silicone polymeric layers (Analog devices accelerometers), and siloxane SAMs.

Surface-Micromachining Integration with Active Electronics

Integration of surface-micromachined structures with on-chip circuitry can increase performance and simplify packaging. However, issues related to process compatibility and yield have to be carefully considered. The two most common techniques are MEMS-first and MEMS-last techniques. In the MEMS-last technique, the integrated circuit is first fabricated and surface-micromachined structures are subsequently built on top of the silicon wafer. An aluminum structural layer with a sacrificial photoresist layer is an attractive combination due to the low thermal budget of the process (TI micromirror array). However, in applications where mechanical properties of Al are not adequate, polysilicon structural material with an LTO or PSG sacrificial layer must be used. Due to the rather high deposition temperature of polysilicon, this combination requires special attention with regard to the thermal budget. For example, aluminum metallization must be avoided and substituted with refractory metals such as tungsten. This can only be achieved at the cost of greater process complexity and lower transistor performance.

The MEMS-first technique alleviates these difficulties by fabricating the microstructures at the very beginning of the process. However, if the microstructures are processed first, they have to be buried in a sealed trench to eliminate the interference of microstructures

Table 3.2 Several important surface-micromachined sacrificial–structural combinations

System	Sacrificial layer	Structural layer	Structural layer etchant	Sacrificial layer etchant
1	PSG or LTO	Poly-Si	RIE	Wet or vapor HF
2	Photoresist, polyimide	Metals (Al, Ni, Co, Ni-Fe)	Various metal etchants	Organic solvents, plasma O_2
3	Poly-Si	Nitride	RIE	KOH
4	PSG or LTO	Poly-Ge	H_2O_2 or RCA1	Wet or vapor HF
5	PSG or LTO	Poly-Si-Ge	H_2O_2 or RCA1	Wet or vapor HF

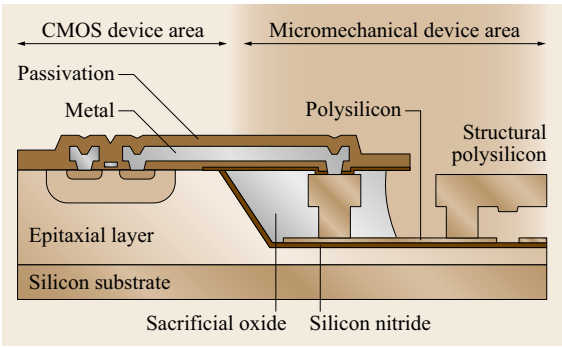

Fig. 3.34 Cross section of the Sandia MEMS-first integrated fabrication process

with subsequent CMOS processes. Figure 3.34 shows a cross section of a MEMS-first fabrication process developed at the Sandia National Laboratory [3.40]. The process starts with shallow anisotropic etching of trenches in a silicon substrate to accommodate the height of the polysilicon structures fabricated later on. A silicon nitride layer is then deposited to provide isolation at the bottom of the trenches. Next, several layers of polysilicon and sacrificial oxide are deposited and patterned in a standard surface-micromachining process. Subsequently, the trenches are completely filled with sacrificial oxide and the wafers are planarized with chemical-mechanical polishing (this avoids complication in the following lithographic steps). After an annealing step, the trenches are sealed with a nitride cap. At this point, a standard CMOS fabrication process is performed. At the end of the CMOS process the nitride cap is etched and the buried structures released by etching the sacrificial oxide.

Three-Dimensional Microstructures Using Surface Micromachining

Three-dimensional (3-D) surface microstructures can be fabricated using surface micromachining. The fabrication of hinges for the vertical assembly of MEMS was a major advance towards achieving 3-D microstructures [3.41]. Optical microsystems have greatly benefited from surface-micromachined 3-D structures. These microstructures are used as passive or active components (micromirror, Fresnel lens, optical cavity, etc.) on a silicon optical bench (silicon microphotonics). An example is a Fresnel lens that has been surface micromachined in polysilicon and then erected using hinge structures and locked in place using micromachined tabs, thus liberating the structure from the horizontal plane of the wafer [3.42, 43]. Various microactuators (e.g., comb drive, and vibromotors) have been used to move these structures out of the silicon plane and into position. Figure 3.35 shows an SEM

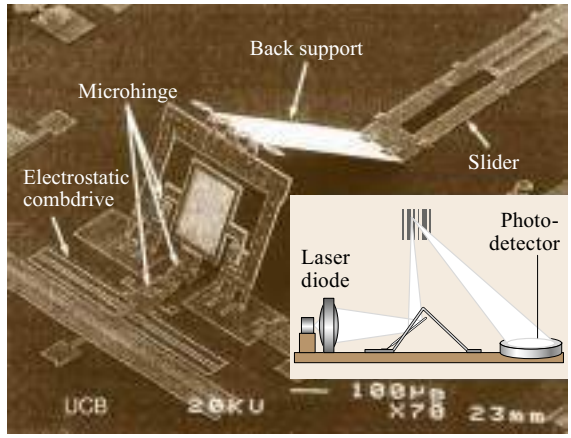

Fig. 3.35 Silicon pin-and-sample hinge scanner with 3-D surface-micromachined structures (after [3.43])

photograph of a bar-code microscanner using a silicon optical microbench with 3-D surface-micromachined structures.

3.2.3 High-Aspect-Ratio Micromachining

The bulk and surface micromachining technologies presented in the previous sections fulfill the requirements of a large group of applications. Certain applications, however, require the fabrication of high-aspect-ratio structures that is not possible with the aforementioned technologies. In this section, we describe three technologies, capable of producing structures with vertical dimensions much larger than their lateral dimensions; these are x-ray lithography (LIGA) and DRIE etching (HEXSIL and HARPSS).

LIGA

LIGA is a high-aspect-ratio micromachining process which relies on x-ray lithography and electroplating (in German: *Lithographie*, *Galvanoformung*, *Abformung*) [3.44, 45]. We already introduced the concept of the plating-through-mask technique in *Surface Micromachining* (Fig. 3.10). With standard UV photolithography and photoresists, the maximum thickness achievable is on the order of a few tens of microns and the resulting metal structures show tapered walls. LIGA is a technology based on the same plating-through-mask idea but can be used to fabricate metal structures of thickness ranging from a few microns to a few millimeters with almost vertical side-walls. This is achieved using x-ray lithography and special photoresists. Due to their short wavelength, x-rays are able to penetrate through a thick photoresist layer with no scattering and define features with lateral dimensions down to 0.2 µm (aspect ratio $> 100:1$).

The photoresists used in LIGA should comply with certain requirements, including sensitivity to x-rays, resistance to electroplating chemicals, and good adhesion to the substrate. Based on such requirements poly-(methyl methacrylate) (PMMA) is considered to be an optimal choice for the LIGA process. Application of the thick photoresist on top of the substrate can be performed by various techniques such as multiple spin-coating, precast PMMA sheets, and plasma polymerization coating. The mask structure and materials for x-ray lithography must also comply with certain requirements. The traditional masks based on glass plates with a patterned chrome thin layer are not suitable because x-rays are not absorbed by the chromium layer and the glass plate is not transparent enough. Instead, x-ray lithography uses a silicon nitride mask with gold as the absorber material (typically formed by electroplating gold to a thickness of 10–20 μm). The nitride membrane is supported by a silicon frame which can be fabricated using bulk micromachining techniques. Once the photoresist is exposed to the x-rays and developed, the process proceeds with electroplating of the desired metal. Ni is the most commonly used, although other metals and metallic compounds such us Cu, Au, NiFe, and NiW are also electroplated in LIGA processes. Good agitation of the plating solution is the key to obtaining a uniform and repeatable result during this step. A paddle plating cell, based on a windshield-wiper-like device moving only a millimeter away from the substrate surface, provides extremely reproducible agitation. Figure 3.36 shows an SEM of a LIGA microstructure fabricated with electroplating nickel.

Fig. 3.36 SEM of assembled LIGA-fabricated nickel structures (after [3.45])

Due to the high cost of the x-ray sources (synchrotron radiation), LIGA technology was initially intended for the fabrication of molds that could be used many times in hot-embossing or injection-molding processes. However, it has been also used in many

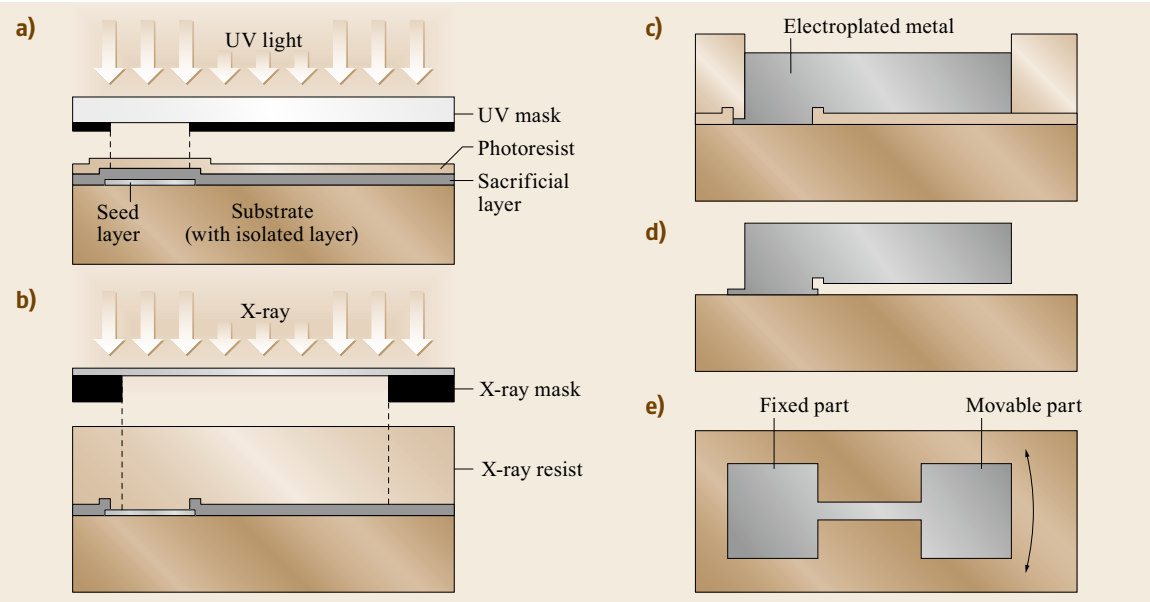

Fig. 3.37a–e Sacrificial LIGA process: **(a)** UV lithography for sacrificial layer patterning, **(b)** x-ray lithography, **(c)** electroplating, **(d)** structure releasing, and **(e)** top view of the movable structure

applications to directly form high-aspect-ratio metal structures on top of a substrate. A cheaper alternative to the LIGA process (with somehow poorer qualities) called UV-LIGA or *poor man's LIGA* has been proposed [3.46, 47]. This process uses SU-8 negative photoresists (available for spin-coating at various thickness ranging from 1 to 500 μm) and standard contact lithography equipment. Using this technique, aspect ratios larger than 20 : 1 have been demonstrated. A major problem of this alternative is the removal of the SU-8 photoresist after plating. Various methods, showing different degrees of success, have been proposed. These include: wet etching with special solvents, burning at high temperatures (600 °C), dry etching, use of a release layer, and high-pressure water-jet etching.

A variation of the basic LIGA process, shown in Fig. 3.37, permits the fabrication of electrically isolated movable structures, and thus opens more possibilities for sensor and actuator design using this technology [3.48]. This so-called sacrificial LIGA (SLIGA) starts with the patterning of the seed layer. Subsequently a sacrificial layer (e.g., titanium) is deposited and patterned. The process then proceeds as in standard LIGA until the last step, when the sacrificial layer is removed. The electroplated structures that overlap with the sacrificial layer are released in this step.

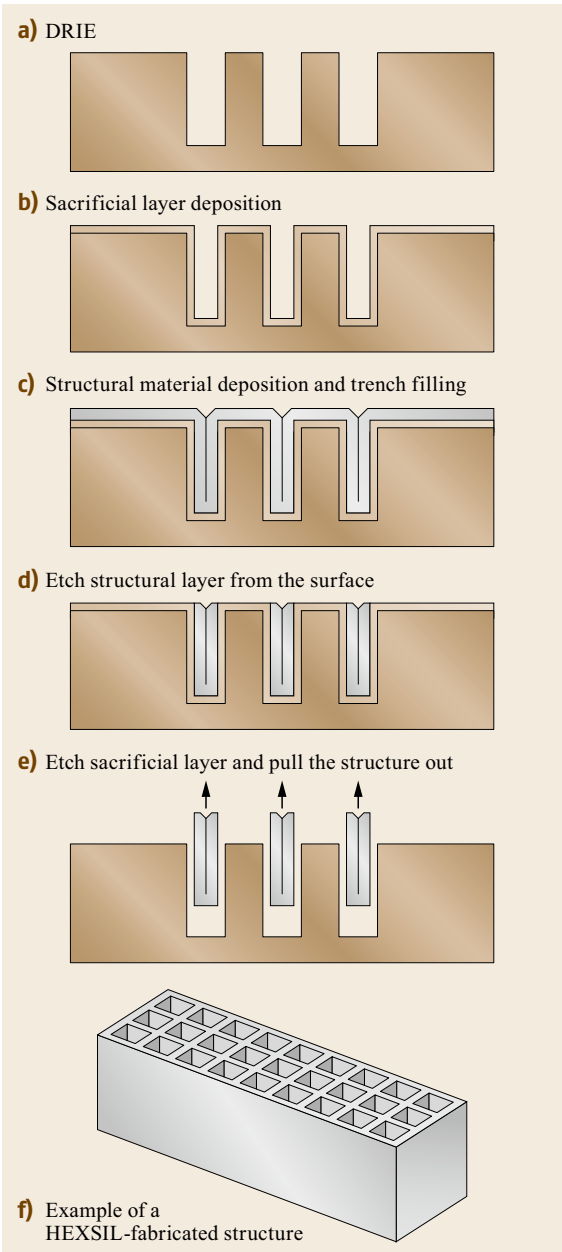

Fig. 3.38a–f HEXSIL process flow: **(a)** DRIE, **(b)** sacrificial layer deposition, **(c)** structural material deposition and trench filling, **(d)** etch structural layer from the surface, **(e)** etch sacrificial layer and pull the structure out, and **(f)** example of a HEXSIL-fabricated structure

HEXSIL

The second method for fabricating high-aspect-ratio structures, which is based on a template replication technology, is hexagonal honeycomb polysilicon (HEXSIL) [3.50]. Figure 3.38 shows a simplified process flow. A high-aspect-ratio template is first formed in a silicon substrate using DRIE. Next, a sacrificial multilayer is deposited to allow the final release of the structures. The multilayer is composed of one or more PSG nonconformal layers to provide fast etch release (≈ 20 μm/min in 49% HF) alternated with conformal

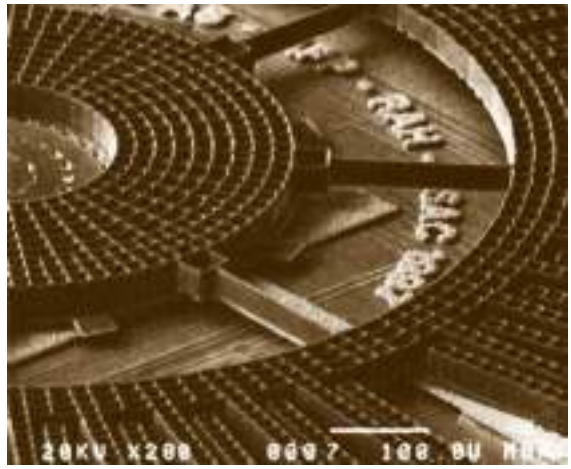

Fig. 3.39 SEM micrograph of an angular microactuator fabricated using the HEXSIL process (after [3.49])

layers of either oxide or nitride to provide enough thickness for proper release of the structures. The total thickness of the sacrificial layer has to be larger than the shrinkage or elongation of the structures caused by the relaxation of the internal (compressive or tensile) stress during the release step. Otherwise the structures will clamp themselves to the walls of the template and their retrieval will not be possible. Any material that can be conformally deposited and yet not damaged during the HF release step is suitable for the structural layer. Structures made of polysilicon, nitride, and electroless nickel [3.51] have been reported. Nickel can only be deposited in combination with polysilicon since a conductive surface is needed for the deposition to occur. After deposition of structural materials a blanket etch (poly-Si or nitride) or a mechanical lapping (nickel) is performed to remove the excess materials from the surface. Finally, a 49% HF with surfactant is used to dissolve the sacrificial layers. The process can be repeated many times using the same template, thus considerably lowering fabrication costs. Figure 3.39 shows an SEM photograph of a microactuator fabricated using the HEXSIL process.

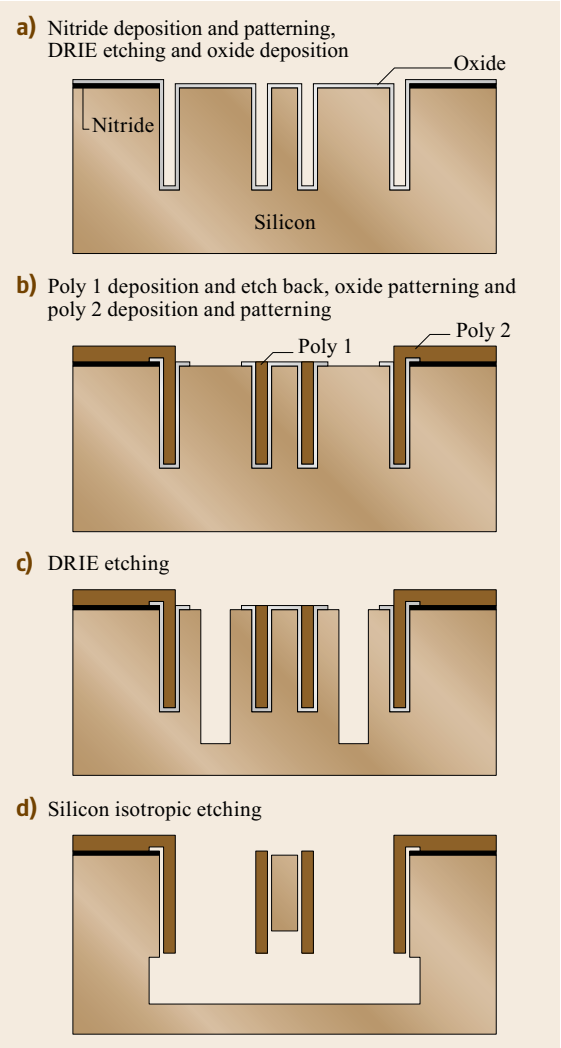

Fig. 3.40a–d HARPSS process flow: **(a)** nitride deposition and patterning, DRIE etching and oxide deposition, **(b)** poly 1 deposition and etch back, oxide patterning, and poly 2 deposition and patterning, **(c)** DRIE etching, and **(d)** silicon isotropic etching

HARPSS

The high-aspect-ratio combined poly- and single-crystal silicon (HARPSS) technology is another technique capable of producing high-aspect-ratio electrically isolated polycrystalline and single-crystal silicon microstructures with capacitive air gaps ranging from submicrometer to tens of micrometers [3.52]. The structures, tens to hundreds of micrometers thick, are defined by trenches etched with DRIE and filled with oxide and poly layers. The release of the microstructures is done at the end by means of a directional silicon etch followed by an isotropic etch. The small vertical gaps and thick structures possible with this technology find application in the fabrication of a variety of MEMS devices, particularly inertial sensors [3.53] and RF beam resonators [3.54]. Figure 3.40 shows the process flow in a cross section of a single-crystal silicon beam resonator. The HARPSS process starts with deposition and patterning of a silicon nitride layer that will be used to isolate the poly structure's connection pads from the substrate. High-aspect-ratio trenches ($\approx 5\,\mu m$ wide) are then etched into the substrate using a DRIE etch. Next, a conformal oxide layer (LPCVD) is deposited. This layer has two functions, to:

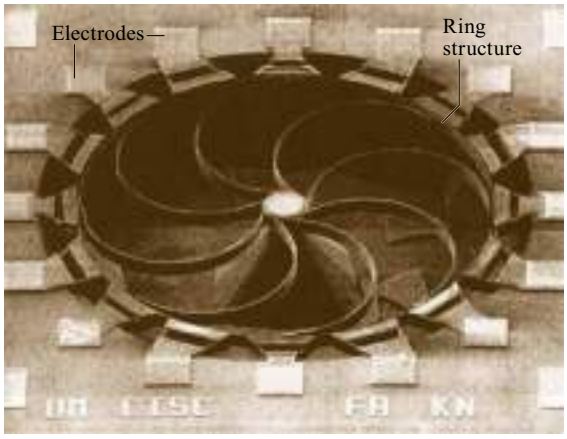

Fig. 3.41 SEM photograph of a microgyroscope fabricated using the HARPSS process (after [3.55])

1. Protect the structures during the dry etch release.
2. Define the submicrometer gap between silicon and polysilicon structures.

Following the oxide deposition, the trenches are completely filled with LPCVD polysilicon. The polysilicon is etched back and the underlying oxide is patterned to provide anchor points for the structures. A second layer of polysilicon is then deposited and patterned. Finally, the structures are released using a DRIE step followed by an isotropic silicon etch through a photoresist mask that exposes only the areas of silicon substrate surrounding the structures. It should be noted that single-crystal silicon structures are not protected at the bottom during the isotropic etch. This causes the single-crystal silicon structures to be etched vertically from the bottom, and thus be shorter than the polysilicon structures. Figure 3.41 shows an SEM photograph of a microgyroscope fabricated using the HARPSS process.

3.3 Nanofabrication Techniques

The microfabrication techniques discussed so far were mostly geared towards fabricating devices in the 1 mm to 1 μm dimensional range (submicrometer dimensions being possible in certain techniques such as HARPSS using a dielectric sacrificial layer). Last decades, a tremendous demand in fabricating submicro- (1 μm–100 nm) and nanostructures (100−1 nm range) [3.56] has led the field. This interest arises from both practical and fundamental viewpoints. At the more scientific and fundamental level, nanostructures provide an interesting tool for studying the electrical, magnetic, optical, thermal, and mechanical properties of matter at the nanometer scale. These include important quantum-mechanical phenomena (e.g., conductance quantization, bandgap modification, coulomb blockade, etc.) arising from confinement of charged carriers in structures such as quantum wells, wires, and dots (Fig. 3.42). On the practical side, nanostructures can provide significant improvements in the performance of electronic/optical devices and sensors. Furthermore some nanomaterials exhibit novel phenomena which would ultimately provide even completely new device concepts. Initially, in the electronic device area investigators have been mostly interested in fabricating nm-sized transistors in anticipation of technical difficulties forecasted in extending Moore's law beyond 32 nm resolution. In addition, optical sources and detectors having nm-size dimensions exhibit improved characteristics not achievable in larger devices (e.g., lower threshold current, improved dynamic behavior, and improved emission line width in quantum dot lasers). These improvements create novel possibilities for next-generation computation and communication devices. In the sensors area, shrinking dimensions beyond conventional optical lithography can provide major improvements in sensitivity and selectivity. Beyond, microfabrication, the so-called More Moore approach relies on higher patterning resolution, either based on charged beams (e.g., energetic electron beams) or advanced masks (such as in directed self assembly (DSA) of block copolymers (BCPs)). Recent trends go beyond these evolutionary approaches. The so-called More than Moore approach includes the idea to become truly disruptive, technologically, and therefore very innovative, for applications. Among other ways, they incorporate novel materials such as carbon nanotubes or nanoscale forms, such as in GaAs or ZnO NWs. Importantly in nanoscale (electronics) fabrication, driven by the pursuit of integration of electronic devices and sensors on flexible susbtrates, as well as system requirements for energy and information autonomy, nanofabrication techniques have been forcedly diversified from the conventional semiconductor processing techniques, such as represented by the rise of ink jet techniques [3.57].

Simply presented, one can broadly divide various nanofabrication techniques into top-down and bottom-

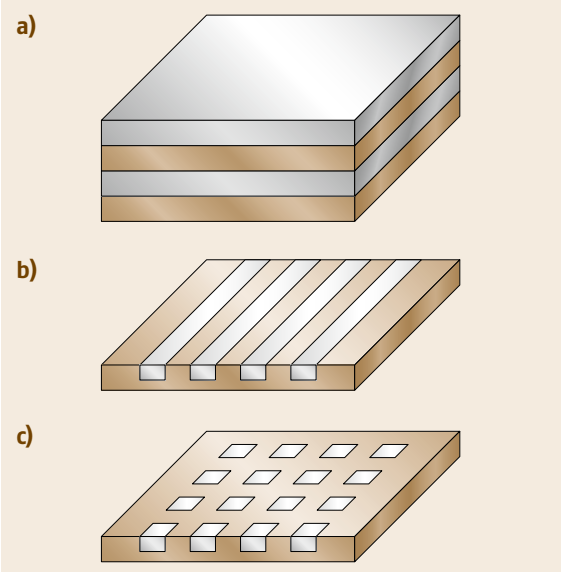

Fig. 3.42a–c Several important quantum confinement structures: **(a)** quantum well, **(b)** quantum wire, and **(c)** quantum dot

up categories. Fabrication sequences often combine both approaches. The first approach starts with a bulk or thin-film material and removes selective regions to fabricate nanostructures; in essence similar to micromachining techniques. The second method relies on integrating nanomaterials, molecular recognition and self-assembly to fabricate nanostructures out of smaller building blocks (molecules, colloids, and clusters). As can be anticipated, the top-down approach is an off-shoot of standard lithography and micromachining techniques (More Moore). On the other hand, the bottom-up approach has a more chemical engineering and material science flavor and relies on fundamentally different principles (towards More than Moore). In this chapter, we will shortly discuss several nanofabrication techniques that are not covered in other chapters of this Handbook. These include:

1. E-beam nanofabrication
2. Epitaxy and strain engineering
3. Scanning-probe techniques
4. Self-assembly and template manufacturing.

3.3.1 E-Beam Nanofabrication

In previous sections, we discussed several important lithography techniques used commonly in MEMS and microfabrication. These included various forms of UV (regular, deep, and extreme) and x-ray lithography. However, due to the lack of resolution (in case of the UV) or difficultly in manufacturing mask and radiation sources (x-ray), these techniques are not suitable for nm-scale fabrication. E-beam lithography (EBL) is an alternative and attractive technique for fabricating nanostructures [3.58]. It uses an electron beam to expose an electron-sensitive resist such as poly(methyl methacrylate) (PMMA) dissolved in trichlorobenzene (positive) or polychloromethylstyrene (negative) [3.59]. Safer commercial formulations are done, e.g., in anisole. The e-beam gun is usually part of a scanning electron microscope (SEM), although transmission electron microscopes (TEM) can also be used. Nowadays, dedicated equipments have been developed which include interferometric stages, allowing automated patterning with ultraprecise alignment and stitching at the wafer scale; i. e., so called mix and match (combination of photolithography and EBL) is possible. Although electron wavelengths of the order of 1 Å can be easily achieved, phenomena such as electron scattering in the resist limits the attainable resolutions to > 10 nm. It is a direct writing technique where beam control and pattern generation is achieved through a computer interface, providing full freedom for features design. Importantly, EBL is serial and hence has low throughput. Although this is not a major concern in fabricating devices used in studying fundamental micro/nanophysics, it severely limits industrial, large-scale nanofabrication. EBL in conjunction with processes such as lift-off, etching, and thin film deposition can be used to fabricate countless nanostructures and nanodevices based on its great pattern flexibility and aligment capability. Undoubtedly, the main application of EBL is as a tool for prototyping, where the possibility to interface nano-sized objects and novel nanomaterials largely contributed to their fundamental study and functionality development. Examples can be found in this Handbook, for instance, in Part A and B.

3.3.2 Epitaxy and Strain Engineering

Atomic-precision deposition techniques such as molecular-beam epitaxy (MBE) and metalorganic chemical vapor deposition (MOCVD) have proven to be effective tools in fabricating a variety of quantum confinement structures and devices (quantum well lasers, photodetector, resonant tunneling diodes, etc.) [3.60–62]. Although quantum wells and superlattices are the structures that lend themselves most easily to these techniques (Fig. 3.42a), quantum wires and dots have also been fabricated by adding subsequent steps such as etching and selective growth. Fabrication of quantum well and superlattice structures using epitaxial growth is a mature and well-developed field and therefore will not be discussed in this chapter. As we have concentrated the description to Si-base substrates, we only provide references on quantum wire and dot nanostructure fabrication using basic epitaxial techniques [3.63, 64]. Examples for InGaAs (on GaAs substrate) are found, e.g., in [3.65], as well as examples based in regrowth of epitaxial layers over nonplanar surfaces in [3.64, 66], strain-induced self-assembly [3.64, 67], where the most commonly used material combination is the $In_xGa_{1-x}As$/GaAs system [3.68, 69].

3.3.3 Scanning Probe Microscope Techniques

The invention of scanning probe microscopy (SPM) in the 1980s revolutionized atomic-scale imaging and spectroscopy. In particular scanning tunneling and atomic force microscopes (STM and AFM) have found widespread applications in physics, chemistry, material science, and biology. The possibility of atomic-scale manipulation, lithography, and nanomachining using such probes was considered from the beginning and has matured considerably over the past decade. In this section after a brief introduction to scanning probe

microscopes, we will discuss in detail several nanolithography and machining techniques which have been used to create nm-sized structures, mainly for their foundational relevance in nanopatterning.

SPM systems are capable of controlling the movement of an atomically sharp tip in close proximity to or in contact with a surface with subnanometer accuracy. Piezoelectric positioners are typically used in order to achieve such accuracy. High-resolution images can be acquired by raster scanning the tips over a surface while simultaneously monitoring the interaction of the tip with the surface. In scanning tunneling microscope systems a bias voltage is applied to the sample and the tip is positioned close enough to the surface that a tunneling current develops through the gap (Fig. 3.43a). Because this current is extremely sensitive to the distance between the tip and the surface, scanning the tip in the x–y-plane while recording the tunnel current permits the mapping of the surface topography with resolution on the atomic scale. In a more common mode of operation the amplified current signal is connected to the z-axis piezoelectric positioner through a feedback loop so that the current and therefore the distance are kept constant throughout the scanning. In this configuration the picture of the surface topography is obtained by recording the vertical position of the tip at each x–y-position.

The STM system only works for conductive surfaces because of the need to establish a tunneling current. The atomic force microscopy was developed as an alternative for imaging either conducting or nonconducting surfaces. In AFM the tip is attached to a flexible cantilever and is brought into contact with the surface (Fig. 3.43b). The force between the tip and the surface is detected by sensing the cantilever deflection. A topographic image of the surface is obtained by plotting the deflection as a function of the x–y-position. In a more common mode of operation a feedback loop is used to maintain a constant deflection while the topographic information is obtained from the cantilever vertical displacement. Some scanning probe systems use a combination of the AFM and the STM modes, i. e., the tip is mounted on a cantilever with electrical connection so that both the surface forces and tunneling currents can be controlled or monitored. STM systems can be operated in ultrahigh vacuum (UHV STM) or in air, whereas AFM systems are typically operated in air. When a scanning probe system is operated in air, water adsorbed onto the sample surface accumulates underneath the tip, forming a meniscus between the tip and the surface. This water meniscus plays an important role in some of the scanning probe techniques described below.

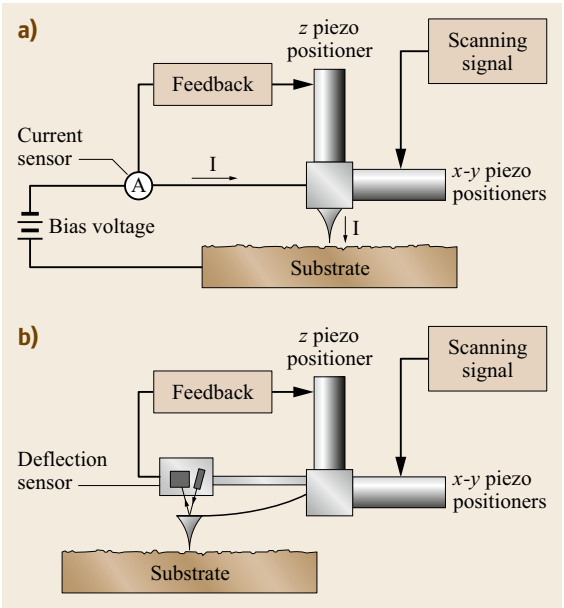

Fig. 3.43a,b Scanning probe systems: **(a)** STM and **(b)** AFM

Scanning-Probe-Induced Oxidation

Nanometer-scale local oxidation of various materials can be achieved using scanning probes operating in air and biased at a sufficiently high voltage (Fig. 3.44). A tip bias of -2 to -10 V is normally used, with a writing speed of $0.1-100\,\mu m/s$ in ambient humidity of 20–40%. It is believed that the water meniscus formed at the contact point serves as an electrolyte such that the biased tip anodically oxidizes a small region of the surface [3.71]. The most common application of this principle is the oxidation of hydrogen-passivated

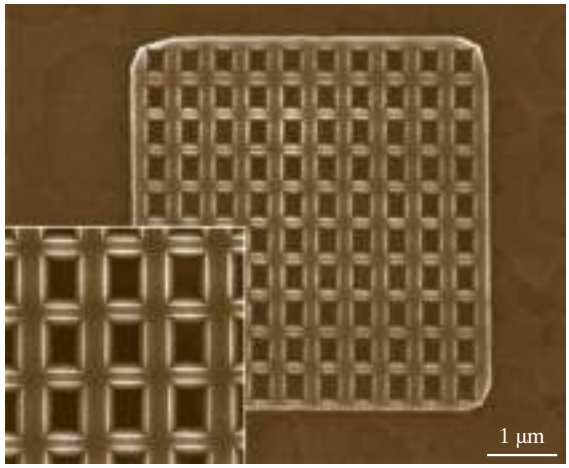

Fig. 3.44 SEM image of an inverted truncated pyramid array fabricated on a silicon SOI wafer by SPM oxidation and subsequent etch in TMAH (pitch is 500 nm) (after [3.70])

silicon. A dip in HF solution is typically used to passivate the silicon surfaces with hydrogen atoms. Patterns of oxide *written* on a silicon surface can be used as a mask for wet or dry etching. Patterns with 10 nm line width have been successfully transferred to a silicon substrate in this fashion [3.72]. Various metals have also been locally anodized using this approach, such us aluminum or titanium [3.73]. An interesting variation of this process is anodization of deposited amorphous silicon [3.74]. Amorphous silicon can be deposited at low temperature on top of many materials. The deposited silicon layer can be patterned and used as, for example, the gate of a 0.1 μm CMOS transistor [3.75], or it can be used as a mask to pattern an underlying film. The major drawback of this technique is poor reproducibility due to tip wear during the anodization. However, using AFM in noncontact mode has proved to overcome this problem [3.71].

Probe Resist Exposure and Lithography

Electrons emitted from a biased SPM tip can be used to expose a resist in the same way e-beam lithography that does (Fig. 3.45) [3.75]. Various systems have been used for this lithographic technique; these include constant-current STM, noncontact AFM, and AFM with constant tip–resist force and constant current. The systems using AFM cantilevers have the advantage that they can perform imaging and alignment tasks without exposing the resist. Resists well characterized for e-beam lithography (e.g., PMMA or SAL601) have been used with scanning probe lithography to achieve reliable sub-100 nm lithography. The procedure for this process is as follows. The wafers are cleaned and the native oxide (in the case of silicon or poly) is removed with a HF dip. Subsequently 35–100 nm-thick resist is spin-coated on top of the surface. The exposure is done by moving the SPM tip over the surface while applying a bias voltage sufficiently high to produce emission of electrons from the tip (a few tens of volts). Development of the resist is performed in standard solutions following the exposure. Features below 50 nm in width have been achieved with this procedure.

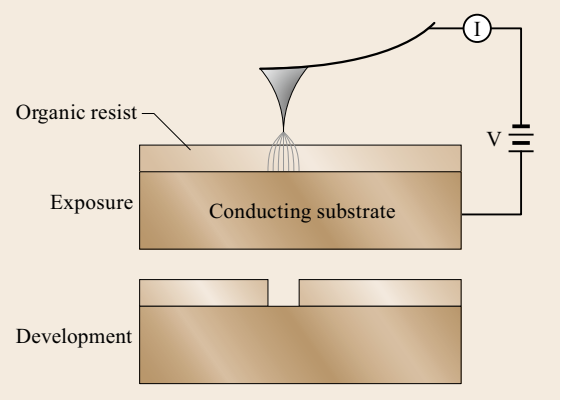

Fig. 3.45 Scanning probe lithography with organic resist

Dip-Pen Nanolithography

In dip-pen nanolithography (DPN) the tip of an AFM operated in air is *inked* with a chemical of interest and brought into contact with a surface. The ink molecules flow from the tip onto the surface as with a fountain pen. The water meniscus that naturally forms between the tip and the surface enables the diffusion and transport of the molecules, as shown in Fig. 3.46. Inking can be done by dipping the tip into a solution containing a low concentration of the molecules followed by a drying step (e.g., blow-drying with compressed difluoroethane). Line widths down to 12 nm with spatial resolution of 5 nm have been demonstrated with this technique [3.76]. Species patterned with DPN include conducting polymers, gold, dendrimers, deoxyribonucleic acid (DNA), organic dyes, antibodies, and alkanethiols. Alkanethiols have been also used as an organic monolayer mask to etch a gold layer and subsequently etch the exposed silicon substrate. One can also use a heated AFM cantilever to control the deposition of a solid organic ink. This technique was recently reported by *Sheehan* et al. in which 100 nm lines of octadecylphosphonic acid (melting point 100 °C) were written using a heated AFM probe [3.77].

Other Scanning Probe Nanofabrication Techniques

A great variety of nanofabrication techniques using scanning probe systems have been demonstrated. A good review on scanning probe lithography highlighting the potential and diversity of materials, working principles and environments, and their potential, can be found in [3.78]. Some of these are proof-of-concept demonstrations and their utility as viable and repeatable fabrication processes continue to be questioned; their direct commercial impact, simply discarded. Regardless of these limitations, one could mention, for

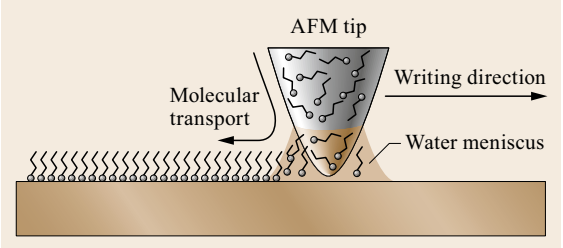

Fig. 3.46 Schematic representation of the working principle of dip-pen nanolithography

example, a STM/AFM tip acting as a plow or engraving tool for mechanical machining [3.79], which can be facilitated by heating the tip above the glass-transition temperature of a polymeric substrate material [3.80].

Atomic emission by local electric fields from the same tip has been used to form mounds (10–20 nm) of metals such as Au, Ag, and Pt [3.81] or to extract single atoms from a semiconductor surface [3.82]. Manipulation of nanoparticles, molecules, and single atoms on top of a surface has also been achieved by simply pushing or sliding them with the SPM tip [3.83]. Metals can also be locally deposited by the STM CVD technique [3.84]. Local electrochemical etching [3.85] and electrodeposition [3.86] is also possible using SPM systems.

Using a single tip to serially produce the desired modification in a surface leads to very slow fabrication processes that are impractical for mass production. Many of the scanning probe techniques developed so far, however, could also be performed by an array of tips, which would increase throughput and make them more competitive compared with other parallel nanofabrication processes. This approach has been demonstrated for imaging, lithography [3.87], and data storage [3.88] using both one- and two-dimensional arrays of scanning probes. With the development of larger arrays with advances in individual control of force, vertical position, and current, we could have seen these techniques being incorporated as standard fabrication processes in the industry.

3.3.4 Self-Assembly and Template Manufacturing

Self-assembly is a nanofabrication technique that involves aggregation of colloidal nanoparticles into the final desired structure [3.89]. This aggregation can be either spontaneous (entropic) and due to the thermodynamic minima (energy minimization) constraints, or chemical and due to the complementary binding of organic molecules and supramolecules (molecular self-assembly) [3.90]. Molecular self-assembly is one of the most important techniques used in biology for the development of complex functional structures. Since these techniques require that the target structures be thermodynamically stable, it tends to produce structures that are relatively defect-free and self-repairing. Self-assembly is by no means limited to molecules or the nanodomain and can be carried out on just about any scale, making it a powerful bottom-up assembly and manufacturing method (multiscale ordering). Another attractive feature of this technique relates to the possibility of combining self-assembly properties of organic molecules with the electronic, magnetic, and photonic properties of inorganic components. Template manufacturing is another bottom-up technique which utilizes material deposition (electroplating, CVD, etc.) into nanotemplates in order to fabricate nanostructures. Due to the simplicity and flexibility of electrochemistry for plating and surface finishing of a broad range of materials, its principle has recently been widely used for electrochemical fabrication of various metallic nanostructures based on various templates. For example, electrochemical deposition has been used to deposit large arrays of nanostructures in nanoporous templates, such as porous alumina. This template-based deposition typically provides metal nanowires as small as 25 nm in diameter and a few micrometers in length [3.91].

The nanotemplates used to fabricate nanostructures are usually prepared using self-assembly techniques. In the following sections, we will discuss various important self-assembly and template manufacturing techniques, which have been heavily investigated. A most sophisticated version of nanofabrication is DSA of BCPs. DSA of BCPs currently holds the highest expectations for More Moore approach, as it is easily compatible with conventional planar technology. Introductory and comprehensive works can be consulted, respectively, in [3.92] and [3.93].

Physical and Chemical Self-Assembly

The central theme behind the self-assembly process is spontaneous (physical) or chemical aggregation of colloidal nanoparticles [3.94]. Spontaneous self-assembly exploits the tendency of monodispersed nano or submicro colloidal spheres to organize into a face-centered cubic (fcc) lattice. The force driving this process is the desire of the system to achieve a thermodynamically stable state (minimum free energy). In addition to spontaneous thermal self-assembly, gravitational, convective, and electrohydrodynamic forces can also be used to induce aggregation into complex 3-D structures. Chemical self-assembly requires the attachment of a single-molecular organic layer (self-assembled monolayer or SAM) to the colloidal particles (organic or inorganic) and subsequent self-assembly of these components into complex structures using molecular recognition and binding.

Physical Self-Assembly

This is an entropy-driven method that relies on spontaneous organization of colloidal particles into a relatively stable structure through noncovalent interactions; for example, colloidal polystyrene spheres can be assembled into a 3-D structure on a substrate which is held vertically in the colloidal solution (Fig. 3.47) [3.95, 96]. Upon the evaporation of the solvent, the spheres aggregate into a hexagonal close-packed (hcp) structure. The

interstitial pore size and density are determined by the polymer sphere size. The polymer spheres can be etched into smaller sizes after forming the hcp arrays, thereby altering the template pore separations [3.97]. This technique can fabricate large patterned areas in a quick, simple, and cost-effective way. A classic example is the natural assembly of on-chip silicon photonic-bandgap crystals [3.95] which are capable of reflecting the light arriving in any direction in a certain wavelength range [3.98]. In this method, a thin layer of silica colloidal spheres is assembled on a silicon substrate. This is achieved by placing a silicon wafer vertically in a vial containing an ethanolic suspension of silica spheres. A temperature gradient across the vial aids the flow of silica spheres. Figure 3.48 shows a cross-sectional SEM image of a thin planar opal template assembled directly on a Si wafer from 855 nm spheres. Once such a template is prepared, LPCVD can be used to fill the interstitial spaces with Si, so that the high refractive index of silicon provides the necessary bandgap.

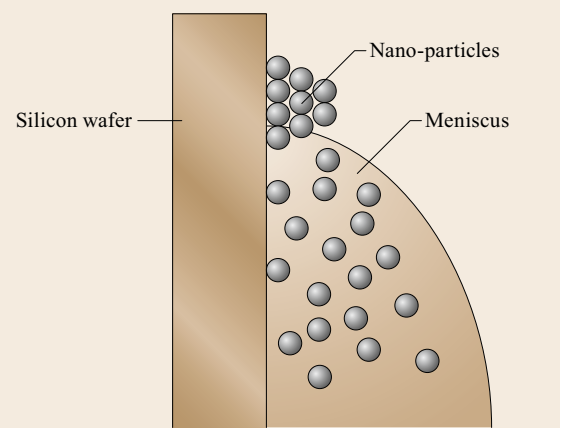

Fig. 3.47 Colloidal particle self-assembly onto solid substrates upon drying in vertical position

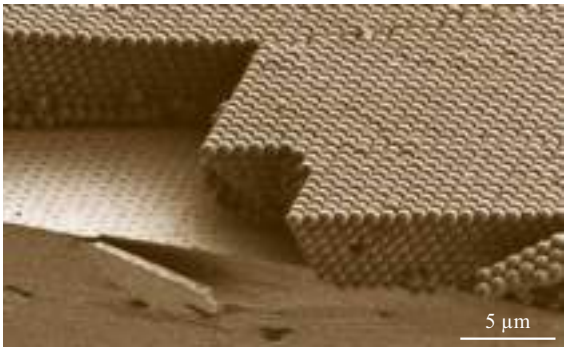

Fig. 3.48 Cross-sectional SEM image of a thin planar opal silica template (spheres 855 nm in diameter) assembled directly on a Si wafer (after [3.95])

One can also deposit colloidal particles onto a patterned substrate (template-assisted self-assembly, TASA) [3.99, 100]. This method is based on the principle that, when an aqueous dispersion of colloidal particles is allowed to dewet from a solid surface which is already patterned, the colloidal particles are trapped by the recessed regions and assemble into aggregates with shapes and sizes determined by the geometric confinement provided by the template. The patterned arrays of templates can be fabricated using conventional contact-mode photolithography which gives control over the shape and dimensions of the templates, thereby allowing the assembly of complex structures from colloidal particles. The cross-sectional view of a fluidic cell used in TASA is shown in Fig. 3.49. This method can be used to fabricate a variety of polygonal and polyhedral aggregates which are difficult to generate [3.101].

Chemical Self-Assembly

Organic and supramolecular SAMs play a critical role in colloidal particle self-assembly. SAMs are robust organic molecules which are chemically adsorbed onto solid substrates [3.102]. Most often they have a hydrophilic (polar) head which can be bonded to various solid surfaces and a long hydrophobic (nonpolar) tail which extends outward. SAMs are formed by the immersion of a substrate in a dilute solution of the molecule in an organic solvent or water (liquid phase) or by exposure to an atmosphere containing such a molecule (gas phase). The resulting film is a dense organization of molecules arranged to expose the end group. The durability of the SAM is highly dependent on the effectiveness of the anchoring to the surface of the substrate. SAMs have been widely studied because the end group can be functionalized to form precisely arranged molecular arrays for various applications ranging from simple, ultrathin insulators and lubricants to complex biological sensors.

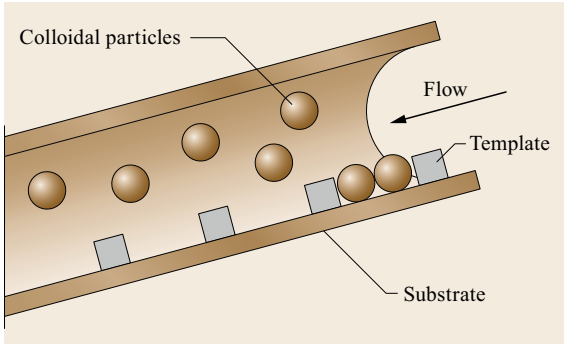

Fig. 3.49 A cross-sectional view of the fluidic cell used for template-assisted self-assembly

Chemical self-assembly uses organic or supramolecular SAMs as the binding and recognition sites for fabricating complex 3-D structures from colloidal nanoparticles. The most commonly used organic monolayers include:

1. Organosilicon compounds on glass and oxidized silicon
2. Alkanethiols, dialkyl disulfides, and dialkyl sulfides on gold
3. Fatty acids on alumina and other metal oxides
4. DNA.

Octadecyltrichlorosilane (OTS) is the most common organosilane used in the formation of SAMs, mainly because of the fact that it is simple, readily available, and forms good, dense layers [3.103, 104]. Alkyltrichlorosilane monolayers can be prepared on clean silicon wafers whose surface is SiO_2 (with almost 5×10^{14} SiOH groups/cm^2). Figure 3.50 shows a schematic representation of the formation of alkylsiloxane monolayers by adsorption of alkyltrichlorosilane from solution onto Si/SiO_2 substrates. Since the silicon–chloride bond is susceptible to hydrolysis, a limited amount of water has to be present in the system in order to obtain good-quality monolayers. Monolayers made of methyl- and vinyl-terminated alkylsilanes are autophobic to the hydrocarbon solution and hence emerge uniformly dry from the solution, whereas monolayers made of ester-terminated alkylsilanes emerge wet from the solution used in their formation. The disadvantage of this method is that, if the alkyltrichlorosilane in the solvent adhering to the substrate is exposed to water, a cloudy film is deposited on the surface due to the formation of a gel of polymeric siloxane. One solution to this problem is the use of alkyldimethylchlorosilanes, which have a single anchoring point, and thus cannot form polymers. Chlorosilanes are sometimes preferred over alkoxysilanes because of their higher reactivity. However, the reactivity of chlorosilanes severely limits the range of functional groups that can be introduced at the end of the hydrocarbon tail. On the contrary, methoxysilanes and ethoxysilanes are commonly available with many functional groups including amino, mercapto, epoxy, and thiocyanate groups, which are often necessary for subsequent binding of colloidal particles and biomolecules. Gas-phase deposition of these molecules yields more uniform layers compared with liquid-phase procedures [3.105]. Soft-lithography-like molds have been used to obtain reactive silane patterns from the gas phase by taking advantage of the characteristic permeability of polydimethylsiloxane (PDMS) to volatile molecules [3.106].

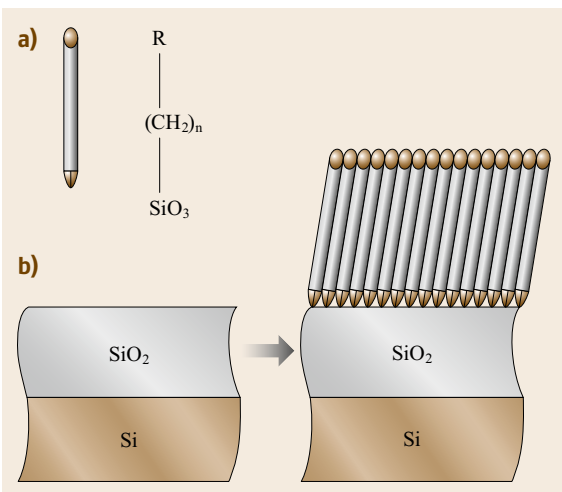

Fig. 3.50 **(a)** Alkylsiloxane formed from the adsorption of alkyltrichlorosilane on Si/SiO_2 substrates. **(b)** Schematic representation of the process

Another important organic SAM system is the alkanethiols ($X(CH_2)_nSH$, where X is the end group) on gold [3.102, 107–109]. A major advantage of using gold as the substrate material is that it does not have a stable oxide and thus can be handled in ambient conditions. When a fresh, clean, hydrophilic gold substrate is immersed (several min to several h) into a dilute solution (10^{-3} M) of the organic sulfur compound (alkanethiols) in an inorganic solvent a close-packed, oriented monolayers can be obtained. Sulfur is used as the head group because of its strong interaction with the gold substrate (44 kcal/mol), resulting in the formation of a close-packed, ordered monolayer. The end group of alkanethiol can be modified to render the adsorbed layer hydrophobic or hydrophilic. Another method for depositing alkanethiol SAM is soft lithography. This technique is based on inking a PDMS stamp with alkanethiol and its subsequent transfer to planar or nonplanar substrates. Alkanethiol-functionalized surfaces (planar, nonplanar, spherical) can also be used to self-assemble a variety of intricate 3-D structures [3.110].

Carboxylic acid derivatives self-assemble on surfaces (e.g., glass, Al_2O_3, and Ag_2O) through an acid–base reaction, giving rise to monolayers of fatty acids [3.111]. The time required for the formation of a complete monolayer increases with decreasing concentration. Higher concentration of the carboxylic acid is required to form a monolayer on gold as compared with on Al_2O_3. This is due to differences in the affinity of the COOH groups (more affinity to Al_2O_3 and glass than gold) and also the surface concentration of the salt-forming oxides of the two substrates. In the case

of amorphous metal oxide surfaces, the chemisorption of alkanoic acids is not unique. For example, on Ag_2O, the two oxygen atoms of the carboxylate bind to the substrate in a nearly symmetrical manner, thus resulting in ordered monolayers with a chain tilt angle of 15–25° from the surface normal. However, on CuO and Al_2O_3, the oxygen atoms bind themselves symmetrically and the chain tilt angle is close to 0°. The structure of the monolayers is thus a balance of the various interactions taking place in the polymer chains.

Deoxyribonucleic acid (DNA), the framework on which all life is built, can be used to self-assemble nanomaterials into useful macroscopic aggregates that display a number of desirable physical properties [3.112]. DNA consists of two strands, which are coiled around each other to form a double helix. When the two strands are uncoiled singular strands of nucleotides are left. These nucleotides consist of a sugar (pentose ring) a phosphate (PO_4), and a nitrogenous base. The order and architecture of these components is essential for the proper structure of a nucleotide. There are typically four nucleotides found in DNA: adenine (A), guanine (G), cytosine (C), and thymine (T). A key property of the DNA structure is that the nucleotides described bind specifically to another nucleotide when arranged in the two-strand double helix (A to T, and C to G). This specific bonding capability can be used to assemble nanophase material and nanostructures [3.113]. For example, nucleotide-functionalized nanogold particles have been assembled into complex 3-D structures by attaching DNA strands to the gold via an enabler or linker [3.114]. In a separate work DNA was used to assemble nanoparticles into macroscopic materials. This method uses alkane dithiol as the linker molecule to connect the DNA template to the nanoparticle. The thiol groups at each end of the linker molecule covalently attach themselves to the colloidal particles to form aggregate structures [3.115].

Template Manufacturing

Template manufacturing refers to a set of techniques that can be used to fabricate 3-D organic or inorganic structures from a nanotemplate. These templates differ in material, pattern, feature size, overall template size, and periodicity. Although nanotemplates can be fabricated using EBL, the serial nature of this technique prohibits its widespread application. Self-assembly is the preferred technique to produce large-area nanotemplates in a massively parallel fashion. Several nanotemplates have been investigated for use in template manufacturing. These include polymer colloidal spheres, alumina membranes, and nuclear-track etched membranes. Colloidal spheres can be deposited in a regular 3-D array using the techniques described in the previous section (Figs. 3.47– 3.49). Porous aluminum oxide membranes can be fabricated by the anodic oxidation of aluminum [3.116]. The oxidized film consists of columnar arrays of hexagonal close-packed pores with separation comparable to the pore size. By controlling the electrolyte species, temperature, anodizing voltage, and time, different pore sizes, densities, and heights can be obtained. The pore size and depth can further be adjusted by etching the oxide in an appropriate acid. Templates of porous polycarbonate or mica membranes can be fabricated by nuclear-track etched membranes [3.117]. This technique is based on the passage of high-energy decay fragments from a radioactive source through a dielectric material. The particles leave behind chemically active damaged tracks which can subsequently be etched to create pores through the thickness of the membrane [3.118, 119]. Unlike other methods, the pore separation and hence the pore density is independent of the pore size. The pore density is only determined by the irradiation process. More recently, electrochemical deposition of metallic nanowires on the step edges of highly oriented pyrolytic graphite (HOPG) templates have also been demonstrated, which produces metallic nanowires with diameters as small as 15 nm. This method has been successfully used for metals such as Cu, Ni, Au, and Pd [3.120, 121].

Subsequent to template fabrication, the interstitial spaces (in the case of colloidal spheres) or pores (in the case of alumina and polycarbonate membranes) in the template are filled with the desired material [3.97, 122]. This can be done by using a variety of deposition techniques such as electroplating and CVD. The final structure can be a composite of nanotemplate and deposited material or the template can be selectively etched, resulting in an air-filled 3-D complex structure. For example, Ni [3.123], Fe [3.124], and Co [3.125] nanowires have been electrochemically grown into porous template matrices. Three-dimensional photonic crystals have been fabricated by electrochemical deposition of CdSe and silicon into polystyrene and silica colloidal assembly templates [3.95, 126]. An interesting example of template-assisted manufacturing is the synthesis of nanometer metallic barcodes [3.127]. These nanobarcodes are prepared by electrochemical reduction of metallic ions into the pores of an aluminum oxide membrane, followed by their release through etching of the template [3.97].

3.4 Summary and Conclusions

In this chapter, we have discussed various micro/nanofabrication techniques used to manufacture structures of a wide range of dimensions (mm–nm). Starting with some of the most common microfabrication techniques (lithography, deposition, and etching), we have presented an array of micromachining and MEMS technologies which can be used to fabricate microstructures down to $\approx 1\,\mu$m. These techniques have attained an adequate level of maturity to enable a variety of MEMS-based commercial products (pressure sensors, accelerometers, gyroscopes, etc.). More recently, nm-size structures have attracted an enormous amount of interest. This is mainly due to their unique electrical, magnetic, optical, thermal, and mechanical properties, leading to a variety of electronic, photonic, and sensing devices with a superior performance compared with their macro counterparts. Subsequent to our discussion on MEMS and micromachining, we presented several important or succesful nanofabrication techniques. Although e-beam and other high-resolution lithography techniques can be used to fabricate nm-size structures, in a top-down fashion, their serial nature and/or cost preclude their widespread application. This has forcedly multiplied the number of nanofabrication processes used by investigators. Efforts to develop alternative and potentially superior techniques such as strain engineering, self-assembly, and nanoimprint lithography have been made. More recently, the focus on novel nanomaterials and bottom-up nanostructured materials synthesis are promoting the quest for a more diverse and flexible combination of the existing methods in (micro and) nanofabrication, beyond conventional semiconductor technology. A paradigmatic example comes from the requirements of werable electronics, boosting the revisiting of, e.g., injet techniques for flexible electronics, while maximum portability requires signal and energy autonomy, therefore, radically advanced device concepts, design and systems.

4. 3-D Nanostructure Fabrication by Focused-Ion Beam, Electron- and Laser Beam

Shinji Matsui, Hiroaki Misawa, Quan Sun

In this chapter, we describe three-dimensional (3-D) nanostructure fabrication techniques using focused-ion-beam (FIB)-induced chemical vapor deposition (CVD), electron-beam (EB)-induced CVD, and femtosecond laser (fs-laser) techniques. We first describe 30 keV Ga^+ FIB-induced CVD using a *phenanthrene* ($C_{14}H_{10}$) source gas as the precursor. A diamond-like amorphous carbon film is deposited during this process; it has a Young's modulus exceeding 600 GPa, making it potentially highly desirable for various applications. A three-dimensional pattern generator system has been developed to make arbitrary three-dimensional nanostructures. We also discuss microstructure plastic art, which is a new field that has been made possible by microbeam technology, and we present examples of such art, including a *micro wine glass* with an external diameter of 2.75 μm and a height of 12 μm. We then discuss free-space nanowiring and show by using a mixture of $C_{14}H_{10}$ and $W(CO)_6$ that the electrical properties indicate an increase in metal content results in a lower resistivity. We also demonstrate that a *Morpho* butterfly scale quasistructure fabricated by FIB-induced CVD has almost the same optical characteristics as a real *Morpho* butterfly scale. We then discuss three-dimensional nanostructure fabrication using EB-induced CVD. Because of the nanometer resolution, EB-induced CVD is now indispensable for mask repair techniques for the 193 nm node. According to real-time observations by transmission electron microscopy, the W clusters, as the initial growth stage, are formed first followed by the W layer which forms as W clusters coalesce due to EB irradiation. We go on to discuss photonic crystals and Smith–Purcell electron optics as examples of three-dimensional nanostructure applications using EB-induced CVD. Finally, we describe femtosecond-laser-assisted micro/nanofabrication which has been recognized as a promising technique to fabricate three-dimensional structures inside transparent materials. The spatial resolution can reach submicrometer levels and even tens of nanometers owing to suppression of the involved heat diffusion and nonlinear adsorption. We discuss three-dimensional femtosecond laser nanofabrication using the direct laser writing technique and multiple beam interference lithography and describe the fabrication of photonic crystals in a photoresist.

4.1 Various 3-D Nanostructure Fabrication Techniques

Recent years have witnessed a number of investigations concerning nanostructure technology. The objective of research on nanostructure technology is to explore the basic physics, technology, and applications of ultrasmall structures and devices with dimensions in the sub-10 nm regime. Electron-beam (EB) lithography is the most widely used and versatile lithography tool for fabricating nanostructure devices and photo masks. EB can focus to diameters of less than 5 nm. The minimum beam diameter of the scanning electron microscope (SEM) and scanning transmission electron microscope (STEM) are 1.5 and 0.5 nm, respectively. While the focused ion beam (FIB) can be focused close to 5 nm. EB and FIB have been used to fabricate various two-dimensional (2-D) nanostructure devices such as single-electron transistors and MOS (metal oxide semiconductor) transistors with nanometer gate-lengths. 10 nm structures can be formed by using a commercially available EB or FIB system with 5−10 nm-diameter beams and a high-resolution resist [4.1]. 2-D nanostructure fabrication is therefore already an established process. Conventional devices have been fabricated by a 2-D processing technique. Developing a three-dimensional (3-D) processing technique presents the possibility of realizing a device with higher functionality. In this chapter, we discuss 3-D nanostructure fabrications using EB-induced chemical vapor deposition (CVD), FIB-induced CVD, and femtosecond laser (fs-laser) techniques.

Beam-induced chemical vapor deposition (CVD) is widely used in the electrical device industry for the repair of chips and masks. This type of deposition is mainly performed on 2-D pattern features. Work has been done on 3-D fabrication by laser, EB, or FIB using beam-induced CVD. In 1990, *Wagner* et al. demonstrated pillars and walls with high aspect ratios achieved using FIB-induced CVD [4.2]. In 1991, *Lehman* et al. demonstrated 3-D microfabrication by laser-induced CVD [4.3]. In 1994, *Koops* et al. demonstrated some applications such as an AFM (atomic force microscopy) tip and a field emitter that were realized with EB-induced CVD [4.4]. In 2000, *Matsui* et al. demonstrated 3-D nanostructure fabrication using FIB-induced CVD [4.5]. FIB- and EB-induced CVD are superior to laser-induced CVD in terms of spatial resolution and beam-scan control. To demonstrate 3-D nanostructure fabrication using a laser, in 1999, *Sun* et al. reported on the fs-laser two-photon-absorption photopolymerization of a 3-D photonic crystal (PhC) structure in a resist [4.6].

4.2 3-D Nanostructure Fabrication by Focused Ion Beam

4.2.1 Focused-Ion-Beam-Induced Chemical Vapor Deposition

Two commercially available FIB systems (SMI9200, SMI2050, SII Nanotechnology Inc., Tokyo, Japan) with a Ga^+ ion beam operating at 30 keV were used to study 3-D FIB-induced CVD. The FIB-induced CVD used a *phenanthrene* ($C_{14}H_{10}$) precursor as the source material. The beam diameter of SMI9200 was about 7 nm and that of SMI2050 was about 5 nm. The SMI9200 system was equipped with two gas sources in order to increase the gas pressure. The nozzles faced each other and were directed at the beam point. The nozzles were set a distance of 40 μm from each other and positioned about 300 μm above the substrate surface. The inside diameter of a nozzle was 0.3 mm. The *phenanthrene* gas pressure during pillar growth was typically 5×10^{-5} Pa in the specimen chamber, but the local gas pressure at the beam point was expected to be much higher. The crucible for the source was heated to 85 °C. Conversely, the SMI2050 system was equipped with a single gas nozzle. The FIB is scanned in order to be able to write the desired pattern via computer control, and the ion dose is adjusted to deposit a film of the desired thickness. The experiments were carried out at room temperature on a silicon substrate.

The deposited film was characterized by observing it with a transmission electron microscope (TEM) and by analyzing its Raman spectra [4.5]. A thin film of carbon (200 nm thick) was deposited on a silicon substrate by 30 keV Ga^+ FIB using a *phenanthrene* precursor gas. The cross-sections of the structures created and its electron diffraction patterns were observed by using a 300 kV TEM. There were no crystal structures in the TEM images and diffraction patterns. It was therefore concluded that the deposited film was amorphous carbon (a-C). Raman spectra of the a-C films were measured at room temperature with the 514.5 nm line of an argon ion laser. The Raman spectra were recorded using a monochromator equipped with a CCD (charge coupled device) multichannel detector. Raman spectra were measured at 0.1−1.0 mW to avoid thermal decomposition of the samples. A relatively sharp Raman band at 1550 cm^{-1} and a broad-shouldered band at around

$1400\,cm^{-1}$ were observed in the spectra excited by the 514.5 nm line. Two Raman bands were plotted after Gaussian line shape analysis. These Raman bands, located at 1550 and $1400\,cm^{-1}$, originate from the trigonal (sp^2) bonding structure of graphite and tetrahedral (sp^3) bonding structure of diamond. This result suggests that the a-C film deposited by FIB-induced CVD is diamond-like amorphous carbon (DLC), which has attracted attention due to its hardness, chemical inertness, and optical transparency.

The coordination of carbon atoms in the carbon-based material formed by CVD of *phenanthrene* assisted by Ga^+ FIB was investigated by the measurement of near-edge X-ray absorption fine structure spectra of the carbon *K*-edge over the excitation energy range 275–320 eV [4.7]. A novel peak observed at 289.0 eV was assigned to the $1\,s \rightarrow \sigma^*$ transition of carbon neighboring the residual Ga. The material formed by this method was found to be Ga-doped DLC which consists of a high sp^3 hybridized carbon. The atomic fraction of the FIB-induced CVD DLC film has been determined as $C : Ga : H = 87.4 : 3.6 : 9.0$ at.% using Rutherford backscattering spectrometry and elastic recoil detection analysis. The hydrogen content of the FIB-induced CVD DLC film was relatively speaking lower than that of DLC films formed by other CVD methods [4.8].

4.2.2 3-D Fabrication Process

A 3-D structure usually contains overhang structures and hollows. Gradual position scanning of the ion-beam during the CVD process causes the position of the growth region around the beam point to shift. When the beam point reaches the edge of the wall, secondary electrons appear at the side of the wall and just below the top surface. The DLC then starts to grow laterally; the width of the vertical growth is also about 80 nm. Therefore, combining the lateral growth mode with rotating beam scanning, it is possible to obtain 3-D structures with rotational symmetry like a wine glass.

The process of fabricating 3-D structures by FIB-induced CVD is illustrated in Fig. 4.1 [4.5]. In FIB-induced CVD processes, the beam is scanned in digital mode. First, a pillar is formed on the substrate by fixing the beam position (position 1). After that, the beam position is moved to within a diameter of the pillar (position 2) and then fixed until the deposited terrace thickness exceeds the range of the ions (a few 10 nm). This process is repeated to make 3-D structures. The key point in making 3-D structures is to adjust the beam scan speed so that the ion beam remains within the deposited terrace, which means that the terrace thickness always exceeds the range of the ions. Growth in the *x*- and *y*-directions is controlled by both beam deflectors. The growth in the *z*-direction is determined by the deposition rate; that is, the height of the structure is proportional to the irradiation time when a deposition rate is constant.

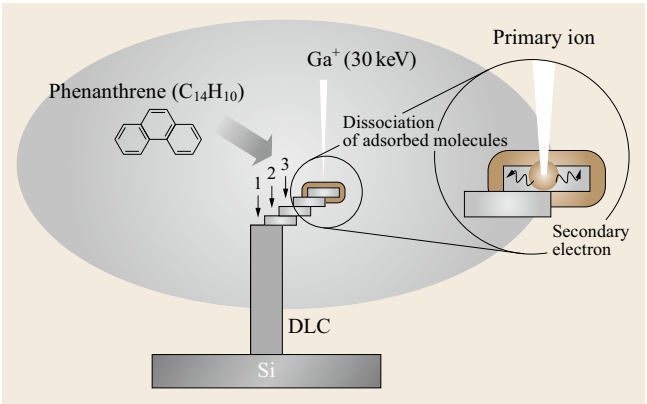

Fig. 4.1 Fabrication process for a three-dimensional nanostructure by FIB-induced CVD

A *micro wine glass* was created on a human hair as a work of microstructure plastic art as shown in the scanning ion microscope (SIM) image in Fig. 4.2. A micro wine glass with an external diameter of 2.75 µm and a height of 12 µm was created [4.5]. The fabrication time was 600 s with a beam current of

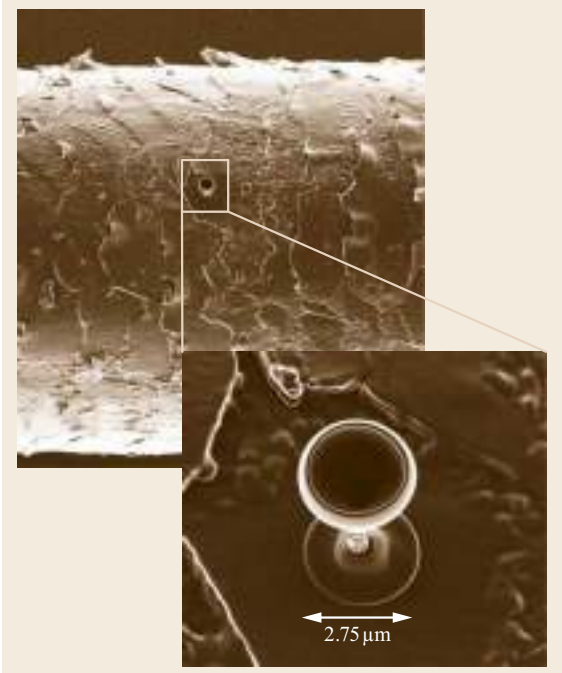

Fig. 4.2 Micro wine glass with an external diameter of 2.75 µm and a height of 12 µm on a human hair

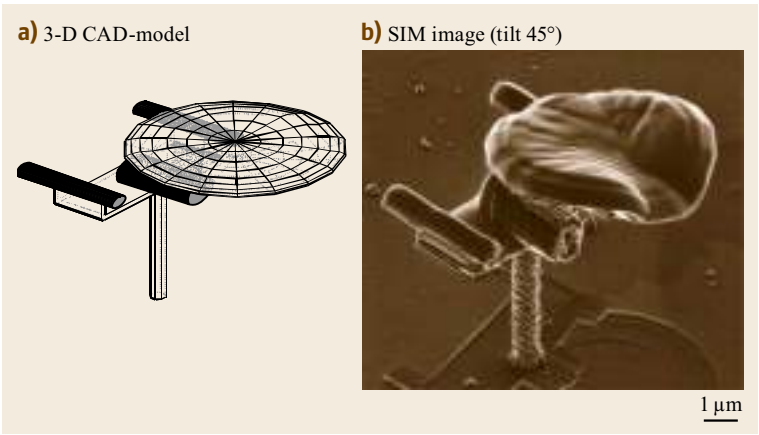

Fig. 4.4a,b *Micro starship Enterprise NCC-1701D*, 8.8 µm long

16 pA. This beautiful micro wine glass shows the potential of the field of microstructure plastic art.

A 3-D pattern generator system was developed to make arbitrary 3-D nanostructures [4.9]. A 3-D multilayer structure is built-up. In the first step of this 3-D pattern-generating system, a 3-D model of the structure, designed using a 3-D computer-aided design (CAD) system (3-D DXF format), is needed. In this case we realized a structure that was shaped like a pendulum. The 3-D CAD model, which is a surface model, is cut into several slices, as shown in Fig. 4.3. The thickness of the slices depends upon the resolution in the z-direction (the vertical direction). The x and y coordinates of the slices are then used to create the scan data (voxel data). To fabricate the overhanging structure, the ion beam must irradiate the correct positions in the correct order. If the ion beam irradiates a voxel located in mid-air without a support layer, the ions intended for the voxel will be deposited on the substrate. Therefore, the sequence of irradiation is determined, as shown in Fig. 4.3. The scan data and blanking signal therefore include the scan sequence, the dwell time, the interval time, and the irradiation pitch. These parameters are calculated from the beam diameter, x-y resolution and z resolution of fabrication. The z resolution is proportional to the dwell time and inversely proportional to the square of the irradiation pitch. The scan data are passed to the beam deflector of the FIB-induced CVD as are the blanking data. The blanking signal controls the dwell time and interval time of the ion beam. Figure 4.4 shows a 3-D CAD model and a SIM image of the starship Enterprise NCC-1701D (from the television series Star Trek) which was fabricated by FIB-induced CVD at $10 \approx 20$ pA [4.9]. The nanospaceship is 8.8 µm long and was realized at about a 1 : 100 000 000 scale on a silicon substrate. The dwell time, interval time, irradiation pitch, and total process time were 80 µs, 150 µs, 2.4 nm, and 2.5 h, respectively. The horizontal overhang structure was successfully fabricated. Figure 4.5 shows a *nano T4 bacteriophage*, which is an artificial version of the virus fabricated by FIB-induced CVD on a silicon surface. The size of the artificial nano *T4 bacteriophage* is about 10 times that of the real virus.

Fig. 4.5 T-4 bacteriophage

To fabricate an arbitrary 3-D nanostructure, it is necessary to understand the growth mechanism that occurs during FIB-induced CVD. With the aim of elucidating these details, in situ observation of 3-D nanostructure growth during FIB-induced CVD using SEM in a FIB–SEM dual-beam system was carried out. As a result, it was demonstrated that the 3-D nanostructure growth depended on the beam profile of the FIB as well as on the FIB irradiation time and scanning speed [4.10].

4.2.3 Mechanical Properties

An evaluation of the mechanical characteristics of such nanostructures is required for material physics. *Buks* and *Roukes* reported a simple but useful technique for measuring the resonant frequencies of nanoscale objects using an SEM [4.11]. The secondary electron detector in the SEM can detect frequencies up to around 4 MHz, so the sample vibration is measured as the oscillatory output signal of the detector. This technique was used to evaluate the Casimir attractive force between the two parallel beams fabricated at a nanoscale. We evaluated the mechanical characteristics of DLC pillars in terms of the Young's modulus, determined using resonant vibration and the SEM monitoring technique [4.12, 13].

The system set-up for monitoring mechanical vibration is shown in Fig. 4.6b. There were two ways of measuring the pillar vibrations. One was active measurement, where the mechanical vibration was induced by a thin piezoelectric device, 300 μm thick and 3 mm square. The piezo device was bonded to the sidewall of the SEM's sample holder with silver paste. The sample holder was designed to observe cross-sections in the SEM (S5000, Hitachi) system. Therefore, the pillar's vibration was observed as a side-view image, as shown in Fig. 4.6a. The range of vibration frequencies involved were 10 kHz up to 2 MHz, which is much faster than the SEM raster scanning speed. Thus, the resonant vibrations of the pillars can be taken as the trace of the pillar's vibration in the SEM image. The resonant frequency and amplitude were controlled by adjusting the power of the driving oscillator.

The other way to measure pillar vibrations is passive measurement using a spectrum analyzer (Agilent, 4395A), where most of the vibration seemed to derive from environmental noise due to rotary pumps and air conditioners. Some parts of the vibration result from the spontaneous vibration associated with thermal excitations [4.11]. Because of the excitation and residual

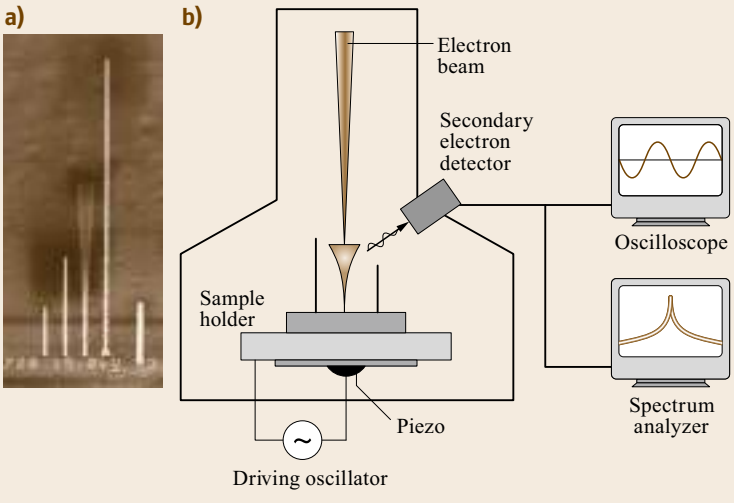

Fig. 4.6 **(a)** SEM image of the vibration. The resonant frequency was 1.21 MHz. **(b)** Schematic diagram of the vibration monitoring system

noise, the pillars on the SEM sample holder always vibrated at a fundamental frequency, even if noise isolation is enforced on the SEM system. The amplitude of these spontaneous vibrations was on the order of a few nanometers at the top of the pillar and high-resolution SEM can easily detect it at a magnification of 300 000.

We arranged several pillars that had varying diameters and lengths. The DLC pillars with the smallest diameter of 80 nm were grown using point irradiation. While we used two FIB systems for pillar fabrication, slight differences in the beam diameters of the two systems did not affect the diameters of the pillars. Larger diameter pillars were fabricated using an area-limited raster scan mode. Raster scanning a 160 nm^2 region produced a pillar with a cross-section of about 240 nm^2 and a 400 nm^2 scan resulted in a pillar with a cross-section of 480 nm^2. The typical SEM image taken during resonance is shown in Fig. 4.6a. The FIB-induced CVD pillars seemed very durable against mechanical vibration. This kind of measurement usually requires at least 30 min, including a spectrum analysis and photorecording, but the pillars still survived without any change in resonance characteristics. This durability of the DLC pillars should be useful in nanomechanical applications.

The resonant frequency f of the pillar is defined by (4.1) for a pillar with a square cross-section and (4.2) for a pillar with a circular cross-section

$$f_{\text{square}} = \frac{a\beta^2}{2\pi L^2}\sqrt{\frac{E}{12\rho}} \tag{4.1}$$

$$f_{\text{circular}} = \frac{a\beta^2}{2\pi L^2}\sqrt{\frac{E}{16\rho}}\,, \tag{4.2}$$

where a is the width of the square pillar and/or the diameter of the circular-shaped pillar, L is the length of the pillar, ρ is the density, and E is the Young's modulus. The coefficient β defines the resonant mode and $\beta = 1.875$ for the fundamental mode. We used (4.1) for pillars that were 240 nm and 480 nm wide and (4.2) for pillars grown by point-beam irradiations. The relationship of the resonant frequency to the Young's modulus, which depends on the ratio of the pillar diameter to the squared length, is summarized in Fig. 4.7. All of the pillars evaluated in this figure were fabricated using the SMI9200 FIB system under rapid growth conditions. Typical growth rates were about 3–5 μm/min for the 100 nm diameter and 240 μm wide pillars and 0.9 μm/min for the 480 nm wide pillars. When calculating the data shown in Fig. 4.7, we assumed that the density of the DLC pillars was about 2.3 g/cm^3, which is almost identical to that of graphite. The inclination of the line in Fig. 4.7 indicated the Young's modulus

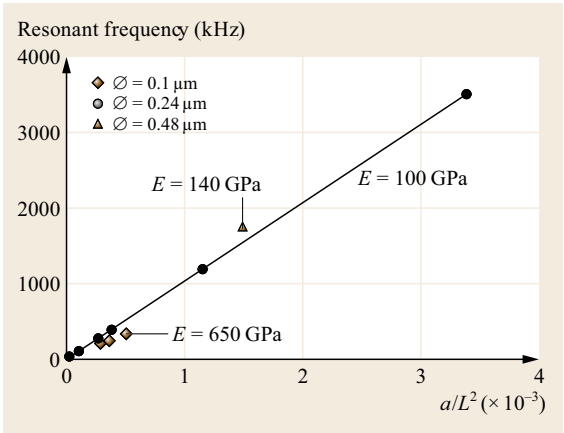

Fig. 4.7 Dependence of resonant frequency on the pillar length

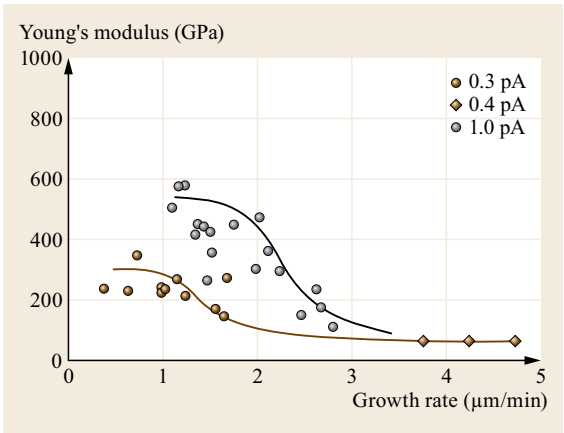

Fig. 4.8 Dependence of Young's modulus on the growth rate

for each pillar. The Young's moduli of the pillars were distributed over a range from 65–140 GPa, which is almost identical to that of normal metals. Wider pillars tended to have larger Young's moduli.

Figure 4.8 shows that the stiffness increases significantly as the local gas pressure decreases. While the absolute value of the local gas pressure at the beam point is very difficult to determine, we found that the growth rate can be a useful parameter for describing the dependence of pressure on Young's modulus. All data points indicated in Fig. 4.8 were obtained from pillars grown using point irradiation. Therefore, the pillar diameters did vary slightly from 100 nm but not by more than 5%. A relatively low gas pressure, with a good uniformity, was obtained by using a single gas nozzle and gas reflector. We use a cleaved side wall of Si tips as the gas reflector, which was placed 10–50 μm away from the beam point so as to be facing the gas

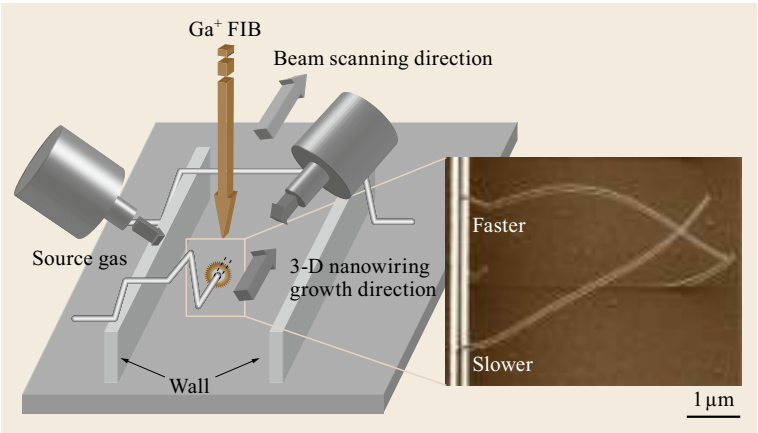

Fig. 4.9 Fabrication of DLC free-space wiring using both FIB-induced CVD and CPG

nozzle. The growth rate was controlled by changing the distance to the wall. While there is a large distribution of data points, the stiffness of the pillar tended to become greater as the growth rate decreased. The two curves in Fig. 4.8 represented data points obtained for a beam current of 0.3 pA (*open circles*) and 1 pA (*solid circles*), respectively. Both curves show the same tendency; the saturated upper levels of the Young's modulus are different for each ion current at low gas pressure (low growth rate). It should be noted that a few pillars' Young's moduli exceeded 600 GPa, which is of the same order as that of tungsten carbide. In addition, these estimations assume a pillar density of 2.3 g/cm^3, but a finite amount of Ga was incorporated with the pillar growth. If the calculation takes the increase in pillar density due to the Ga concentration into account, the Young's modulus exceeds 800 GPa. Such a high Young's modulus reaches that of carbon nanotubes and natural diamond crystals. We think that this high Young's modulus is due to surface modification caused by the direct ion impact. In contrast, when the gas pressure was high enough to achieve a growth rate of more than 3 µm/min, the pillars became soft but the change in the Young's modulus was small. The uniformity of the Young's modulus (as seen in Fig. 4.7) presumably results from the fact that the growth occurred in this insensitive region, where the low levels of source gas limit pillar growth.

Various 3-D mechanical parts can be made with this useful, high Young' modulus. *Kometani* et al. reported DLC electrostatic nanoactuators and bio-nanotools such as injectors and manipulators [4.14–18]. Nakamatsu et al. reported a DLC nanospring with a 130 nm spring section diameter, which showed behavior similar to that of a macroscale spring. The estimated shear modulus of the DLC nanospring was about 70 GPa. This value is very close to that of a conventional coil spring made of steel [4.19].

4.2.4 Free-Space Nanowiring

All experiments were carried out in a commercially available FIB system (SMI9200:SII NanoTechnology Inc.) using a beam of 30 kV Ga^+ ions. The beam was focused to a spot size of 7 nm at a beam current of 0.4 pA and it was incident perpendicular to the surface. The pattern-drawing system (compute pattern generator, CPG-1000: Crestec Co., Tokyo, Japan) was added to the FIB apparatus to draw any patterns. Using the CPG, it is possible to control beam scan parameters such as scanning speed, *x*–*y* direction, and blanking of the beam, and so 3-D free-space nanowiring can be performed [4.20].

Figure 4.9 illustrates the free-space nanowiring fabrication process using both FIB-induced CVD and CPG. When *phenanthrene* ($C_{14}H_{10}$) gas or tungsten hexacarbonyl [$W(CO)_6$] gas, which is a reactive organic gas, is evaporated from a heated container and injected into the vacuum chamber by a nozzle located 300 µm above the sample surface at an angle of about 45° with respect to the surface, the gas density of the $C_{14}H_{10}$ or $W(CO)_6$ molecules increases on a substrate near the gas nozzle. The nozzle system creates a local high-pressure region over the surface. The base pressure of the sample chamber is 2×10^{-5} Pa and the chamber pressure upon introducing $C_{14}H_{10}$ and $W(CO)_6$ as a source gas was 1×10^{-4} and 1.5×10^{-3} Pa, respectively. If a Ga^+ ion beam is irradiated onto the substrate, $C_{14}H_{10}$ or $W(CO)_6$ molecules adsorbed on the substrate surface are decomposed and deposited onto the surface of the substrate. The direction of deposition growth can be controlled through the scanning direction of the beam. The material deposited using $C_{14}H_{10}$ gas was DLC, as confirmed by Raman spectra and it had a very large Young's modulus of 600 GPa [4.5, 12].

After the two walls shown in Fig. 4.9 were formed, free-space nanowiring was performed by adjusting the

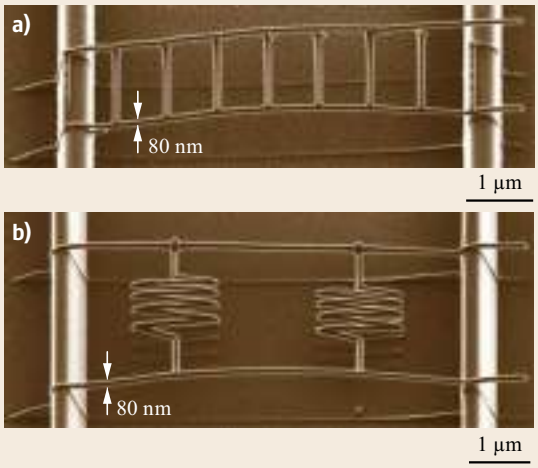

Fig. 4.10 (a) DLC free-space wiring with a bridge shape. (b) DLC free-space wiring with parallel resistances

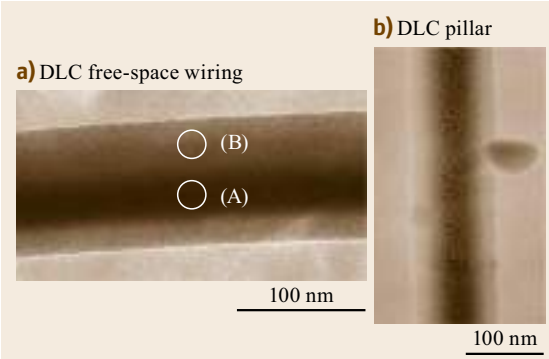

Fig. 4.11a,b TEM images of (a) DLC free-space wiring and (b) DLC pillar

beam scanning speed. The ion beam used was a 30 kV Ga^+ FIB and the irradiation current was 0.8−2.3 pA. The x and y scanning directions and the beam scanning speed were controlled by the CPG. The height in the z-direction was proportional to the irradiation time. Deposition is made to occur horizontally by scanning the beam at a certain fixed speed in the direction of a plane. However, if the beam scanning speed is faster than the nanowiring growth speed, it grows downward or drops. Conversely, if the scanning speed is too slow, the deposition grows slanting upward. Therefore, it is very important to carefully control the beam scanning speed when growing a nanowire horizontally. It turns out that the optimal beam scanning speed to realize a nanowire growing horizontally, using two $C_{14}H_{10}$ gas guns, is about 190 nm/s. The expected pattern resolution for the FIB-induced CVD is around 80 nm, because both the primary Ga ion and secondary-electron scattering occur over distances around 20 nm [4.12, 21].

Figure 4.10 shows examples of free-space nanowiring fabricated by FIB-induced CVD and CPG. All of the structures shown were fabricated using $C_{14}H_{10}$ gas as a precursor gas. Figure 4.10a shows nanobridge free-space wirings. The growth time was 1.8 min and the wiring width was 80 nm. Figure 4.10b shows free-space nanowires with parallel resistances. The growth time was 2.8 min and the wiring width was again 80 nm.

The free-space nanowiring structures were observed using 200 keV TEM. The analyzed area was 20 nm Φ. Figure 4.11a,b show TEM images of DLC free-space wiring and a pillar. It became clear from these EDX (energy dispersive X-ray) measurements that the dark part (A) of Fig. 4.11a corresponds to the Ga core and the outside part (B) of Fig. 4.11a corresponds to amorphous carbon. This free-space nanowiring therefore consists of amorphous carbon with a Ga core. The center position of the Ga core is actually located below the center of the wiring. However, in the case of the DLC pillar, the Ga core is located at the center of the pillar. To investigate the difference between these core positions, the Ga core distribution in free-space nanowiring was observed in detail by TEM. The center position of the Ga core was about 70 nm from the top, which was 20 nm below the center of the free-space nanowiring. We calculated an ion range of 30 kV Ga^+ ions into amorphous carbon, using transport of ions in matter (TRIM), of 20 nm. The calculation indicates that the displacement of the center of the Ga core in the nanowiring corresponds to the ion range.

Kometani et al. proposed a technology to fabricate ultralong horizontal free-space nanowires by using the growth angle dependency of the specimen current and carrying out feedback control of the scanning speed of the Ga^+ FIB [4.22, 23]. The feedback control system monitors the specimen current and controls the FIB scanning speed in real-time while judging the value of the specimen current. In order to verify the effect of real-time feedback control, FIB was scanned laterally 15 μm with a uniform scanning speed (80 nm/s), from the tip of a nanopillar as shown in Fig. 4.12. As Fig. 4.12a shows, the nanowire turned downward after growing approximately 2 μm due to the change in growth characteristics. With the change in nanowire growth angle, the generation of secondary electrons also changed and thus, the specimen current changed during growth, as shown in Fig. 4.12b. Conversely, as shown in Fig. 4.12c, the effect of feedback control was obvious in that the nanowire grew almost horizontally and arrived at its goal length of 15 μm without turning downward. During growth with feedback control, the specimen current remained in the permission range,

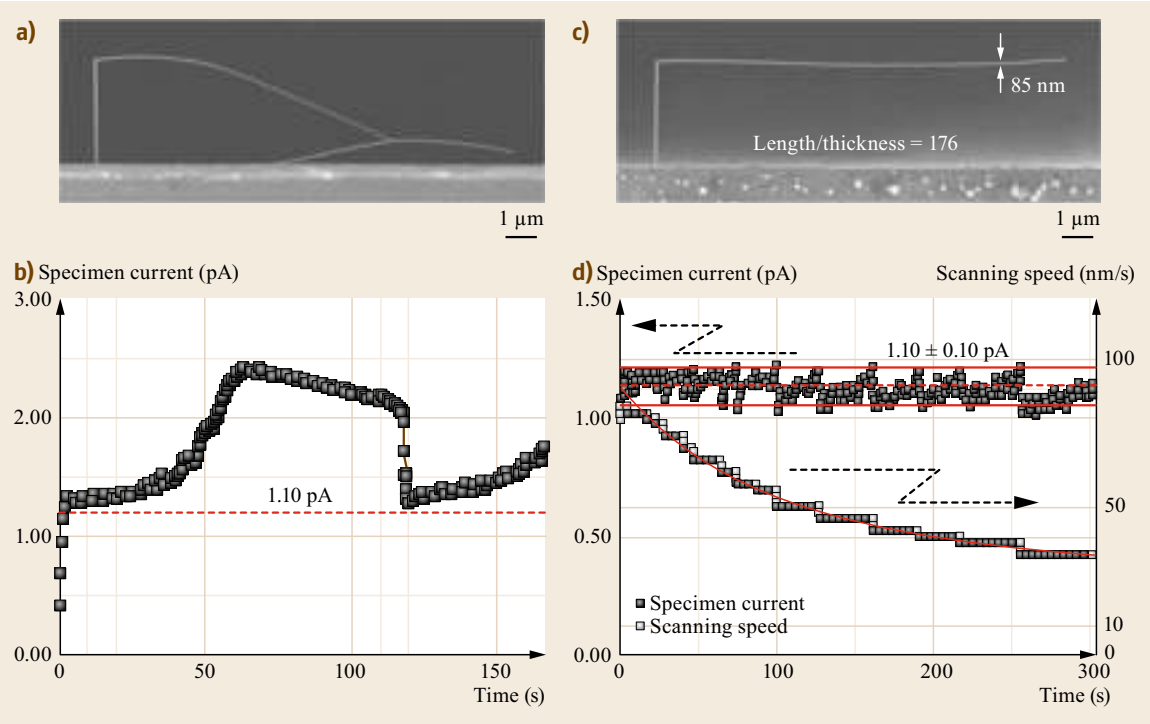

Fig. 4.12a–d Growth results for a 15 μm long free-space nanowire. **(a)** Nanowire grown without feedback control, **(b)** change in specimen current without feedback control, **(c)** nanowire grown with feedback control, and **(d)** changes in specimen current and scanning speed of the Ga^+ FIB with feedback control. as shown in Fig. 4.12d. Furthermore, an ultralong horizontal free-space nanowire with a length of more than 30 μm and a length-to-thickness ratio as high as 300 was achieved.

Electron holography is a useful technology for direct observation of electrical and magnetic fields at nanoscale and can also provide useful information by detecting the phase shift of the electron wave due to the electrical and magnetic field. The technique requires an electron biprism, which plays the important role of dividing the electron wave into a reference wave and an objective wave. The biprism is composed of one thin filament and two ground electrodes. It is important to fabricate a filament that is as narrow as possible to obtain an interference fringe with a high contrast and good fringe quality. However, fabricating the filament with a diameter below 500 nm is very difficult, because a conventional electron biprism is fabricated by pulling a melted glass rod by hand. To overcome this problem, we introduced a new electron biprism fabrication technique using FIB-induced CVD and evaluated the characteristics of the new biprism. The 80 nm DLC thin wiring works as the filament of the biprism. The diameter and length of the filament are 80 nm and 15 μm, respectively. The results demonstrate the adequacy of the thin filament fabricated by FIB-induced CVD and the new biprism is very useful for accurate observation with a high contrast and good fringe quality in electron holography [4.24].

4.2.5 Electrical Properties

The electrical properties of free-space nanowiring fabricated by FIB-induced CVD using a mixture of $C_{14}H_{10}$ and $W(CO)_6$ were measured [4.20]. Nanowires were fabricated on a Au electrode. These Au electrodes were formed on a 0.2 μm thick SiO_2-on-Si substrate by an EB lithography and lift-off process. The two-terminal electrode method was used to measure the electrical resistivity of the nanowiring. The electrical resistivity (Fig. 4.13a) fabricated using only a $C_{14}H_{10}$ source gas, was 1×10^2 Ωcm. The elemental contents were 90% C and 10% Ga, as measured by an SEM-EDX spot beam. The *I*–*V* curves (b), (c), and (d) correspond to increasing $W(CO)_6$ content in the gas mixture. The *I*–*V* curves (b)–(d) show that as the $W(CO)_6$ content increases, the W content increases. Moreover, the Ga content also increased because nanowiring growth slowed; the irra-

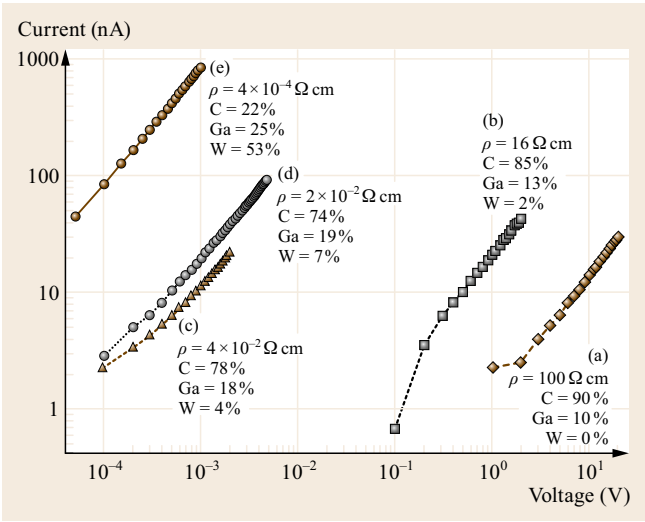

Fig. 4.13 Electrical resistivity measurement for nanowiring. Electrical resistivity ρ was calculated using I–V curves. Elemental contents C, Ga, and W were measured by SEM-EDX

diation time of the Ga FIB became longer. The electrical resistivities of the *I–V* curves (b), (c), and (d) were 16×10^{-2}, 4×10^{-2}, and $2\times10^{-2}\,\Omega$cm, respectively. The electrical resistivity of (e), which was fabricated using only a $W(CO)_6$ source gas, was $4\times10^{-4}\,\Omega$cm. Increasing the Ga and W metallic content decreases the electrical resistivity, as shown by the SEM-EDX measurements in Fig. 4.13. These results indicate that increasing the metallic content results in lower resistivity.

Kometani et al. demonstrated a piezo resistive effect in a DLC nanostructure [4.25] and superconductivity with a T_c as high as 5.8 K in tungsten-carbide nanowires deposited from the precursor mixture of $W(CO)_6$ and $C_{14}H_{10}$ [4.26]. Furthermore, a W−C superconductor–normal metal–superconductor (SNS) Josephson junction was fabricated and a Fraunhofer-like oscillation of critical current in the junction with four periods was observed [4.27].

4.2.6 Brilliant Blue Observation from a *Morpho* Butterfly Scale Quasistructure

The *Morpho* butterfly has brilliant blue wings and the source of this intense color has been an interesting topic of debate for a long time. Because of an intriguing optical phenomenon, the scales reflect an interfered brilliant blue color for any angle of incidence of white light. This color is called a structural color, meaning that it is not caused by pigment reflection [4.28]. When we observed the scales with an SEM (Fig. 4.14a), we found 3-D nanostructures 2 μm in height, 0.7 μm in width, and with a 0.22 μm grating pitch on the scales. These nanostructures cause a similar optical phenomenon to the iridescence produced by a jewel beetle.

We duplicated the *Morpho* butterfly scale quasistructure with a commercially available FIB system (SMI9200: SII Nanotechnology Inc.) using a Ga^+ ion beam operating at 30 kV [4.29]. The beam diameter was about 7 nm at 0.4 pA. The FIB-induced CVD was performed using *phenanthrene* as a precursor. In this experiment, we used a computer-controlled pattern generator, which converted 3-D CAD data into a scanning signal, which was passed to an FIB scanning apparatus in order to fabricate a 3-D nanostructure [4.9]. The scattering range of the Ga^+ primary ions is about 20 nm and the range of the secondary electrons induced by the Ga^+ ion beam is about 20 nm, so the expected pattern resolution of the FIB-induced CVD is about 80 nm. Figure 4.14b shows an SIM image of the *Morpho* butterfly quasistructure fabricated by FIB-induced CVD using the 3-D CAD data. This result demonstrates that

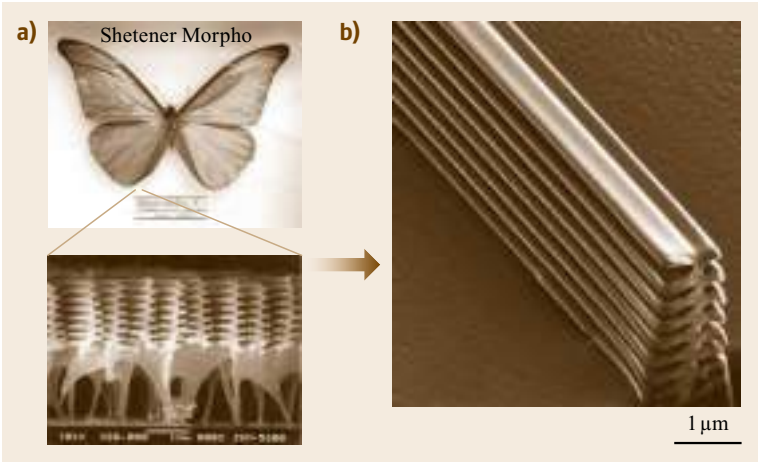

Fig. 4.14a,b *Morpho* butterfly scales. **(a)** Optical microscope image showing top view of *Morpho* butterfly. SEM image showing a cross-sectional view of *Morpho* butterfly scales. **(b)** SIM images showing inclined view of *Morpho* butterfly scale quasistructure fabricated by FIB-induced CVD

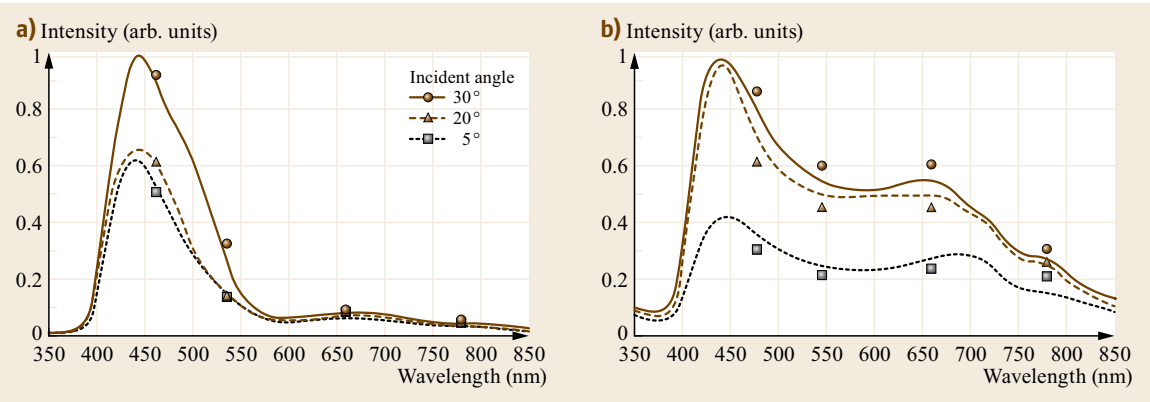

Fig. 4.15a,b Intensity curves of the reflection spectra for **(a)** *Morpho* butterfly scales. **(b)** *Morpho* butterfly scale quasistructure

FIB-induced CVD can be used to fabricate such a quasistructure.

We measured the reflection intensities from *Morpho* butterfly scales and the *Morpho* butterfly scale quasistructure optically; white light from a halogen lamp was directed onto a sample with angles of incidence ranging from 5 to 45°. The reflection was concentrated by an optical microscope and analyzed using a commercially available photonic multichannel spectral analyzer system (PMA-11: Hamamatsu Photonics K.K., Hamamatsu City, Japan). The intensity of light incident from the halogen lamp had a peak at a wavelength close to 630 nm.

The *Morpho* butterfly scale quasistructure was made of DLC. The reflectivity and transmittance of a 200 nm thick DLC film deposited by FIB-induced CVD, measured by the optical measurement system at a wavelength close to 440 nm (the reflection peak wavelength of the *Morpho* butterfly), were 30 and 60%, respectively. Therefore, the measured data indicated that the DLC film had high reflectivity near 440 nm, which is important for the fabrication of an accurate *Morpho* butterfly scale quasistructure. We measured the reflection intensities of the *Morpho* butterfly scales and the quasistructure with an optical measurement system and compared their characteristics. Figure 4.15a,b respectively show the reflection intensities from *Morpho* butterfly scales and the quasistructure. Both gave a peak intensity near 440 nm and showed very similar reflection intensity spectra for various angles of incidence. We have thus successfully demonstrated that a *Morpho* butterfly scale quasistructure fabricated using FIB-induced CVD has almost the same optical characteristics as real *Morpho* butterfly scales.

4.3 3-D Nanostructure Fabrication by Electron Beam

4.3.1 Electron-Beam-Induced Chemical Vapor Deposition

When an EB is irradiated onto a substrate, source gas molecules adsorbed on the substrate are dissociated into nonvolatile and volatile materials by an EB-induced surface reaction. Nonvolatile materials are deposited on the substrate, while volatile materials are evacuated. Nanostructures can be fabricated by EB-induced CVD, because beam diameters, as small as 1 nm, can be formed with an SEM or STEM. Computer-controlled direct writing is also possible for EB-induced CVD. Metals, semiconductors, and inorganic metals can be deposited in this way.

In 1976, *Broers* et al. were able to deposit nanometer-scale carbon contamination structures in a STEM with electrons of 45 keV energy [4.30]. In 1984, *Matsui* and *Mori* obtained the first metal-containing deposits by introducing a metal-organic gas ($Cr(C_6H_6)_2$) vapor into the vacuum chamber of an SEM [4.31]. In the over 30 years since the first experiments, many metal-containing structures have been deposited by EB-induced CVD under a wide range of experimental conditions [4.32–48]. The first metal-containing 3-D nanostructures were deposited in 1986 by *Koops* et al. [4.33], using an SEM.

Several excellent reviews have been published in recent years [4.49–51]. In addition, the principle, spatial resolution, mechanical properties, and magnetic and electric properties of EB-induced CVD have been reported [4.52–55]. Furthermore, various device applications including electrodes for carbon nanotube devices,

plasmonic gold nanostructures, domain wall conduit behavior in cobalt nanowires, optical monopole antenna and metamaterials have been demonstrated [4.56–61]. Its nanometer resolution has led to EB-induced CVD being indispensable for mask repair techniques for the 193 nm node [4.62].

In situ Observation of Electron-Beam-Induced CVD by Auger Electron Spectroscopy

When source gas molecules adsorbed on a substrate are dissociated by EB irradiation, Auger electrons are emitted from deposited materials at the same time. Therefore, the growth process of the deposited material can be observed in situ by Auger electron spectroscopy (AES) [4.63]. Figure 4.16 shows an in situ AES observation system for EB-induced surface reactions. This system was constructed by modifying a conventional AES apparatus. A source chamber and mass flow controller (MFC), which controls the source gas flow rate, were added to the conventional AES apparatus. The system was evacuated by an ion pump (IP) with a 2×10^{-9} Torr base pressure after bake-out. This system also contains an EB gun, a cylindrical mirror analyzer (CMA), and an Ar ion gun. The source gas is introduced through the MFC and the source gas molecules are adsorbed onto the substrate. The source gas molecules adsorbed onto the substrate are dissociated by a primary EB from the AES system and nonvolatile materials are deposited onto the substrate. At the same time, Auger electrons are emitted from the deposited material surface. Therefore, the growth process of the deposited materials can be observed in situ by detecting Auger electrons using the CMA. In this experiment, in situ AES observation has been carried out for W deposition using a WF_6 source gas on a Si(100) substrate. The EB voltage and current were 10 keV and 1 μA, respectively. This experiment was carried out by point beam exposure. The minimum beam diameter of the AES apparatus is ≈ 1 μm. However, a ≈ 30 μm beam diameter, which was obtained by defocusing, was applied to avoid beam profile effects and to obtain a uniformly deposited film. Therefore, the beam current density was $\approx 0.14\,A/cm^2$. The EB was irradiated at room temperature. It was estimated from calculations that the temperature increase on the sample during EB exposure was less than 10 °C.

Figure 4.17 shows Auger intensity variations during EB irradiation at 3.5×10^{-7} Torr WF_6 source gas pressure. W Auger intensity increases exponentially as the EB exposure time increases. W Auger intensity saturates at a 10 min exposure time, because the deposited W film thickness reaches the escape depth. Conversely, Si Auger intensity decreases, because the deposited W film was formed on an Si substrate. The contents (at.%) calculated from the AES spectrum, as shown in Fig. 4.17, were 85% W, 7.5% F, and 7.5% O at 15 min exposure time. It is believed that O originates from residual oxygen in the source and sample chambers. If an ultrahigh vacuum of the order of 10^{-10} Torr is achieved in both chambers, a higher quality film will be deposited. A growth rate for EB-induced CVD has been calculated on the assumption of layer growth. The calculated growth rate at 3.5×10^{-7} Torr is 0.15 nm/min.

In situ Observation of Electron-Beam-Induced CVD by TEM

The growth process of the deposited material can be observed in situ by TEM, if WF_6 source gas molecules are adsorbed on a TEM specimen [4.64]. The EM-002A

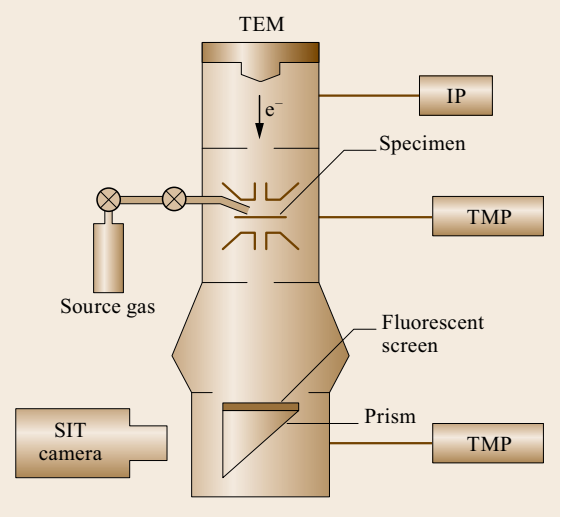

Fig. 4.18 Experimental arrangement diagram of TEM in situ observation. The gas-introducing system and VTR system are included. SIT: Silicon Intensifier Target, TMP: turbo-molecular pumps

(Akashi Beam Technology Corp.) electron microscope was employed, equipped with a real-time TV monitoring system, specially improved for in situ observation as shown in Fig. 4.18. The microscope resolution was 0.23 nm at 120 keV, which allowed the imaging of individual rows of atom columns in W crystals. To reduce problems in regard to specimen contamination, the instrument was operated with an ultrahigh vacuum pumping system with turbo-molecular pumps (TMP) and ion pumps. The gas injection tube had a 3 mm inner diameter and was about 5 mm from the sample surface. Fine and spherical Si particles, about 60 nm in diameter, were used as TEM specimens. The small particles were made by a gas evaporation method in argon under a reduced atmosphere, where the Si vapor was condensed into small particles. They were less than 100 nm in diameter and were usually covered with 1–3 nm thick SiO_2. The gas molecules were adsorbed on the fine Si particles, which were on the TEM specimen grid. The gas molecules were excited by the TEM's EB and dissociated into W metal and F_2 gas. W metal was deposited on the Si surface and growth occurred. The growth process was observed in situ at a single atom resolution level by an electron microscope equipped with a TV monitoring system. All micrographs were reproduced from single frames of the video tape recorder (VTR) tape. Two types of experiments were performed in this experiment. First, the EB was irradiated on a WF_6 adlayer formed on the fine Si particle surface, in order to clarify an initial growth process of EB-induced CVD. Second, the EB was irradiated on the Si fine particle surface while WF_6 was flowing on the surface, to study the layer growth process of EB-induced CVD.

Figure 4.19 shows a typical series of electron micrographs of in situ TEM observation variations during EB irradiation for the WF_6 adlayer. These micrographs were selected from a VTR tape which ran over a 30 min

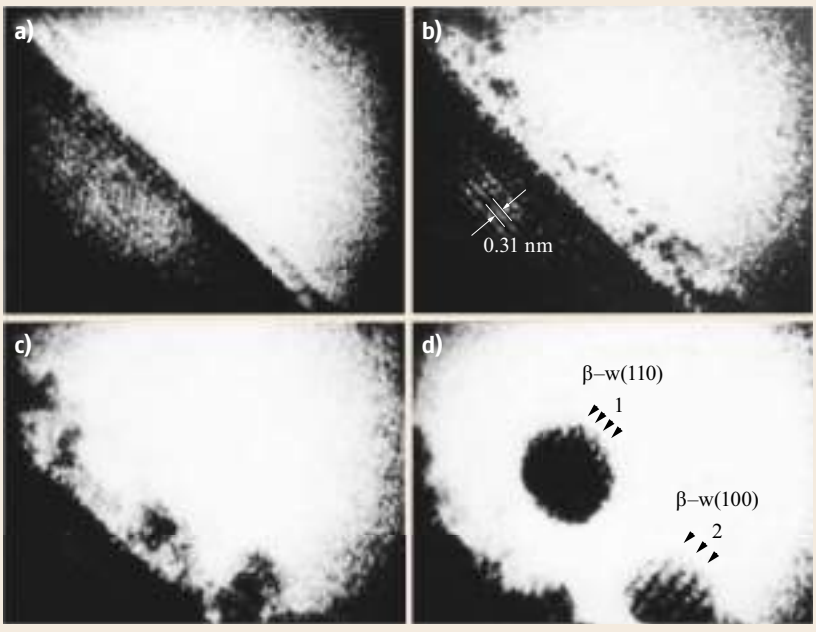

Fig. 4.19a–d EB exposure time dependence of W cluster growth on a Si particle. Exposure times: **(a)** 0 min, **(b)** 3 min, **(c)** 15 min, and **(d)** 30 min

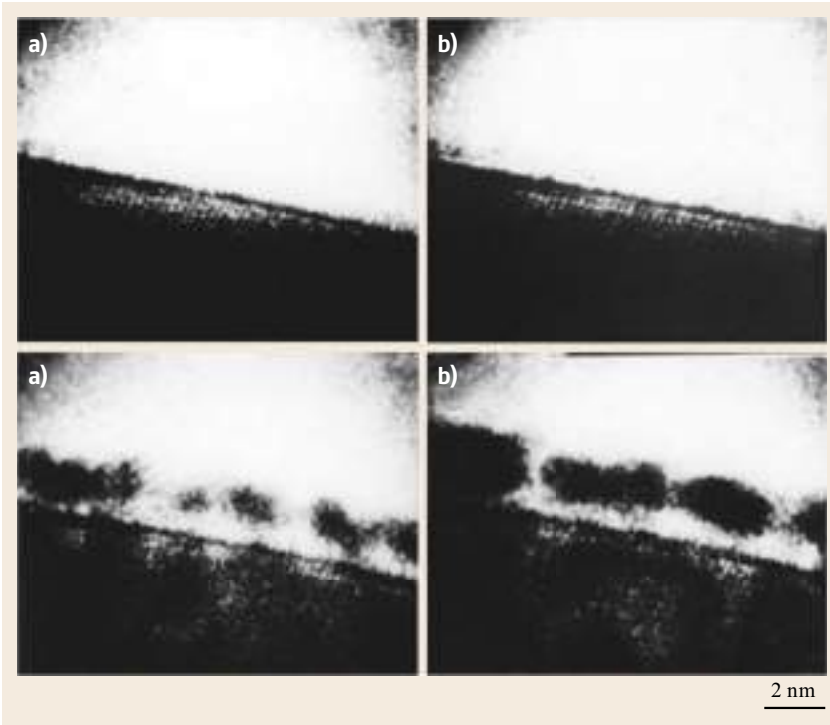

Fig. 4.20a–d EB exposure time dependence of W layer growth on fine Si particles at 5×10^{-7} Torr WF_6 gas pressure. Exposure times: **(a)** 0 s, **(b)** 15 s, **(c)** 25 s, and **(d)** 30 s

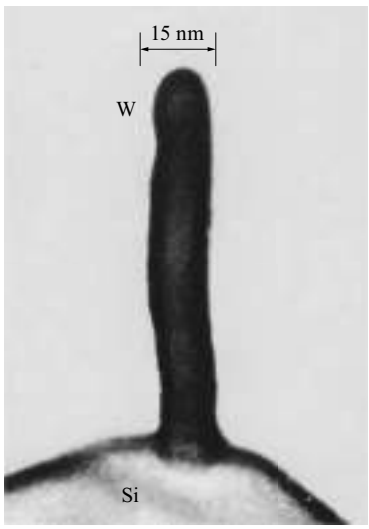

Fig. 4.21 Electron micrograph for a W rod with 15 nm diameter. The W rod was fabricated using a 120 kV EB with 3 nm diameter

span. Electron beam irradiation times for Fig. 4.19a–d were 0, 3, 15, and 30 min, respectively. This result indicates that W atoms, dissociated by EB irradiation from the WF_6 adlayer, coalesced and grew under EB irradiation. According to the real-time observation on a TV screen, moving clusters often collided with each other, causing coalescence. Figure 4.20 shows TEM in situ observation variations during EB irradiation under 5×10^{-7} Torr WF_6 gas pressure. Electron beam irradiation times were 0, 15, 25, and 30 s for Fig. 4.20a–d, respectively. These micrographs indicate that the W clusters were formed as the initial growth state and then the W layer was formed by coalescence of the clusters due to EB irradiation. A nanometer-scale W rod was fabricated by a focused EB (3 nm diameter) moved manually under a 1×10^{-6} Torr WF_6 gas atmosphere. Electron beam energy was 120 keV and its current density was $\approx 100\,A/cm^2$. The moving speed of the beam was 1 nm/s. The EB was parallel to the substrate and its scanning direction was normal to the surface. An electron micrograph of the fabricated W rod is shown in Fig. 4.21. The rod's radius was ≈ 15 nm. The bright inner rod contrast shows that the center of the rod was probably tungsten silicide. The beam conditions for rod formation were not the same as those for taking electron micrographs. The EB was spread to about a 1 μm diameter for taking this photograph.

High Resolution of Electron-Beam-Induced CVD by STEM

Tanaka et al. reported on the resolution of EB-induced CVD by STEM [4.43]. The TEM instrument used in this study was a JEM-2000VF with a field emission gun and the base pressure of the chamber was 1×10^{-7} Pa. The deposition apparatus was attached to a vacuum port of the TEM column. It consisted of a variable leak valve, a gas nozzle ≈ 1 mm in diameter, and a heating system.

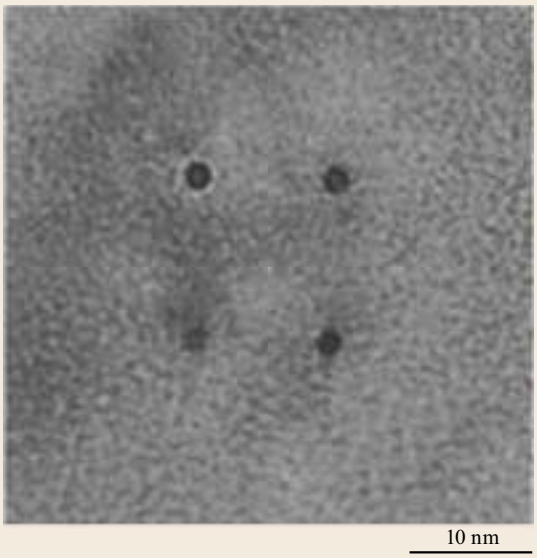

Fig. 4.22 TEM image of W nanodots deposited over deferent times. The *top left* dot was fabricated over 15 s, the ones on the *right* were fabricated over 10 s, and the *bottom left* nanodot was fabricated over 5 s. (Reprinted with permission from [4.43])

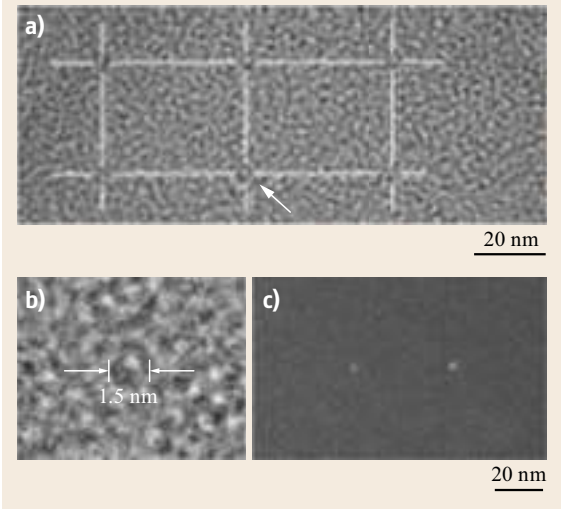

Fig. 4.23a–c An array of the smallest W nanodots ever achieved by EB-induced CVD: **(a)** TEM image of the array; **(b)** magnified image of one of the dots shown by the *arrow* in **(a)**; **(c)** the corresponding HAADF-STEM (High-angle annular dark-field-scanning transmission electron microscope) image. (Reprinted with permission from [4.43])

The substrates were Si(111), conventionally dimpled and ion-milled. Most of the EB-induced CVD experiments were performed on the thinnest parts of the substrate, mostly amorphized during the ion milling. The precursor gas was $W(CO)_6$ and the EB-induced CVD was carried out at room temperature. The microscope was operated at 200 kV. The EB intensity was $\approx 5 \times 10^3 - 5 \times 10^4$ A/cm^{-2} and the prove size was $\approx 1-2$ nm. By using a 2 nm probe, arrays of dots were fabricated successfully from $W(CO)_6$. Figure 4.22 shows a TEM image of one of the arrays. Irradiation times for dot manufacture were 15 s (*top left*), 10 s (*top right* and *bottom right*), and 5 s (*bottom left*), respectively. The pressure during the deposition was kept at 2×10^{-6} Pa. The distance between the dots in the horizontal direction was $\approx$ 12 nm and in the vertical direction was $\approx$ 14 nm. Their structure was shown to be mixed amorphous W-C as they contain carbon from the precursor gas. It was recognized that dot size decreased as irradiation time was shortened. Size measurements showed that the 15 s dot was $\approx$ 3 nm in diameter, the 10 s dots were $\approx$ 2.5 nm, and the 5 s dot was $\approx$ 2 nm, respectively.

Figure 4.23 shows an array of dots formed with a 1 nm probe and a deposition period of 5 s. In Fig. 4.23a, a TEM image of the array is shown. The dots are located at the intersection points of the white lines. They are so small that it is hard to distinguish them from the amorphous substrate. The size of the dot is $\approx$ 1.5 nm. To prove that they really were mixed tungsten nanodots, HAADF-STEM images were taken for the same substrate, which produces Z-contrast images, i. e., the image is atomic number sensitive in that a heavy atom makes a brighter contrast. Figure 4.23c shows one of these images. The distance between the dots and the size of the dots almost match those of the TEM images, thus indicating that they are the nanodots.

4.3.2 3-D Nanofabrication by Electron-Beam-Induced CVD

Koops et al. reported on 3-D nanostructure fabrication using EB-induced CVD. This technique is very well suited for rapid-prototyping of photonic crystals (PhCs) [4.39]. The nanolithography tool in use is based on a SEM (JSM 6300 F, JEOL Ltd.) with the beam control system VIDAS (Kontron). All possible precautions have been taken to compensate for thermal drifts, mechanical vibrations, and magnetic interference by external compensating systems. These measures allow high-precision fabrication of 2-D arrays of dielectric rods with the dimensions required for PhCs. A specially designed environmental chamber is used for supply of precursor material to the waveguide sample [4.37]. The EB-induced CVD process renders 2 nm edge roughness for the deposited rods. This is a surface quality which is unreachable by standard lithography or beam-assisted etching techniques. It allows one to minimize scattering of photons. The high-resolution TEM image shown in Figure 4.24 proves a wall roughness of < 2 nm for a rod grown by EB-induced CVD using cyclopentadienyl-platinum-trimethyl as the precursor material. Electron-beam-induced CVD constructs the rods from nanocrystals of 2 nm diameter embedded into a carbonaceous matrix. This results in an edge roughness of below 2 nm, which is an outstanding feature of this process, as demonstrated in Fig. 4.24.

PhCs with cubic, hexagonal, or honeycomb elementary cells are fabricated under computer control. A VIDAS macro language allows one to quickly adjust the design parameters of the crystals that are to be grown. There are no other process steps required to generate a crystal by this time-consuming growth process. Using 25 keV electrons and a 20 pA current, a crystal of 100 rods is grown in 40 min. Over this period, the sample in the microscope is not allowed to drift more than 20 nm. Figure 4.25 shows a cubic PhC, which is grown inside a prefabricated gap in a PMMA (Poly(methyl methacrylate)) waveguide for investigation of the transmission properties of the PhC. The pitch is 580 μm, the rod diameter is 150 nm, and the height is 2.5 μm. Characterization of PhCs and related devices is a very challenging task. This is because of the small size of the devices, having diameters of 3–6 λ, which is 4.5–9 μm at $\lambda = 1.5$ μm. Monomode fibers have a core diameter of 9 μm. Therefore, a well-designed optical beam converter is required to couple light into PhCs. To measure the polarization-dependent transmission of PhCs, a sophisticated metrology set-up was used. The transmission measurement did prove a band gap filter in the regime from 1250–1650 nm.

Electron-beam-induced CVD is a rapid prototyping technology with a high resolution and accuracy to investigate the activity and characteristics of PhCs and PhC devices. Recently, *Tasco* et al. reported on fabrication of 3-D nanohelices for chiral photonics by FIB- and EB-induced CVD [4.65]. The initial promising results prove the applicability of the technology and the optical action of the devices.

Electron-beam-induced CVD can build similar structures in sub-μm dimensions with wires of 80–200 nm. Figure 4.26 shows a 3-D build-up with conducting material resembling a field-emission electron source, with an emitter tip and an extractor ring around it [4.40]. The structure has a capacitance of 24 aF between the tip and the ring.

4.4 3-D Nanostructure Fabrication by Laser

4.4.1 3-D Nanostructure Fabrication by Femtosecond Laser

The advent of laser micro/nano fabrication can be traced back to the 1960s, soon after the invention of the laser. The observed photomodifications of laser rod materials and the formation of ripples on irradiated surfaces revealed the potential of laser structuring of materials. The development of the ultrafast fs-laser led to the development of the field of laser material processing, and fs-laser-assisted micro/nano fabrication has since been recognized as a promising technique to fabricate 2-D structures on the surface of materials or 3-D structures inside transparent materials [4.66, 67]. The spatial resolution of laser fabrication can reach submicrometer levels and even tens of nanometers owing to the suppression of the involved heat diffusion and nonlinear absorption.

Principles and Methods of Femtosecond Laser Nanofabrication

The mechanisms of fs-laser nanofabrication are based on the photomodification of materials. Photomodification can be categorized into different types such as optical damage or modification of the refractive index in transparent dielectric materials, ablation on the surfaces of solid materials, and multiphoton photopolymerization in photoresists or resins. Currently, there are several 3-D fs-laser nanofabrication methods. The most widely used methods are the direct laser writing (DLW) technique and multiple beam interference lithography, as schematically shown in Fig. 4.27.

Here, we have chosen the DLW technique as an example to explain the most common principles of fs-laser nanofabrication. Typically, DLW is performed by scanning a tightly focused fs-laser beam in accordance with a designed 3-D pattern. The photomodification processes occur in the waist of the focused laser beam, where the optical field intensity is highest. The effective photomodification region can be approximated by an ellipsoid, as illustrated in Fig. 4.27a. The use of tightly focusing optics (i. e., an objective lens with a high numerical aperture) typically allows the lateral dimensions of the ellipsoid to approximate the wavelength λ. For 3-D nanofabrication inside materials, the materials must be transparent at the laser wavelength so that nonlinear absorption is considered for photomodification. Because of the nonlinearity, the effective absorbing region can be even smaller than that of the focal spot, enabling structural resolution beyond the optical diffraction limit. For fs-lasers operating at near-infrared and visible wavelengths, feature sizes of 100–300 nm in 3-D structures are easily achievable. In some special cases, especially for linear structures, a resolution of tens of nanometers has also been demonstrated.

Alternatively, multiple beam interference lithography can be used for laser nanofabrication. This method involves exposing a photosensitive medium to a periodic interference field created by several coherent laser beams that overlap at nonzero mutual angles. Typically, the original beam passes through an optical element (i. e., beam splitter, prism, or grating) that splits the beam into several coherent beams to form the desired interference patterns. In particular, 3-D periodic or quasiperiodic structures can be created with a resolution on the order of several hundred nanometers. Compared to the DLW technique, larger scale structures can be easily implemented. However, this technique is not as flexible as DLW, in which any desired 3-D geometry can be achieved.

Various Nanostructures Fabricated by Femtosecond Laser

A wide range of materials can be used for DLW, including silica or other glasses (by optical damaging), liquid photopolymerizable resins (by photosolidification), or photoresists (by photopolymerization). The

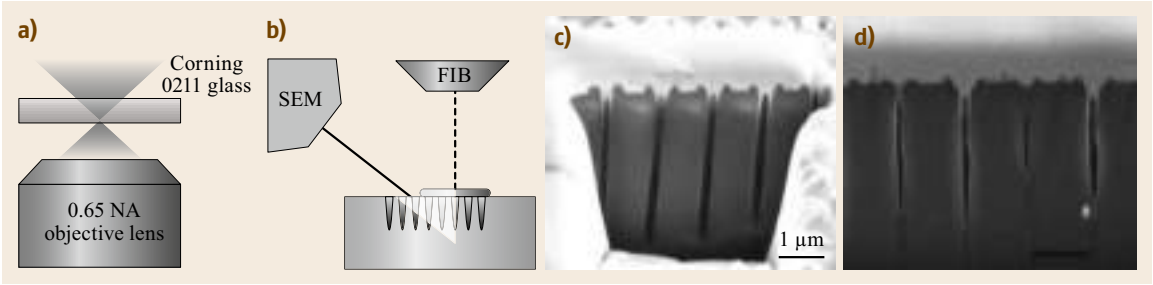

Fig. 4.28 **(a)** An illustration of the machining geometry for the array of nanochannels. **(b)** A sample examined under a dual-beam FIB–SEM to study the cross-sections of nanochannels. **(c)** An example cross-section for back side machining. **(d)** An example cross-section for front side machining (after [4.68])

first example, shown in Fig. 4.28, is high-aspect ratio nanochannel formation in glass by single tightly focused fs-laser pulses [4.68]. The nanochannels can be fabricated from both the back (Fig. 4.28c) and front (Fig. 4.28d) of the glass sample. Here, the width of the nanochannels is in the 150–240 nm range, much smaller than the width (344 nm) of the focused laser beam, providing clear proof that the structural resolution or the feature size of the structures fabricated by fs-lasers can be considerably smaller than the optical diffraction limit.

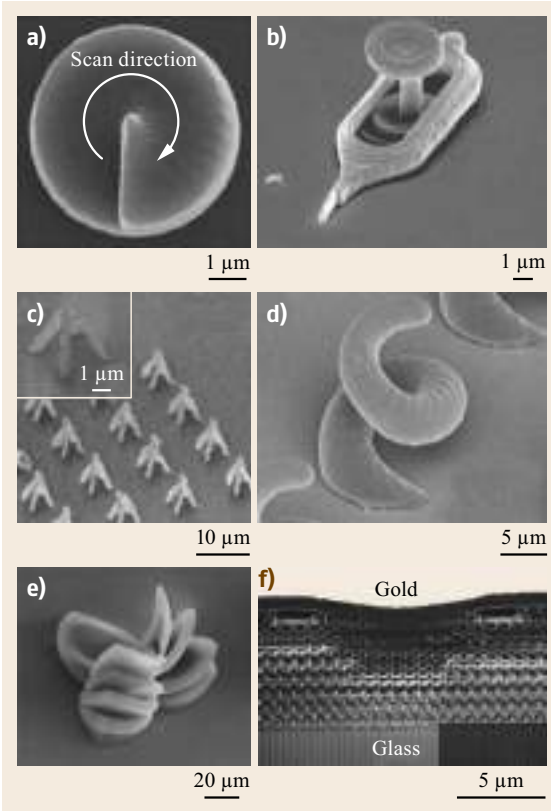

Figure 4.29 shows various 3-D micro/nanostructures fabricated using fs-lasers by different research groups. Direct fs-laser photopolymerization in resists was used to fabricate a high-resolution microscopic spiral phase plate (Fig. 4.29a) that can be used to generate vortex beams [4.69]. Using a similar technique, movable micromanipulators with submicron probe tips were also fabricated and demonstrated the ability to manipulate nanoscale objectives (Fig. 4.29b) [4.70]. Metal micro/nanostructures that may have applications in metamaterials can also be fabricated by fs-lasers. Figure 4.29c shows an array of freestanding 3-D 5 µm high silver pyramids fabricated by fs-laser DLW based on multiphoton photoreduction in a metal-ion solution [4.71]. Coating a polymeric template fabricated by fs-laser DLW with metal using the selective electroless metal plating technique is another approach for obtaining metal structures. Silver spiral structures were obtained using this method, as shown in Fig. 4.29d [4.72]. Biomimetic and biological nanofabrication were also demonstrated using a so-called dynamic laser prototyping technique based on fs-laser DLW. For example, the flower blooming process has been successfully mimicked and a typical bloomed *flower* is shown in Fig. 4.29e [4.73]. Figure 4.29f shows an fs-laser-fabricated 3-D invisibility-cloaking structure operating at optical wavelengths [4.74]. These examples demonstrate the versatility of fs-laser nanofabrication.

4.4.2 3-D Nanodevices: Fabrication of Photonic Crystals

PhCs are periodically structured materials that have attracted much attention owing to their unique properties, such as the manipulation of light propagation at a certain range of frequencies, called photonic band gaps (PBGs) or stop bands. Thus far, a variety of PhC structures have been investigated both theoretically and experimentally. For 1-D (one-dimensional) or 2-D PhCs, periodicity is present only in one or two dimensions, respectively and therefore such PhCs can be formed by many methods. Fabrication of 3-D PhCs is more difficult, especially for those with PBGs at the optical frequencies.

Fabrication of Photonic Crystal in Photoresists by DLW

Fs-laser structuring of materials is a promising technique for successful implementation of 3-D PhCs with spatial resolutions in the hundred-nanometer range. In particular, since 1999, the two-photon polymerization technique in photoresists or resins by DLW has been demonstrated as a powerful tool for the fabrication of 3-D PhCs [4.75, 76]. Two popular PhC geometries are often used in our DLW technique. The first is the woodpiles architecture (Fig. 4.30a,b), and the second is the square spiral architecture (Fig. 4.30c). Regarding the resist materials, SU-8 was previously the most frequently used resist, but organic-inorganic hybrid resists such as SZ2080 have now also become popular.

The optical setup for 3-D DLW used in our experiments is schematically shown in Fig. 4.30d. A chirped-pulsed amplifier (CPA) Ti:sapphire laser (Hurricance, Spectra-Physics) was used as the light source for DLW. It delivered ≈ 120 fs-laser pulses at a central wavelength of 800 nm with a repetition rate of 1 kHz. The laser beam was sent to an optical microscope (IX71, Olympus) and was focused into the sample by an oil-immersion objective lens (magnification 100×, numerical aperture NA = 1.40) along the z-direction. The sample was mounted on a piezoelectric transducer-controlled 3-D translation stage (x-y: P-517.2CL and z: P-518.ZCL, from Physik Instrumente), allowing fabrication within a volume of $100 \times 100 \times 100\,\mu m^3$ with an accuracy of ≈ 2 nm. After exposure to the laser, the samples were developed and rinsed.

The square spiral architecture was proposed to have complete PBGs. The square spiral structures were successfully fabricated from silicon using the glancing angle deposition (GLAD) method which uses the growth of silicon spirals on prepatterned substrates [4.80]. However, the DLW technique enables easier fabrication of both square spirals and circular spirals. Furthermore, variants with greater complexity (e.g., those containing defects or phase-shifted spirals) that are sometimes necessary for a particular application or optimization of the PBG properties can only be fabricated by DLW. Figure 4.31a,b show typical square spiral and circular PhCs, respectively, fabricated by DLW [4.77]. Here, the adjacent spirals are interlaced with each other. The ability to create defects in PhCs by DLW is also illustrated

The *top inset* shows the transmission spectrum of the sample with $c = 1.55$ μm. The central wavelengths of the reflectivity peaks are indicated in the plot in micrometers, demonstrating the stop bands in the telecommunications spectral range. **(c)** SEM image of a woodpile PhC in SZ2080, **(d)** transmission and reflection spectra of the woodpile structure, with the stop band centered at 1.3 μm. ((**a**,**b**) from [4.78], (**c**,**d**) after [4.79])

in Fig. 4.31a, where an L-shaped line defect is formed. Notably, the π-phase shift between the adjacent spirals, as shown in Fig. 4.31b, would not be achievable by the GLAD technique. The reflection and transmission spectra of this type of square spiral PhC are presented in Fig. 4.31c, showing that the photonic stop bands are in the infrared wavelength range of 2–6 μm.

For other types of spiral PhCs, where the spirals are not interlaced, the lattice constant can be reduced to $\approx$ 1 μm as shown in Fig. 4.32a [4.78]. In this case, the stop band can be engineered in the telecommunication wavelengths, as shown in Fig. 4.32b. For woodpile PhCs, it is also possible to tailor the stop band in this wavelength range. For example, Fig. 4.32c,d show an SEM image and reflection spectra, respectively, of a typical woodpile PhC [4.79]. The stop band is located at 1.3 μm. However, engineering the stop band to shift to a shorter wavelength and even into the visible region is very difficult. Such engineering may require the reduction of the voxel size using low-pulse energy close to the polymerization threshold. This will cause the structure to shrink [4.79, 81], as discussed below.

Shrinkage

Shrinkage is usually an undesirable feature for photopolymerized micro/nanostructures fabricated by the

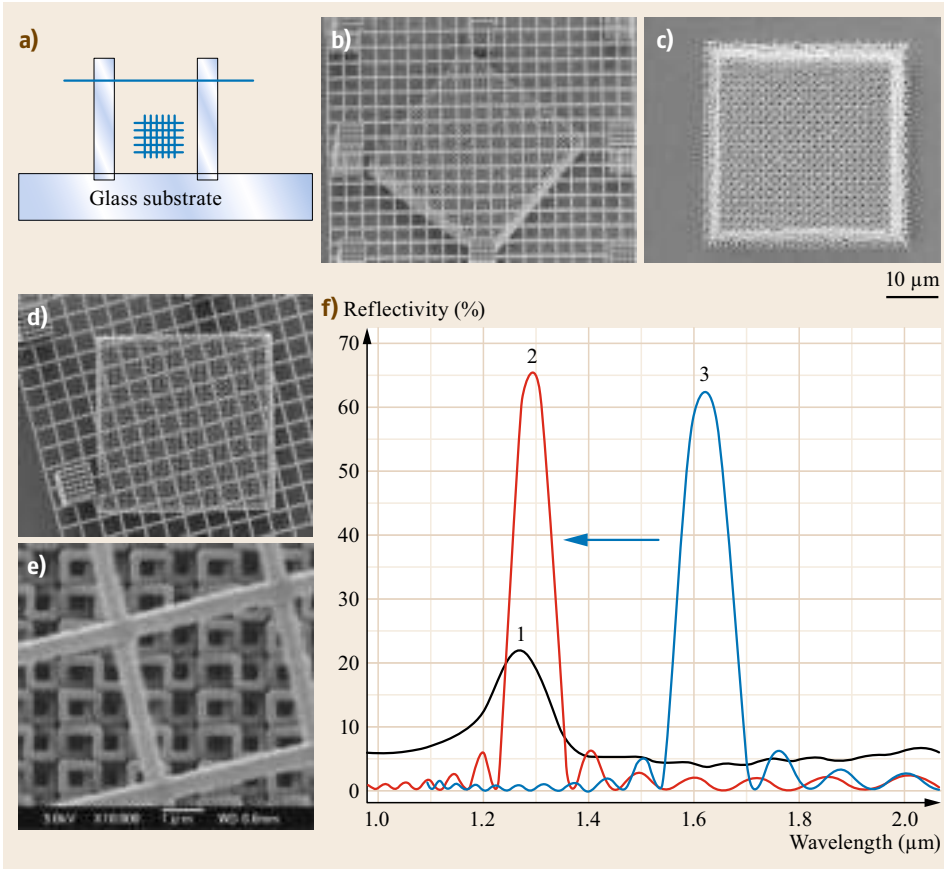

Fig. 4.33 **(a)** Schematic diagram of freestanding architecture fabrication. **(b)** SEM image (oblique view) of a freestanding square spiral PhC in SZ2080. DLW technique in resists. The shrinkage is normally nonuniform because the bottom of a conventional structure is attached to the substrate. We proposed a way to fabricate freestanding structures that can enable highly uniform shrinkage [4.81]. Figure 4.33a illustrates the concept of the freestanding architecture. These structures were fabricated while floating on the substrates. However, such structures would escape during the development process. To prevent this, we also fabricated cages to house the freestanding structures. An SEM image (oblique view) illustrating this approach is presented in Fig. 4.33b, which shows that after development the freestanding PhC is moved from its original position (*center* of the cage) as fabricated. The structure still exhibits some shrinkage. However, by comparing conventional and freestanding PhCs (Fig. 4.33c,d), we find that the freestanding PhC shows almost uniform shrinkage, in contrast to the nonuniform shrinkage observed in the conventional PhC. The fabricated freestanding structures allowed us to quantitatively measure the shrinkage, defined as $(W_0 - W)/W_0$, where W and W_0 are the measured structure width and the corresponding design value, respectively. It was found that the amount of shrinkage depends on the pulse energy used for DWL and that the maximum shrinkage can reach 20% with the lowest allowable pulse energy, beyond which the structure collapses. The freestanding PhCs still exhibit high structural quality and good periodicity, as shown in Fig. 4.33e. Therefore, such PhCs exhibit good optical properties and their stop bands can be scaled towards shorter wavelengths, thus benefiting from uniform shrinkage, as illustrated in Fig. 4.33f.

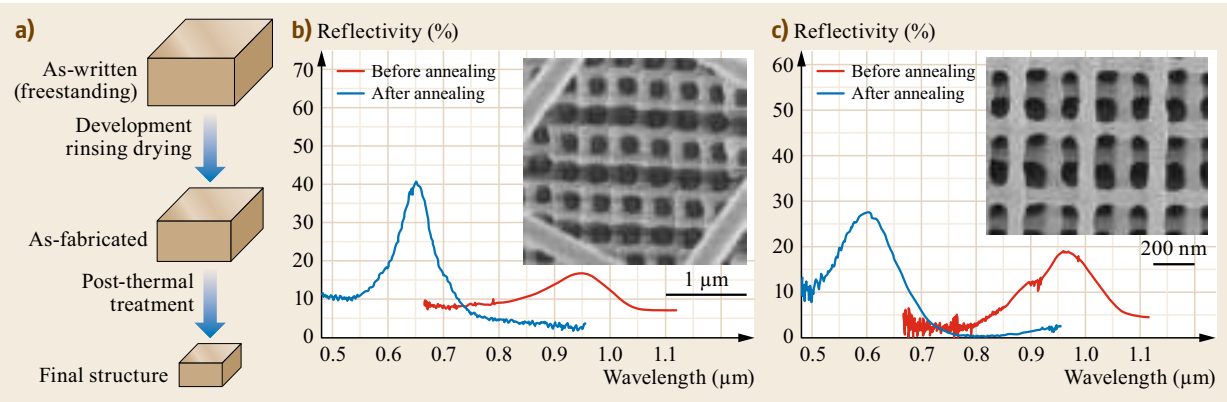

Fig. 4.34 **(a)** Schematic diagram of combined freestanding architecture and post-thermal treatment. Reflection spectra of a square spiral PhC **(b)** and a woodpile PhC **(c)** before and after annealing. The final stop bands for the spiral and woodpile architectures are 650 and 600 nm, respectively. The *insets* in **(b)** and **(c)** are SEM images of the corresponding PhCs

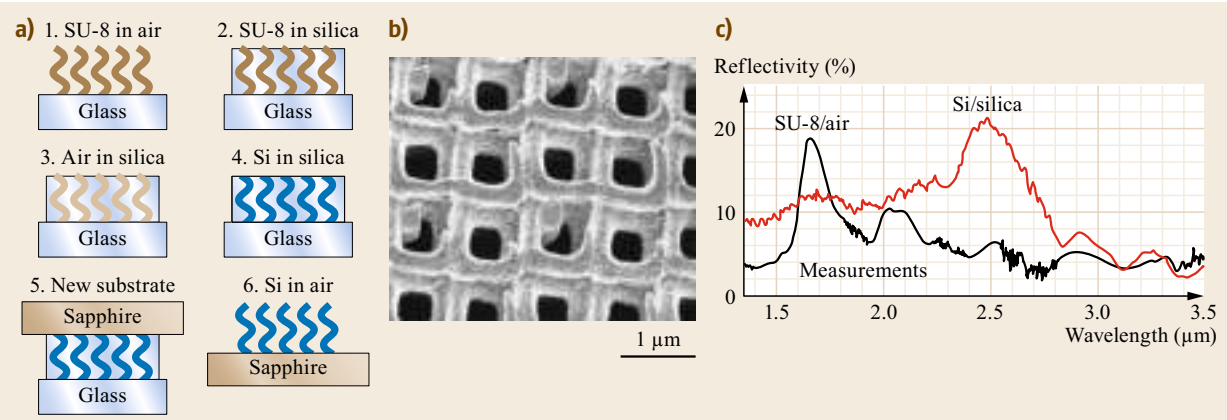

Fig. 4.35 **(a)** Main steps of the double-inversion process of SU-8 templates by silicon. **(b)** SEM image of the silicon PhC fabricated by the double-inversion technique. **(c)** Reflection spectra of the 3-D spiral PhC template of SU-8 before and after its replication by silicon. We also investigated the effect of the drying process on the shrinkage. By measuring the evolution of the optical properties of fabricated PhCs and recording online optical images during the drying process, we demonstrated that the drying process plays the most important role in the structural shrinkage of photopolymerized structures [4.83]. Furthermore, we found that the structures experienced additional shrinkage when we baked the fabricated structures. This was mostly because our material was an organic-inorganic resist, so the organic part could be degraded during the thermal treatment. We then hypothesized that very large uniform shrinkage could be achieved if we combined the freestanding configuration and such post-thermal treatment, as illustrated in Fig. 4.34a. By carefully choosing the lattice constant of a square spiral PhC and the irradiated pulse energy, we successfully obtained a shrinkage magnitude as large as 46% after baking at 300 °C for 3 h. Owing to such large shrinkage, the stop band of the PhC was successfully shifted into the visible range. As clearly shown in Fig. 4.34b, the stop band was centered at 650 nm, while prior to the thermal treatment it was centered at 950 nm. It is important to note that previously the stop band position of a square spiral PhC fabricated by DLW could hardly reach 1 μm. Additionally, the lattice constant of the PhC was reduced to below 400 nm (*inset* in Fig. 4.34b); this was impossible to achieve with the conventional DLW technique without employing the freestanding configuration and post-thermal treatment. For the woodpile PhCs, we even succeeded in pushing the stop band to 600 nm after annealing, as shown in Fig. 4.34c. The shrinkage can also be used to improve the structural resolution of DLW-fabricated micro/nano structures. As shown in the

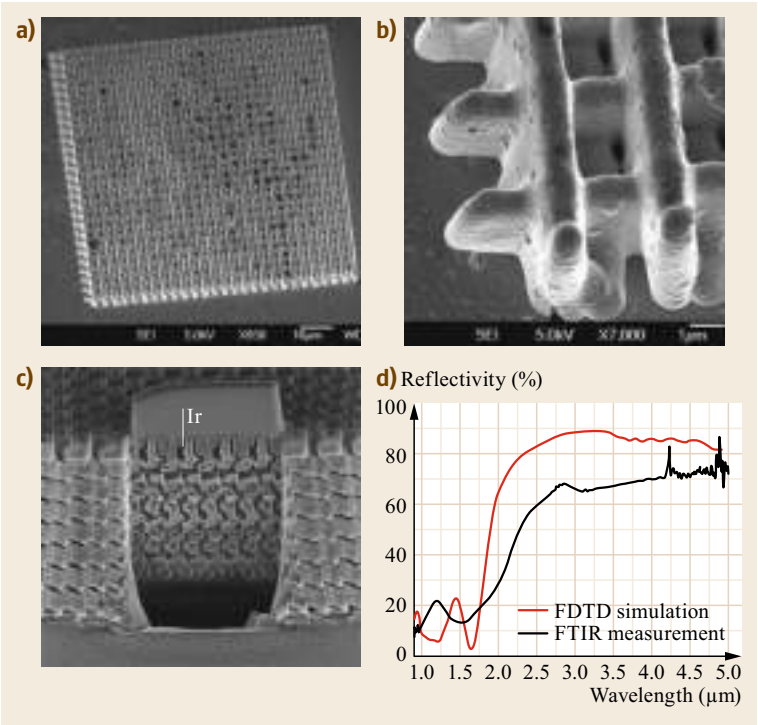

Fig. 4.36 **(a,b)** SEM images of a woodpile PhC coated by Ni film using electroless coating. **(c)** SEM image of a square spiral PhC coated by Ir. The layer of Ir was confirmed by the cross-section cut by FIB. **(d)** FTIR measured and FDTD calculated optical reflection spectra at infrared wavelengths. ((**a,b**) from [4.84])

insets of Fig. 4.34b,c, the linewidth of the structure is only $\approx 100\,\mathrm{nm}$.

Replication of PhCs with Other Materials

The polymeric PhCs fabricated by DLW cannot have omnidirectional PBGs owing to the low index contrast between the photoresist and the surrounding air (1.6–1 for SU-8, 1.5–1 for SZ2080). Nevertheless, the polymeric PhCs are suitable for subsequent infiltration by other dielectric materials with a higher refractive index or a metal material.

As one example, we applied the double-inversion technique to invert the templates to silica structures and then again inverted to the silicon structure [4.82], as schematically shown in Fig. 4.35a. Figure 4.35b shows the SEM image of the replicated PhC after the double-inversion process. Compared to the templates, the PBG band was shifted to a longer wavelength because of the higher refractive index contrast, as shown in Fig. 4.35c.

Polymeric templates can also be coated with metals using metallic coating techniques. Figure 4.36a,b show a woodpile PhC coated by a film of nickel using electroless coating [4.84]. Figure 4.36c shows a square spiral PhC coated by an iridium film using atomic layer deposition. As observed from both the experimental measurement and finite-difference time-domain (FDTD) simulation of the reflection spectra shown in Fig. 4.36d, the iridium PhCs exhibit a very wide photonic band gap with a sharp band edge, showing potential for photonic and energy applications.

5. Nanoimprint Lithography

Helmut Schift, Anders Kristensen

Nanoimprint lithography (NIL) is an emerging high-resolution parallel patterning method, mainly aimed towards fields in which electron-beam and high-end photolithography are costly and do not provide sufficient resolution at reasonable throughput. In a top-down approach, a surface pattern of a stamp is replicated in a material by mechanical contact and three-dimensional material displacement. This can be done by shaping a liquid followed by a curing process for hardening, by variation of the thermomechanical properties of a film by heating and cooling, or by any other kind of shaping process using the difference in hardness of a mold and a moldable material. The local thickness contrast of the resulting thin molded film can be used as a means to pattern an underlying substrate at the wafer level by standard pattern transfer methods, but also directly in applications where a bulk modified functional layer is needed. This makes NIL a promising technique for high-volume manufacturing of nanostructured components. At present, structures with feature sizes smaller than 5 nm have been realized, and the resolution is limited by the ability to manufacture the stamp relief. For historical reasons, the term nanoimprint lithography refers to a hot embossing process (thermal NIL). In ultraviolet (UV) NIL, a photopolymerizable resin is used together with a UV-transparent stamp. In both processes thin-film squeeze flow and capillary action play a central role in understanding the NIL process. In this chapter we will give an overview of NIL, with emphasis on general principles and concepts rather than specific process issues and state-of-the-art tools and processes. Material aspects of stamps and resists are discussed. Specific applications are presented, where imprint methods have significant advantages over other structuring methods. We conclude by discussing the areas where further development in this field is required.

Take a piece of wax between your fingers and imprint your fingerprints into it from both sides. The pressure produced is sufficiently high to replicate the soft surface pattern of your skin into the wax by mechanical deformation. The process is facilitated by the heat resulting from your blood circulation, which softens the wax in order to make it deform until it conforms to the three-dimensional (3-D) pattern of your skin. The pattern resolution of below 1 mm is similar to that of the first records fabricated over 100 yr ago in celluloid. In 1887 *Berliner* applied for a patent on a so-called gramophone, which resembles Edison's phonograph with its wax-coated roll [5.1]. The information is inscribed into wax coated onto a zinc disk. The tracks are cut through the wax down to the solid zinc and are etched before using the zinc disk as a mold to press thermoplastic foils. With a playing time of little more than 1 min, those disks had track widths below 1 mm and resolution in the sub-100 μm range. Over the years the track size was reduced to below 200 μm. The materials changed from shellac to vinyl filled with carbon black. Today's digital versatile discs (DVDs) have pit sizes of below 400 nm and are fabricated in polycarbonate (PC) in a few seconds by injection molding. Disc formats such as blu-ray (BD) with further reduced pit sizes of 100 nm are the current state of the art [5.2, 3].

In this introduction some basic concepts of molding polymers are illustrated, ranging from the shaping of thin films by mechanical pressure to patterning of curable liquid resins by capillary action. The process is closely linked to the choice of stamps, molding materials, and needs to take into account the type of pattern transfer after molding is completed. A softened material can be deformed by pressure and the difference in mechanical properties makes it possible to replicate its surface pattern in a parallel, reproducible way. The squeezing of a thin film of wax leads to a lateral flow of material, but because of the high viscosity the process will slow down quickly and a residual layer, which cannot be thinned down to zero, will remain. Furthermore, the softness of the stamp and the viscosity of the material will determine the completeness of molding and thus the replication fidelity. Similar concepts of molding processes can be observed in daily life, such as imprinting a footprint into snow or clay, or making waffles by casting a liquid dough between two patterned iron plates with subsequent thermocuring, or by replicating a seal into wax (Fig. 5.1). One common important prerequisite of these molding processes is that the mechanical properties of the molded material can be changed by pressure, temperature or chemical processing. The material must be shaped in a viscous state but should keep its form during demolding. The imprint in snow is a hard molding by local densification, while the clay hardens by the squeezing out of water. The waffle is cured due to the thermochemical changes in the dough, and the seal can be demolded with high fidelity because the heat of the wax dissipates into the seal and the wax hardens during cooling. The processes described here are very similar to molding of viscous thermoplastic materials in the nanoimprint lithography (NIL) process [5.4, 5], where a thickness profile in a thin polymer film is generated by pressure, however, with the surprising difference that features below 10 nm can be replicated with unprecedented precision (Fig. 5.2). In contrast to conventional methods based on exposure and development, limitations imposed by the wavelength of exposure or by chemical reactions can be overcome.

The example with the fingerprint may even serve for the illustration of ink transfer in microcontact printing (μCP), as one example of soft lithography (SL) [5.6, 7]. While for NIL a hard stamp would ensure a more complete molding, here the softness of the stamp is essential to make a conformal contact of every protrusion, but at the expense of a possible reduction of the feature resolution due to local deformations in the stamp.

In this chapter we provide an overview of the different processes currently called nanoimprinting, from hot embossing of thermoplastic materials to molding and curing of liquid resins. After this introduction into the basics of molding, Sect. 5.1 places the two main NIL techniques into the context of the emerging nanopatterning methods for lithography and their difference to μCP. Section 5.2 describes the nanoprint and nanoimprint processes, beginning with a discussion about soft and hard elements in mechanical patterning, polymer properties and pattern transfer and their use in thermal and UV-assisted patterning of resists. It discusses the thermal NIL process as an important subset of processes, giving an insight into squeeze flow of thin films. Section 5.3 presents essential fabrication meth-

ods for stamps and tools for NIL. It discusses current materials and tools for NIL, ranging from stamps and resists to NIL machines. Section 5.4 presents typical applications that are currently envisaged both at an industrial and at a laboratory scale. Although for many people the main driving force behind NIL is its use as next-generation lithography (NGL) for complementary metal-oxide-semiconductor (CMOS) chip fabrication, the reader will be introduced to other applications that do not have the demanding overlay requirements imposed by multilevel processes. We conclude with an outlook in Sect. 5.5, where we discuss the prospects of NIL and aspects of its commercialization. Further information can be found in the references, but not least within this handbook in the chapters about silicon micromachining (Chap. 3) and soft printing (Chap. 6). In this chapter we restrict ourselves to the lithographic patterning of thin films on hard substrates. We present basic concepts rather than state-of-the-art tools and hot scientific issues. As a complement to this chapter, the reader is advised to refer to three publications. A review on NIL [5.8] deals with a range of process issues relevant for research and industry, and a deeper insight into advanced concepts of printing. Specific NIL processes and process flows for a variety of applications are presented in the NaPa (NanoPattering) library of processes (NaPa LoP) [5.9]. After 20 yr of NIL, in which NIL has become a technology much beyond infancy, other reviews have been presented [5.10, 11]. Finally, there are book chapters that refer to manufacturing-related issues of NIL technologies [5.12].

5.1 Emerging Nanopatterning Methods

Nanoimprint Lithography (NIL) is a replication technique that has been proven to provide a resolution unmatched by many other techniques, while at the same time offering parallel and fast fabrication of micro- and nanostructures. On the one hand, this enables the technique to branch out into fields where large areas covered by nanostructures or a number of identical structures for statistical evaluation are needed. This was often impossible due to the low throughput of serial lithographic research tools. On the other hand, the resolution achieved so far by molding is still higher than that used in the industrial manufacturing of processors and memory chips with high-end photolithography (PL). This makes NIL a promising technology for NGL. Apart from these advantages molding offers more: by creating a 3-D resist pattern by mechanical displacement of material, the patterning of a range of specific functional materials and polymers becomes possible, without loss of their chemical properties during molding. Furthermore, this ability can be used to fabricate complex structures e.g., by building up devices with embedded channels or patterning of functional materials e.g., for polymer electronics. These processes are presented in more detail in Sect. 5.2 of this chapter.

In this section we present the basic concepts of NIL and how it can conform to the requirements of state-of-the-art nanofabrication techniques. NIL uses, as do other lithographic techniques, the concept of resist patterning (which can be also found in different chapters in this Handbook). The resist patterns are generated by molding of a viscous material and hardened by cooling and curing, while in PL the resist is patterned by selective local chemical modification of a positive or negative resist by exposure and subsequent wet development. The two main NIL methods are outlined in Fig. 5.3. For lithographic applications, as needed in microelectronics and optics, NIL is in competition with other emerging patterning techniques, which are predominantly probe-based approaches (electrons, photons). Its success will mainly depend on the ability to solve processing issues such as resolution and throughput. It is also important to develop reliable tools with

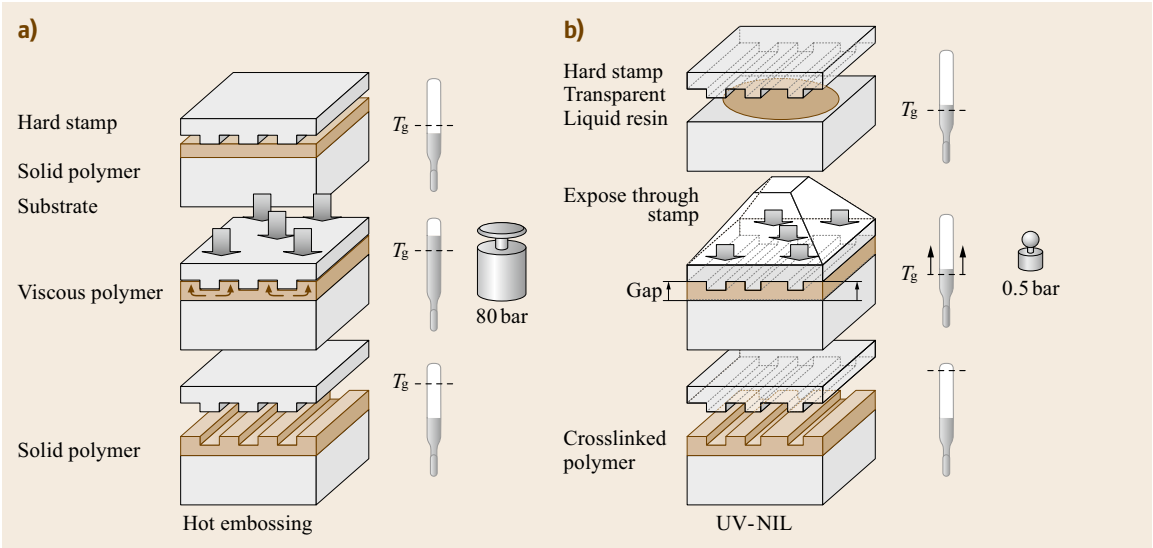

Fig. 5.3a,b Schematic of NIL process: **(a)** thermal NIL (hot embossing) and **(b)** UV-NIL. In both cases a thickness profile is generated in the thin polymer layer. After removing the residual layer, the remaining polymer can serve as a masking layer that can be used as a resist for pattern transfer

a long lifetime, which can be used in combination with other cleanroom process technologies, and to establish standard processes, which can be scaled up to common wafer and substrate sizes.

5.1.1 Next-Generation Lithography

With its integration into the International Technology Roadmap for Semiconductors (ITRS) on NGL in 2003 for the 32 nm node and beyond, NIL has become more than a simple high-resolution method [5.13] (Table 5.1). Since then it has been considered as a candidate for replacing or complementing advanced optical lithographic methods for the fabrication of processors and solid-state memory chips, which over the years have been developed and pushed to higher resolution with a vast investment of resources. Over more than 50 yr, Moore's law has described with amazing accuracy the reduction of feature sizes (and cost per transistor), and therefore serves as a roadmap for the developments needed for future microchips [5.14]. It is driven by economic considerations, and leads to a competition between different candidate manufacturing methods. These do not only have to provide the resolution of smallest feature sizes (node), but also issues such as alignment (overlay of several masking levels), critical dimensions (CD), simple mask fabrication, high throughput (mass manufacturing), and low defectivity, resulting in low cost of ownership (CoO, i. e., no dependence on large machines such as synchrotrons, back-ups and redundancy of tools and masks), which become increasingly difficult to meet if smaller exposure wavelengths have to be used. To date (2017), the semiconductor chip industry has reached 11 nm, which shows the ability of traditional techniques to advance towards smaller nodes, which in the case of 193 nm (DUV) PL was possible by immersion of the lens-resist gap with liquid and self-aligned multiple (mask) patterning techniques. NIL is no longer considered as the only candidate with the ability to reach the requirements of the next few nodes, but still has cost advantages when compared to the huge investments made for extreme ultraviolet (EUV) lithography. As a replacement or complement to existing NGL techniques, it will probably be used in combination with bottom-up techniques for resolution enhancement (mostly for stamps) or functional surfaces. However, as a 1X technique (no projection) the stamp will need to have the same feature sizes as the features to be generated on the device.

As seen in the last years, even huge financial and apparent physical limits have been overcome in developing several techniques towards the next nodes. However, in the case of NIL there is the hope that for chip manufacturing it will be more cost-effective than other techniques. The investments are expected to be lower than for the current front runners, EUV PL or parallel electron-beam exposure. In many other applications, where the introduction of a single lithographic step of 20 cents per masking layer presents a huge investment, alternatives such as NIL are considered as the only way out of this spiral of rising investments.

Table 5.1 ITRS roadmap showing the resolution of different lithographic patterning techniques, and practical and actual resolution limits for different lithography methods. From [5.13], revised and updated

Lithography type	Practical resolution limit (nm)	Ultimate resolution limit (nm)
UV/contact/proximity photolithography	2500	125
Deep UV projection (DUV)	20–40	11 (multiple patterning)
EUV projection (soft x-rays, 13.6) with mask	20–40	7 (multiple patterning)
EUV interference lithography (13.6/6.8)	20	7/4
Ion beam	20–40	Resist: 10–20
Electron beam (low energy beam arrays)	20–40	Resist: 7–20
Thermal nanoimprint (hot embossing)	10–40	0.2–5
UV nanoimprint (hard stamp)	10–40	0.2–5
UV nanoimprint (soft stamp)	50–100	10
Soft lithography (contact printing)	50–500	10
Scanning probe microscopy methods	15	0.5 (atomic resolution)

5.1.2 Nanoprint and Nanoimprint Lithography

Micro-Contact Printing – Ink Transfer by Conformal Contact

NIL is a high-throughput, high-resolution parallel patterning method in which a surface pattern of a stamp is replicated in a material by mechanical contact and 3-D material displacement. Nanoprinting (known as microcontact printing (μCP)), in contrast to nano-*im*printing, transfers an ink from stamp surface protrusions onto a substrate by mechanical contract. Such an ink consists of (linear) chain molecules with the ability to adhere or bind to surface atoms and often create monomolecular films which – due to their density and chemical properties – can act as resists [5.6, 7]. However, such films, in the case of self-assembled monolayers (SAMs) are only 1–2 nm thick, and present chemical contrast against specific etchants. This process has demonstrated sub-100 nm resolution and in principle can pattern much smaller structures, if lateral diffusion of densely printed molecules is inhibited. While NIL is clearly directed towards high-resolution applications, μCP is for research applications mostly in the area of biotechnology. The invention of the technology dates back to 1994 and has similarities to flexographic printing approaches.

The term *soft lithography* (SL) describes a quality of the mold – compliancy and often also elasticity – which is also characteristic to NIL variants such as capillary-assisted molding. SL uses a soft stamp that is able to conform to nonideal substrates i. e., to different length scales of surface height variations. This can be given by surface undulations and deviations in structure height due to roughness, local surface patterns and particles, as well as thickness variations (*waviness*) over the entire substrate area. Due to the compliancy of both its micro- and nanosized stamp protrusions and its backbone (typically a plate several 100 μm to some mm thick) the stamp is able to close local gaps and even *seal* cavities from each other. The compliancy needed for *conformal printing* is however also a matter of pressure and the relative softness of the stamp towards the imprinted material and substrate.

Molding of Thermoplastic Resists by Thermal NIL

NIL was first reported as thermoplastic molding [5.15–17], and is therefore often referred to as thermal NIL (here also named T-NIL) or hot embossing lithography (HEL) [5.5, 18, 19]. The unique advantage of a thermoplastic material is that the viscosity can be changed to a large extent by simply varying the temperature. Figure 5.4 shows viscosity plotted against temperature for various thermoplastic polymers i. e., poly(methyl methacrylate) (PMMA) with different molecular weight, and some commercial resists [5.8, 20]. Switching between solid and a highly viscous state is possible within a range of some tens of degrees Celsius. The first stage of the NIL process is the molding of a thin thermoplastic film using a hard master. During a process cycle the resist material is made viscous by heating and shaped by applying pressure (Fig. 5.5). Here the thermoplastic film is compressed between the stamp and substrate and the viscous polymer is forced to flow into the cavities of the mold, conforming exactly to the surface relief of the stamp. When the cavities of the stamps are filled, the polymer is cooled down, while the pressure is maintained. Thus the molten structure is frozen. After relieving the pressure, the stamp can be retrieved (demolded) without damage, and reused for the next molding cycle.

Molding of UV-Curable Resists by UV-NIL

With the integration of light sources into imprint machines, UV-NIL was developed for curable resists [5.21–24]. The basic difference between UV-NIL and T-NIL is that a resin, which is liquid at room temperature, is shaped at a moderate pressure, and by exposing light through the transparent stamp, the resin is crosslinked and hardened (similar to negative tone resist

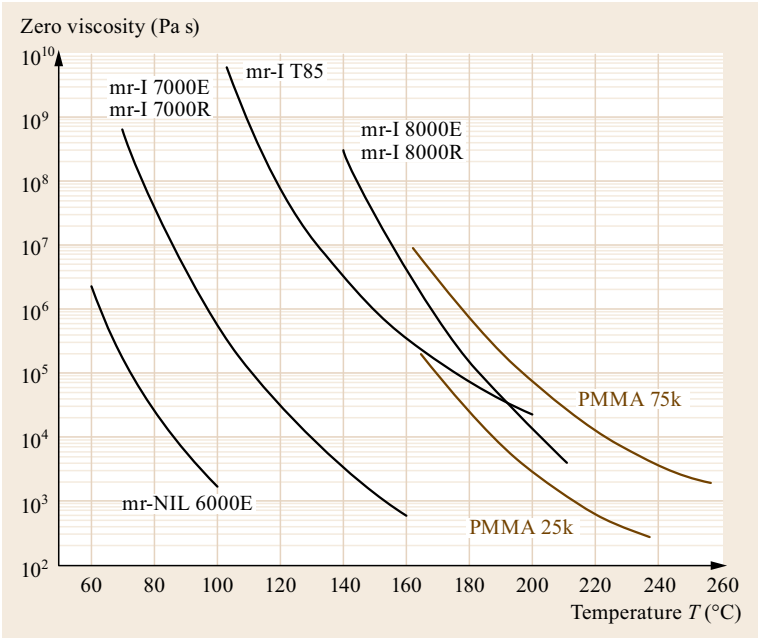

Fig. 5.4 Graph showing zero shear viscosities for some standard resists for thermal NIL for different polymers, taken from different sources: PMMA with M_w of 25–75k and commercial resists (after [5.8, 9]). It shows the potential of rheology and of the large variation of viscosity of thermoplastic polymers with temperature. These curves are presented for the temperature range characterized above the viscous T_g. A process window for imprint is limited by high viscosity where unwanted viscoelastic effects become dominant and molding slow. Lower viscosities than 10^3 Pa s are often not useful because it is often achieved with too low M_w or too high $T_{imprint}$ (after [5.8])

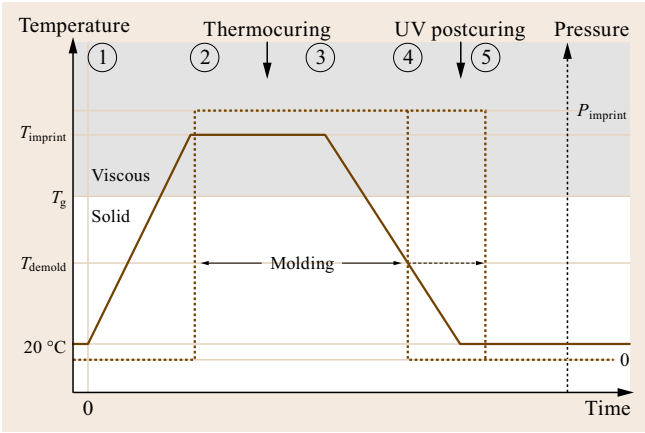

Fig. 5.5 Typical process sequence: schematics of process sequence used for hot embossing (temperature–pressure diagram with time dependence), (1) begin heating, (2) begin embossing, (3) begin cooling, (4) demolding at elevated T, (5) demolding at ambient T

processes). The stamp either sinks down to the substrate or must be kept at constant distance from the substrate during both filling and exposure, due to the low resist viscosities. The mechanical setup has to be able to compensate for wedge errors in a low-imprint-pressure process. Patterning on nonflat substrates or over topography therefore requires a planarization strategy and often small stamps. Because of the small pressures, stamps made of soft materials on a rigid backbone can be used. These soft imprint approaches (*soft lithography*) have become popular for large-area imprint and small and moderate volume manufacturing; e.g., patterned sapphire substrates (PSS). Hard stamps are used in the so-called jet-and-flash imprint lithography (JFIL) approach, favored by Canon Nanotechnologies (CNT, formerly Molecular Imprints Inc., MII) for semiconductor chip manufacturing [5.25].

Pattern Transfer: A Two-Step Process with Window Opening and Conversion

In many cases the lithographic process is only complete when the resist pattern is transferred into another *functional* material. The dimensions (lateral structure size and height) are often similar to the film thickness used. In NIL, in comparison to standard electron (EBL) or photolithography (PL), pattern transfer is a two-step process. First the thin polymer film is transformed into a masking layer. For this, the residual layer remaining in the thin areas of the resist has to be removed, which is done by homogeneously thinning down the entire resist in an (ideally) anisotropic etching process. This way, process windows are opened to the substrate, which allows the substrate to be altered by attack by plasma, etching solutions, deposition of materials and other changes. Because the thinning down of the resist for window opening is also a cleaning step (called descum), it is similar to the wet development of the exposed resist used in PL.

There are an increasing number of process variations, which are mostly variants of the established T-NIL and UV-NIL processes, particularly those using special methods of pattern transfer (e.g., re-

Table 5.2 Comparison of hot embossing (NIL) and UV-imprint (UV-NIL), with typical parameters of current processes

Type of NIL/properties	Thermal NIL (hot embossing (HEL))	UV-NIL (hard stamp)
Basic process sequence (Fig. 5.5)	1) Spin-coat thermoplastic film 2) Place stamp on film 3) Heat until viscous 4) Emboss at high pressure 5) Cool until solid 6) Demold stamp	1) Dispense liquid resin 2) Parallel alignment of stamp with defined gap 3) Imprint at low pressure 4) Expose with UV light through stamp and crosslink 5) Demold stamp
Pressure p (bar)	20–100	0–5
Temperature T_{mold} (°C)	100–200	20 (ambient)
Temperature T_{demold} (°C)	20–80	20 (ambient)
Resist	Solid, thermoplastic $T_g \approx 60$–$100\,°C$	Liquid, UV-curable
Viscosity η (Pa s)	10^3–10^7	10^{-2}–10^{-3}
Stamp material	Si, SiO_2 (opaque)	Glass, SiO_2 (transparent)
Stamp area	Full wafer, > 200 mm diameter	Limited by control of gap Gen2 panel $370 \times 470\,mm^2$
Stamp contact	Facilitated by bending	Planarization layer
Embossing time	From seconds to minutes	< 1 min (per exposure)
Advantage	Low-cost, large-area equipment and stamps	Low viscosity, low pressure, alignment through stamp
Challenge	Process time, thermal expansion due to thermal cycle	Step and repeat needed for large areas
Development needed	Alignment, residual layer homogeneity	Material variety
Step and repeat	Step and stamp with $4 \times 4\,mm^2$ stamps	Jet and flash (JFIL) with $33 \times 26\,mm^2$
Hybrid approaches	Thermoset resists: embossing and curing before demolding	Thermoplastic resists: hot molding and UV-curing before demolding
Advantage	Low temperature variation cycle: demolding at high temperature possible	Solid resist: single-step wafer-scale imprint possible

versal imprint) and hybrid processes (combinations of different processes). All the processes have their specific advantages, e.g., while UV-NIL can be performed at room temperature, hot embossing is often low-cost since nontransparent silicon stamps can be used. The major characteristics of typical processes, along with those of hybrid approaches, are summarized in Table 5.2 and presented in more detail in [5.8].

5.2 Nanoimprint Process

Molding techniques based on imprint processes make use of the differences between the mechanical properties of a structured stamp and a molding material. The viscous molding material is shaped by pressing the hard stamp into it, until the polymer conforms to the stamp surface. In hot embossing processes we mostly deal with thermoplastic materials whose mechanical properties can be repeatedly and reversibly changed from a solid into a viscous state by simply varying the temperature. In order to achieve a reasonable process time and yield, this is normally carried out under high pressure. Thermal NIL deals with a viscosity range that is considered as sufficiently low to enable significant squeeze flow over large distances, but high enough that bending of wafers can be used to equilibrate surface undulations of common substrates and pattern density variations in stamps. While squeeze flow governs high-viscosity molding (where pressure is the driving force to displace the viscous material), in UV-NIL low pressure or even mold filling by mere capillary action (where surface energy controls the wetting and spreading of the viscous material) is possible if very-low-viscosity resins are used. In this section we want to take a closer look at the squeeze flow of thin polymer films as used for thermal NIL, a concept that is quite general and enables us to get an insight into possible parameter variation for process optimization. We will give a brief introduction to the theory of polymers and discuss the implications for NIL [5.26, 27]. This will enable the reader to understand rheology in NIL from a practical point of view. More fundamental questions of squeeze flow are discussed in [5.28] or in [5.29]. In the section on curable resists, we will introduce concepts mainly used in UV-NIL, such as soft UV-NIL.

5.2.1 Limits of Molding

Polymers used as resists in NIL are defined by their chemical composition and physical properties. In the case of molding these are often long-chain molecules with a molecular weight M_w. The polymer M_w is important because it determines many physical properties. Some examples include the temperatures for transitions from liquids over viscoelastic rubbers to solids, and mechanical properties such as stiffness, strength, viscoelasticity, toughness, and viscosity. However, if the M_w is too low, the transition temperatures will be too low and the mechanical properties of the polymer material will be insufficient to be useful as hard resist for pattern transfer, e.g., in reactive ion etching, metal evaporation or electroplating.

It has been known for a long time that polymers can replicate topographies with high fidelity. Up to now, 5 nm resolution of polymer ridges with a pitch of 14 nm has been demonstrated, but even atomic steps in sapphire wafers have been replicated. In comparison to methods like electron-beam lithography (EBL), where a nanoscale chemical contrast can be can be produced by local irradiation-induced chain scission, the polymer chains are only moved and deformed during molding, thus keeping their properties such as M_w. Molding topographic details down to a few nanometers means that single polymer chains have to deform or flow.

A polymer is a large molecule made up of many small, simple chemical units, joined together by chemical reaction. For example, polyethylene $CH_3{-}(CH_2)_n{-}CH_3$ is a long chain-like molecule composed of ethylene molecules $CH_2{=}CH_2$. Most artificially produced polymers are a repetitive sequence of particular atomic groups, and take the form [–A–A–A–]. The basic unit A of this sequence is called a monomer unit, and the number of units n in the sequence is called the degree of polymerization. The molecular weight M_w of a polymer is defined by the weight of a molecule expressed in atomic mass units (amu). It may be calculated from the molecular formula of the substance; it is the sum of the atomic weights of the atoms making up the molecule. For example, poly(methyl methacrylate) (PMMA), a classic resist material, exhibits very good resolution for both EBL and NIL. A high-M_w PMMA, typically above 500 kg/mol (also denoted 500k), is normally used for EBL, since the development contrast between exposed and unexposed areas increases with M_w [5.30]. A lower M_w, of some tens of kg/mol, is patterned in NIL, due to the strong increase in temperature-dependent viscosity with M_w. Apart from their mobility it is expected that shorter chains, which in the case of amorphous polymers are normally present as entangled coils, can move more easily into small mold cavities. A convenient way of expressing the size of a macromolecule present as a statistical coil aggregate is the radius of gyration R_g.

A polymeric liquid, whilst retaining the properties of a liquid, follows a rubber-like elasticity. Substances with both viscous and elastic properties are called viscoelastic. Considering the fact that that molding is achieved by deformation of a polymer network at a molecular level, the question is how the polymer can be permanently shaped and whether the replicated structure will deform back due to internal reordering and relaxation of polymer chains.

The reduced viscosity of polymers at higher temperatures is a result of the increasing ability of the chains to move freely, while entanglements and van der Waals interaction of the chains are reduced. The glass transition of a thermoplastic polymer is related to the thermal energy required to allow changes in the conformation of the molecules at a microscopic level, and above T_g there is sufficient thermal energy for these changes to occur.

Most of our considerations here are valid for a range of practical process parameters, as used in current thermal NIL processes, where linear behavior can be assumed (Newtonian flow regime). This is in particular the case at molding temperatures well above T_g. For thermoplastic molding, however, the T_g is only a rough indication of a temperature for fast molding. More suitable than T_g is the flow temperature T_f, which characterizes a point at which viscosity drops to practical values for molding needed for fast NIL (i. e., $10^3{-}10^7$ Pa s, about 50 °C above T_g for 25k PMMA, Fig. 5.6) [5.8].

5.2.2 Squeeze Flow of Thin Films

During imprinting, linear movement of a stamp is transformed into complex squeeze flow of the viscous material. In the thin polymer films used in NIL, a small vertical displacement of the stamp results in a large lateral flow. The two surfaces of the stamp and the substrate have to come entirely in contact with each other and keep this contact until the desired residual layer thickness is reached. Furthermore, new concepts are possible such as roll embossing (roll-to-roll NIL) and soft imprint using flexible stamps. In Fig. 5.7, the imprint of a stamp with line cavities is schematically shown.

Before imprint, the polymer film has an initial thickness h_0 and the depth of the microrelief is h_r. For a fully inserted stamp, the film thickness under the single stamp protrusions (elevated structures) with width s_i is h_f. We can calculate this specific residual layer height h_f by applying the continuity equation with the

assumption that the polymer melt is incompressible (conservation of polymer volume). It can be directly deduced from the area fill factor ν, i. e., ratio of the area covered by cavities to the total stamp area.

A simple model for the squeezed polymer flow underneath the stamp protrusion is obtained by treating the polymer as an incompressible liquid of constant viscosity, and solving the Navier–Stokes equation with nonslip boundary conditions at the stamp and substrate surfaces. According to this model, given for line-shaped stamp protrusions and cavities in [5.8, 31], we find the following expression, known as the Stefan equation, for the film thickness $h(t)$ underneath the stamp protrusion when a constant imprint force F is applied to the single stamp protrusion

$$\frac{1}{h^2(t)} = \frac{1}{h_0^2} + \frac{2F}{\eta_0 L s^3}\, t\,. \tag{5.1}$$

Inserting the final thickness $h_\mathrm{f} \equiv h(t_\mathrm{f})$ in (5.1) gives the imprint time

$$t_\mathrm{f} = \frac{\eta_0 L s^3}{2F}\left(\frac{1}{h_\mathrm{f}^2} - \frac{1}{h_0^2}\right)\,. \tag{5.2}$$

For many practical cases a constant pressure under each stamp protrusion $p = F/(s\,L)$ can be assumed.

As a direct consequence of the Stefan equation it can be seen that, at identical pressure, small (narrow) stamp protrusions will sink faster than large (wide) ones. The stamp geometry can therefore be optimized by reducing the dimensions of the protrusions. While stamps with nanopillar arrays, as shown in Fig. 5.2, would allow fast imprint of some microseconds, using standard NIL process parameters, already protrusions of some hundreds of micrometers would increase imprint times to some hours. The strong dependence of the imprint time on the pressing area has the consequence that, for a fully inserted stamp relief (full contact over the total stamp area), the flow practically stops (schematically shown in Fig. 5.8). For this case, s becomes large and flow continues only towards the stamp borders. It is also evident that there is only weak influence of the imprint force ($t_\mathrm{f} \propto 1/F$). At first sight there is a similar weak influence for η_0. However, the viscosity can be changed significantly by varying the temperature. For practical use, it is quite important that trade-offs are possible between structure height, resist thickness, pressure, and temperature. For example, within certain limits, a low imprint pressure can be compensated by a longer time or a higher temperature.

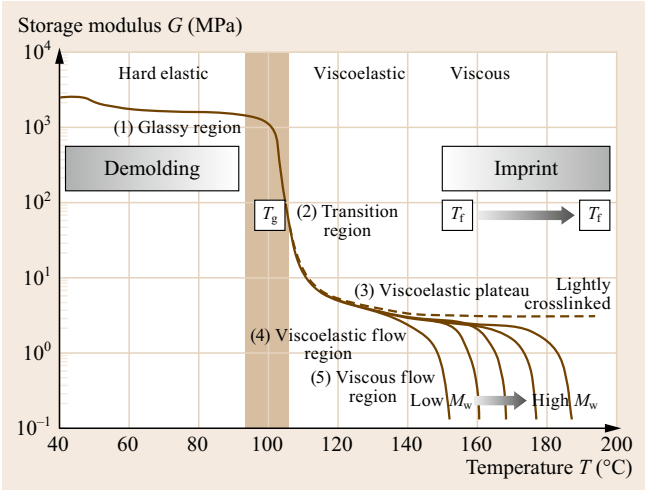

Fig. 5.6 Mechanical properties of polymers dependent on temperature, molecular weight, and crosslinking (after [5.26]). Schematic for a polymer with a T_g around 100 °C for normal process conditions. Particularly important for thermal NIL are the large drops of G at two temperatures, T_g and T_f. At T_g the thermomechanical properties between stamp and polymer become sufficiently different for repeated molding. T_f characterizes a point at which viscosity drops to practical values for molding needed for fast imprint

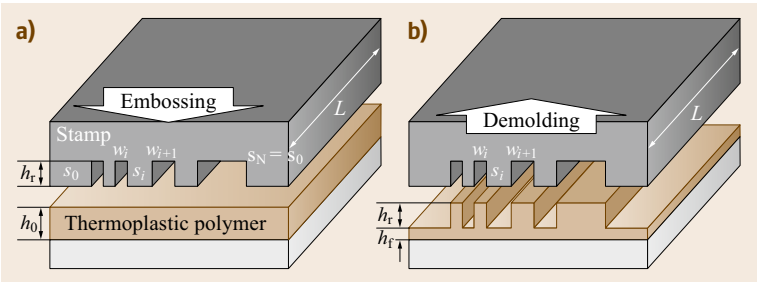

Fig. 5.7a,b Geometrical definitions used for the description of the flow process for a stamp with line cavities and protrusions: **(a)** before molding, and **(b)** after demolding. In the case of viscous molding, where volume conservation can be anticipated, the residual layer thickness can be calculated from geometrical parameters such as the initial film thickness and the size and density of cavities

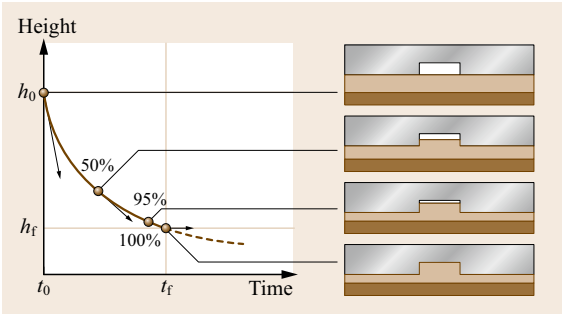

Fig. 5.8 Schematics (*right*) of the squeeze flow of a compressed polymer film into one cavity. Once the cavity is filled the stamp continues to sink but at a much slower rate (*left*), as a direct consequence of the Stefan equation

The implications of squeeze flow are discussed in more detail in [5.19, 32], including rheological issues, bending of stamps in large-area imprint and influence of vacuum and self-assembly [5.33–36].

It is has to be noted that while the Stefan equation governs the sinking of the stamp on the basis of squeeze flow, very small stamp protrusions with high aspect ratio deviate from this behavior. The slowing down is then more governed by the Stokes drag, which does not allow the polymer to proceed upwards in an narrow cavity due to the reduced wetting of the sidewalls [5.36]. In contrast to this, for large stamp protrusions, bending of the entire stamp e.g., in areas of high density of cavities where sinking is enhanced, enables printing faster than predicted by the Stefan law.

5.2.3 Residual Layer Thickness Homogeneity

The main difference between NIL and lithography based on exposure and development is that a residual layer below the stamp protrusions is left after demolding. As seen before, this is a result of the molding process slowing down due to the squeeze flow. For many applications, when pattern transfer has to be achieved after the imprinting, it is important to determine the final residual thickness h_f of this polymer layer (Fig. 5.7) before the next process step. Furthermore it is important to know the thickness variation over the imprinted area. Otherwise, parts of the structure will be lost during pattern transfer. As will be shown in the following, bending of stamps has to be taken into account, as well as effects such as air inclusions, dewetting and self-assembly of resist [5.35]. In most cases a homogeneous residual layer can be achieved by optimizing the pattern design, but also by using adapted processes that create thin residual layers independent from design. In contrast to this, pattern transfer processes that are insensitive to thickness variations have to be used, e.g., by using a resist with high etch resistance or an intermediate layer as a hard mask. The following examples demonstrate how soft and hard elements for equilibration are used to achieve a homogeneous molding.

5.2.4 Demolding

During demolding the rigid stamp is detached from the molded structure, which can be in a parallel way when using small, rigid stamps, or by delamination, if thin, wafer-like substrates are used. If fully molded, the thickness profile in the resist exhibits the inverse polarity of the relief of the stamp surface. The demolding process, also called de-embossing, is normally performed in the frozen state, i. e., when both mold and molded material are considered solid. For thermoplastic materials this happens at a temperature well below T_g, but high enough that frozen stress due to thermal contraction does not lead to damage during demolding. In such cases in which the resist is cured before demolding i. e., crosslinked by exposure or heat, demolding can take place at temperatures similar to the molding temperature. A successful demolding process relies on a controlled balance of forces at the interfaces between stamp, substrate and molded polymer film. Therefore mechanical, physical and chemical mechanisms responsible for adhesion have to be overcome. The following effects have to be avoided or reduced [5.37] (Fig. 5.9):

- Undercuts or negative slopes in the stamp may lead to mechanical interlocking of structures, which in their frozen state are elastically elongated and deformed before ripping. Sidewalls with positive or at best vertical inclination are prerequisite for demolding without distortion.
- Friction due to surface roughness may occur during the sliding of molded structures along vertical cavity walls. The effect of this can only be overcome if the surface of the molded material is elastic and enables gliding of the wall without sticking.
- The enlarged surface area of the patterned stamp leads to an increase of hydrogen bridges and van der Waals forces, or other chemical bonding effects due to ionic, atomic and metallic binding. This effect can only be overcome if the stamp surface can be provided with sufficient anti-adhesive properties.

The most critical point is that demolding forces largely depend on the geometry of the mold, and the overall design of a stamp structure has to be taken into account. Therefore structures with high aspect ratio may be more prone to ripping, and if many neighboring

structures exert high forces to the underlying substrate, whole areas of resist may be detached from the substrate surface. Anti-adhesion layers on the mold can reduce friction forces, but have to be thin and durable. In thermal NIL the expansion coefficient of the substrate $\alpha_{substrate}$ and of the stamp α_{stamp} should be similar, to avoid a distortion due to mechanical stress induced by the cooling. In the case of very thin polymer layers, the lateral thermal expansion of the resist is determined by the substrate. For structures with a higher aspect ratio the demolding temperature T_{demold} should be well below T_g to enable the demolding of a hardened resist without distortion, but as near as possible to T_g, because the stress induced by thermal shrinkage should not be exceeded in critical areas where structures tend to break.

5.2.5 Curing of Resists and UV-Assisted NIL

Curing by UV exposure, by thermal treatment or chemical initiation is a way to crosslink polymers and to make them durable for demolding [5.21, 22, 38–43]. A high reaction speed, as caused by a high exposure dose, high initiator content or curing at high temperatures, leads to fast, but weak crosslinking, whereas a slow reaction leads to highly polymerized, tougher materials because the slow polymerization enables a more complete process. As shown in Sect. 5.1.2, different process strategies have been developed. In most of them the curing step is independent from the molding step, and can be initiated by light or a specific temperature after the molding is complete. Because curing involves a change in the physical conformation of the polymer, it always goes along with a volumetric shrinkage of the polymer. For example, acrylate polymerization is known to be accompanied by volumetric shrinkage that is the result of chemical bond formation. Consequently, the size, shape, and placement of the replicated features may be affected. In the following the main processes that involve curing are presented in more detail:

- In the UV-NIL process, the resist is cured after molding, but before demolding of the stamp. The process relies on the photopolymerization of a low-viscosity, acrylate-based solution. Shrinkage was found to be less than 10% of the total volume in most cases. The liquid is a multicomponent solution. The silylated monomer provides etch resistance in the O_2 transfer etch, and is therefore called an etch barrier. Crosslinking monomers provide thermal stability to the cured etch barrier and also improve the cohesive strength of the etch barrier. Organic monomers serve as mass-persistent components and lower the viscosity of the etch barrier formulation. The photoinitiators dissociate to form radicals upon UV irradiation, and these radicals initiate polymerization.
- Polymer chemistries with oxygen inhibition do not cure within ambient atmosphere. Therefore stamps with inherent permeability to gas (e.g., PDMS) are not usable. When using hard stamps, resin between stamp and substrate will cure upon exposure, while the excess material on the stamp borders will stay soft. Many UV-NIL resists are noxygen non-inhibiting.
- If a solid curable resist exhibits thermoplastic behavior, it can be molded at an elevated temperature and then crosslinked, either before or after demolding. The advantage of the process is that low-M_w resists with a low T_g can be provided, which can be processed at moderate temperatures. However, before pattern transfer, a hardening is often necessary. They can also be used for mix-and-match with PL or for polymeric stamp copies.
- Thermoset resists can be crosslinked by heat. Here it is of advantage that the temperature for molding is lower than the curing temperature. Then the structure is first molded and then heated to its crosslinking temperature to induce crosslinking, before the stamp is demolded from the hardened surface relief.

More information about curing and multilayer resists can be found in Sect. 5.3 of this chapter.

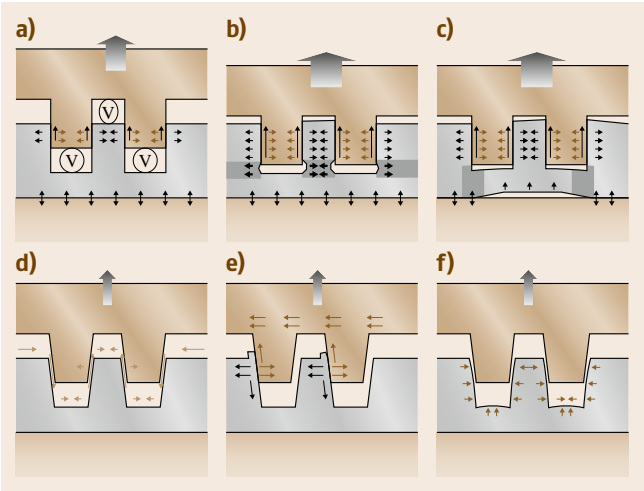

Fig. 5.9a–f Demolding issues: **(a)** generation of vacuum voids (V), **(b)** elongation and ripping of single structures, **(c)** ripping of resist from substrate, **(d)** penetration of air into voids (inclined sidewalls), **(e)** shrinkage and generation of rims, **(f)** relaxation of frozen-in-strain (after [5.8])

5.2.6 Mix-and-Match Methods and Combination with Directed Self-Assembly

Mix-and-match approaches are used to combine the advantages of two or more lithographic processes or simply to avoid their mutual disadvantages [5.44–46]. It is also a way to improve throughput and reliability, e.g., since the fabrication of large-area nanostructures is often costly, the definition of microstructures can be done with PL, while the nanopatterning of critical structures in small areas is done by NIL. In many cases NIL would be used as the first process step and by adding alignment structures along with the nanopatterns, the less critical structures can be added after the NIL step using PL with an accuracy given by the mask aligner (in the range of 1 μm).

5.2.7 Multilayer and Multilevel Systems

Multilayer resists systems are used if the etching selectivity of a masking layer has to be enhanced, e.g., for the fabrication of high-aspect-ratio structures, or undercuts to be generated, e.g., when lift-off or a planarization layer has to be employed for printing over topography [5.47, 48].

The most important application of double resists is for low-pressure processes such as UV molding (Fig. 5.10). For prestructured substrates with topography, a planarization layer is needed, because the low pressure of below 1 bar is often not sufficient to achieve a conformal contact of the transparent mask with the nonflat substrate surface. Otherwise parts of the resist stay unmolded.

Often top layers with high etching resistance, e.g., silicon-containing resists (similar to hardening by silanization) are chosen for UV-NIL. After molding the top layer, the pattern is transferred into the underlying planarization (transfer) layer. The top layer can be kept thin, while the etching depth can be further generated by choosing a thick bottom layer. Normally the tone of a stamp pattern is inversed when etching is used for pattern transfer. The tone can be preserved if another tone reversal process is used. This can be achieved by imprinting a pattern into the thick transfer layer, and by spin coating a silicon-containing resin on top of it. If the top residual layer of the planarized film is etched away, the high etch resistance of the silicon remaining in the trenches of the bottom layer will enable patterning of the transfer layer with reversed tone. This strategy has the advantage that stamp contamination containing silicon residues is avoided [5.49].

The 3-D patterning capability of NIL makes it possible to reduce the number of process steps in contact layer fabrication of microchips by using innovative pattern transfer. The connection of the transistors is done using several levels of lateral wires, each contacted vertically by through holes. This contact layer of a chip is fabricated using lithography and copper electroplating. For the wiring scheme of a chip, as shown in Fig. 5.11, eight levels of wiring layers are needed, each of which is done in a so-called dual hard damascene process. A two-tiered stamp with three height levels makes it possible to pattern the through holes as well as the wires in one step [5.50–52]. In this way, several exposure steps can be replaced by a single imprint with patterns of different residual polymer layer thickness. Similarly, a so-called SAIL (SAIL) process was developed that allows the patterning of transistors on flexible electronics, with several aligned metal layers. This is achieved by imprinting a multilevel pattern into a resist, and by subsequent etching of each resist level followed by a selective etching step where the metal layers are etched. Figure 5.11 shows the pattering scheme for one level of the contact layer of an IBM power computer microprocessor. Obducat has used a similar process for the generation of micrometer-sized contact holes in printed circuit boards and Hewlett

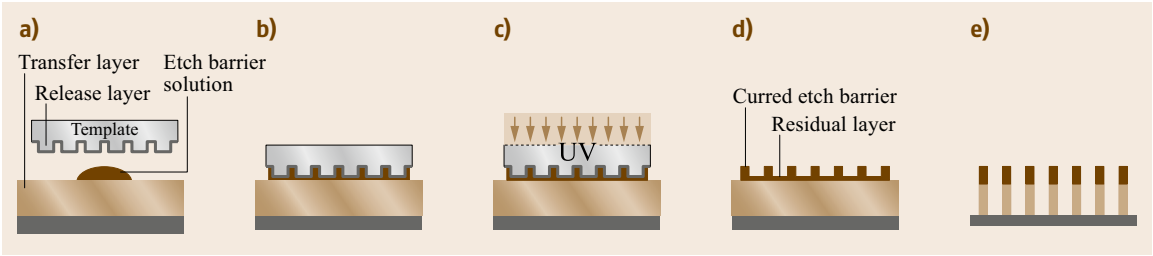

Fig. 5.10a–e Process scheme of UV imprint and pattern transfer, using a double layer (also called direct JFIL). The molded top layer, also called the etch barrier, is coated on a transfer layer, which serves as a planarization layer. It has also antireflective properties for the UV exposure through the stamp. **(a)** Dispensing of viscous resist droplet, **(b)** imprint, **(c)** UV exposure and curing, **(d)** demolding of hardened resist, **(e)** residual layer etch and transfer into bottom layer (breakthrough etch/window opening)

Packard employed the SAIL process for flexible electronics.

5.2.8 Reversal NIL and Layer Transfer

In contrast to NIL, in reversal NIL the resist is patterned either directly on the stamp or on an auxiliary substrate, e.g., by spin coating, casting or imprint, and then transferred from the mold to a different substrate by bonding. Thus patterned resist structures are obtained as in direct NIL, and even embedded channels can be created. The concept is well presented in [5.53–55]. In reversal NIL it is possible to transfer patterns onto substrates that are not suitable for spin coating or have surface topographies. However, complete transfer does not only depend on a good balance of the surface energies, but also on the pattern density and roughness of the structures. As an example, embedded channels generated by reversal NIL are shown in Fig. 5.12 [5.53].

5.3 Tools and Materials for Nanoimprint

Mechanical nanofabrication techniques based on molding require tools and materials with matched mechanical properties. The mold has to be made from a material that is sufficiently hard to sustain at least one processing cycle. From the viewpoint of mass fabrication, a mold is considered as a tool that survives the molding process unaltered and uncontaminated, and thus can be reused many times after each molding step. In this way many identical replicas can be drawn (copied) from one mold. Due to the conformal molding, the surface of these

copies is the negative structure of the original (inverted polarity). Therefore a true replica of the mold is generated, when a negative is again molded into a positive structure. Here, we use the terms replica and copy in the more general sense that also negatives are considered as true copies of an original.

For thermal NIL as well as UV-NIL, single-step wafer-scale processing and step-and-repeat approaches have been developed. The aim is to make the reader familiar with concepts rather than presenting machines and materials sold on the market.

5.3.1 Resist Materials

Resists used for NIL are either used as an intermediate masking layer for the substrate or as a functional layer for a specific application. Both the processing properties and those for the final application purpose have to be considered. Many resists, as those used for PL and EBL, exhibit thermoplastic behavior. A typical example is PMMA, a regular linear homopolymer, with a short side-chain. It is used as a high-resolution standard material for EBL and also as bulk material for hot embossing and injection molding. When used as an etching mask, e.g., for Si, it exhibits a sufficient, but not high etching resistance. The glass transition temperature T_g of PMMA (100–120 °C) is low enough to enable molding at temperatures below 200 °C, but high enough to ensure a sufficient thermal stability in etching processes. Acrylate-based polymers can also be used with crosslinking agents. Apart from PMMA, a number of resists have been developed and characterized; they exhibit different T_g values, and were optimized for greater etching resistance, better flow at lower temperatures or equipped with intrinsic release properties. In Table 5.3 we give an overview of NIL resists with references to further information on these materials. Further information can be found in [5.9].

UV-curable NIL materials are composed of a mixture of monomers (or prepolymers) and a suitable photoinitiator, and often chemicals are added that decrease the effect of radical scavengers on photopolymerisation [5.56–59]. Immediately during contact of the stamp with the liquid mixture, filling of the mold starts by capillary forces, which pulls the stamp towards the substrate. Therefore, the general strategy is as follows: low viscosities are needed both for rapid dispensing and filling of mold cavities. Thin resin layers on top of a thicker transfer layer are used to achieve a homogeneous film thickness. Crosslinking and photopolymer conversion is adapted to achieve high curing speed and high etch resistance in the following breakthrough plasma etching process.

In UV-NIL a chemical reaction between stamp and the resist cannot be excluded. Small feature sizes along with high silicon content and a large degree of crosslinking make any residual imprint polymer left on the mold almost impossible to remove from the template without damaging the expensive quartz template. It was shown that a fluorosilane release layer applied to an UV-NIL stamp undergoes attack by acrylate, methacrylate and vinyl ether UV-curable resist systems, pointing to its degradation being intrinsic to the chemistries involved. Future resist chemistries have

Table 5.3 Thermoplastic or thermocurable materials used as resist layers for thermal and combined thermal and UV-NIL processes, with values for glass transition temperature T_g, recommended imprint temperature range $T_{imprint}$, viscosity η and Young's modulus E (after [5.9])

Material	T_g and $T_{imprint}$	$\eta(T)$ and resulting E	Comments
Thermoplastic (for variothermal molding)			
Poly(methyl metacrylate) (PMMA)	T_g 100–120 °C, $T_{imprint}$ 140–190 °C	10^5–10^7 Pa s (170 °C); 380–540 MPa	The *classic* NIL resist, also suitable for grayscale electron beam lithography
mr-I 7000 R[a]	T_g 55 °C $T_{imprint}$ 120–140 °C	$< 3 \times 10^4$ Pa s (120 °C)	Low T_g NIL polymer with very good flow ability and high plasma etch resistance, effective release force reduction due to fluorinated additives, 12 nm resolution proved
mr-I 8000 R[a]	T_g 155 °C $T_{imprint}$ 150–180° *C*	$< 10 \times 10^4$ Pa s (175 °C)	NIL polymer with very good flow ability, good thermal stability and high plasma etch resistance, effective release force reduction due to fluorinated additives
Thermoplastic and UV-curable (crosslinking during photoradiation for combined NIL and UV-photolithography)			
mr-NIL 6000 E[a]	T_g 1 °C (before imprint, no T_g after imprint) $T_{imprint}$ 65–70 °C	$< 2 \times 10^3$ Pa s (100 °C)	Low T_g NIL resist for combined thermal and UV-NIL (STU from Obducat), mix-and-match, multilevel patterning, reverse UV-NIL

to satisfy the criterion of low reactivity toward antiadhesive coatings and stamp materials [5.60, 61].

5.3.2 Stamps

Stamps are characterized by a 3-D surface profile with protruding and recessed areas that are placed on a backbone conforming to the molding tool and the substrates to be used. The formed cavities, once the protruding areas are in contact with the moldable material, are filled during the process by displacement. Not only the mechanical, but also optical and chemical properties are important when choosing a stamp material for NIL. Critical mechanical parameters and their implications for NIL are hardness and thermal stability (lifetime and wear), thermal expansion coefficients and Poisson's ratio (dimension mismatch leading to distortions during demolding), roughness (higher demolding force and damage), Young's modulus (bending), and notch resistance (lifetime and handling). Issues related to fabrication are processability (etching processes, selectivity, cleanroom environment) and surface quality (resolution). The use in a NIL process is determined by additional properties such transparency, conductivity, wetting and antisticking properties (with/without antiadhesive coating, e.g., by covalent coating), availability and cost (standard materials and sizes, tolerances, processing equipment and time), and how easy it is to employ in NIL (e.g., fixing by clamping, thermobonding, gluing). In Table 5.4 we give a brief overview of mechanical and thermal properties of materials used for stamps. Further information can be found in [5.9, 62].

UV-NIL and Soft Lithography with Conformable Stamps in Low Pressure Imprint

The forces on the stamp protrusion with liquid resists are induced by capillary action rather than by squeeze flow and are therefore low. Therefore in UV-NIL, compliant stamps made from elastomeric materials e.g., PDMS (poly-dimethyl siloxane), a UV transparent rubber, can also be applied. The concept of layered stamps – a thin PDMS relief coated on a harder substrate – is particularly useful in full wafer concepts. It combines the complementary mechanical properties of a soft surface relief for the achievement of local conformal contact and a rigid, but bendable backbone, which can be used for mounting and alignment. A process

working with moderate resist viscosities (with $\eta_0 =$ 50 mPa s and below) for providing liquid films by spin coating was developed and can be applied at reduced environmental pressure in [5.39].

5.3.3 Stamp Fabrication and Tooling

Any kind of process generating a surface profile in a hard material can be used to fabricate stamps for NIL. The most common lithographic processes are based on resist patterning with subsequent pattern transfer. Therefore the requirements for these processes such as resolution, aspect ratio, depth homogeneity, sidewall roughness, and sidewall inclination are similar to the processes needed to do pattern transfer after NIL. For highest resolution down to sub-10 nm, both serial and parallel fabrication methods are available, however, with different area, throughput, and freedom of design. The processes are standard processes for nanolithography, such as electron beam lithography (EBL), even focused ion beam (FIB) lithography, but also interference lithography (IL), which also can be used directly for patterning. For large-area patterning with relaxed requirements on resolution, or for mix-and-match with high resolution techniques, photolithography (PL) has become a standard process. For 3-D topographies, apart from multiple patterning techniques, grayscale lithography and 2-photon-polymerization are more and more used. Using stamp copies instead of the original (as described for PDMS in the section before) is a way of enhancing the lifetime of a stamp, simply because the original is reserved for the copying process. There are different methods to generate copies from hard masters with proved resolutions below 100 nm: materials are now available that offer not only high replication fidelity down to 10 nm, but are also suitable for copying e.g., the fabrication of working stamps or of bendable molds that are used for roll-to-roll processes. A specific advantage of stamp manufacturing by copying is the possibility of use of resolution enhancement. Apart from combination of lithography with directed self-assembly, atomic layer deposition followed by spacer etching has been become popular because it enables the use of the original structures as guiding structures for further topography or chemical contrast selective processing. As an alternative to electroplating, imprinting into and casting of polymers, ormocers (hybrid organic and inorganic materials) and silicones (rubber-like *soft* stamps) have become popular ways of preparing stamp copies for prototyping and fabrication of a moderate number of replicas. However, the lifetime of polymeric molds is still low in comparison to nickel and silicon molds and good solutions for anti-adhesive coatings have to be found. Sylgard 184 from Dow Corning enables the fabrication of a number of transparent templates with sub-μm details. The liquid is cured by heat, and the PDMS solid is peeled away from the stamp original. Newer formulations with higher Young's moduli enable resolutions down to 50 nm. Hybrid molds use different materials for the surface relief and the support. They consist of a substrate plate as a mechanical support covered with a thin polymer layer with a nanostructured relief. In the case of NIL they have the advantage that a substrate material can be chosen with thermomechanical properties adapted to the substrate to be patterned. Furthermore it is useful if thin flexible substrates are needed.

The methods differ mostly in the properties of the materials used for the stamps (mechanical robustness, thermal expansion coefficient, transparency, fabrication tolerance) and the surface properties of the patterned relief (anti-adhesive coating possibility).

5.3.4 Anti-adhesive Coatings

One of the most important tasks for NIL is to provide stamps with good antisticking surface properties [5.63, 64]. The stamp surface should allow the molded surfaces to detach easily from the mold, and once released, provide a low friction resulting in a continuous vertical sliding movement without sticking. Nanoscopic interlocking of structures caused by sidewall roughness should be elastically absorbed by the molded material, while the surface maintains its antisticking properties. Because the molded polymer film is squeezed between the two surfaces of stamp and substrate, they need to exhibit opposite surface properties. The adhesion at both interfaces must be different to an extent that while the polymer film adheres perfectly at the substrate surface, the stamp can be separated from the structures without any damage at any location of the stamp. If the stamp material does not exhibit good anti-adhesive properties to the molded material, the stamp has to be coated with a thin antistiction layer (ASL). A low-surface-energy release layer on stamp surfaces not only helps to improve imprint qualities, but it also increases the stamp lifetime significantly by preventing surface contamination. An ASL has to be chemically inert and hydrophobic, but at the same time allow a filling of the mold cavities when the polymer is in its viscous state.

One of the major advantages of using Si or SiO_2 stamps for NIL is that they can be coated using silane chemistry. Fluorinated trichlorosilanes with different carbon chain lengths are commonly used due to their low surface energy, high surface reactivity, and high resistance against temperature and pressure. They support multiple long imprint sequences with repeated temper-

ature cycles higher than 200 °C. Currently it seems that as long as mechanical abrasion can be avoided, the silanes match the *normal use lifetime* of a Si stamp, which is some tens of cycles for NIL in a laboratory environment or thousands if automated step-and-repeat imprint processes or injection molding processes are used. For mass manufacturing it is advisable to use resists with intrinsic antisticking properties e.g., fluorinated components that are able to migrate towards the stamp's surface while being imprinted. The silane coating can be performed by immersion in a solution of iso-octane, or by chemical vapor deposition (CVD), either at ambient pressure by heating the silane on a hot plate or by applying a moderate vacuum of some mbar. One of the most prominent advantages of the vapor deposition method is that it is not affected by the wetting ability of a surface, and that it is suitable for stamp surfaces with extremely small nanostructures.

A commercially available silane used is shown in Fig. 5.13. F_{13}-OTCS = (tridecafluoro-1,1,2,2-tetrahydrooctyl)-trichlorosilane is the standard material for anti-adhesive coatings on silicon.

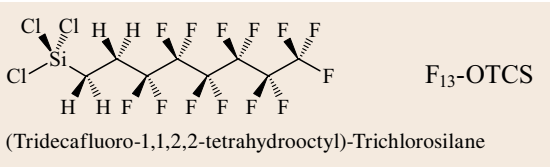

Fig. 5.13 Molecular structures of a fluorinated silane with a reactive trichlorosilane head group and a long alkyl chain with fluorine substituents (length about 2 nm). The silane binds covalently to the silicon oxide of the stamp surface and is used as the standard coating of silicon stamps in NIL

5.3.5 Machines

NIL can be carried out using three different types of machines:

1. Single step (Fig. 5.14a,b)
2. Step-and-repeat (Fig. 5.14c)
3. Roller imprinting.

An imprinting machine needs a precise pressing mechanism with high requirements on uniformity and homogeneity over large areas [5.8, 65–67]. At the same time it should adapt to local variations of pressure and temperature, due to imperfections and tolerances in stamps and substrates, and simply because the stamp protrusions are inhomogeneously distributed.

Imprint machines generate a desired pressure pattern over the total area of the stamp. High throughput for manufacturing devices at the full wafer scale can be achieved either by parallel patterning of large areas or by fast repeated patterning using a semiserial stepping process. The pressure field can also be applied sequentially by using a rigid but stepped imprint mechanism or continuously scanned pressure field, as used in roll embossing (or roller imprint) (Fig. 5.15). In all cases a defined area of the molding material is sandwiched between the solid stamp and substrate, which are backed up by a pressing mechanism.

Single-Step Wafer-Scale NIL (Large Area)

Single-step NIL machines pattern the surface on an entire wafer (current state 300 mm) or extended substrate (e.g., Gen2 panel $370 \times 470\,mm^2$) in one step. Thus the stamp must have the same size as the substrate to be patterned. The simplest mechanism for full-wafer imprint is a parallel plate imprint system. A linear movement

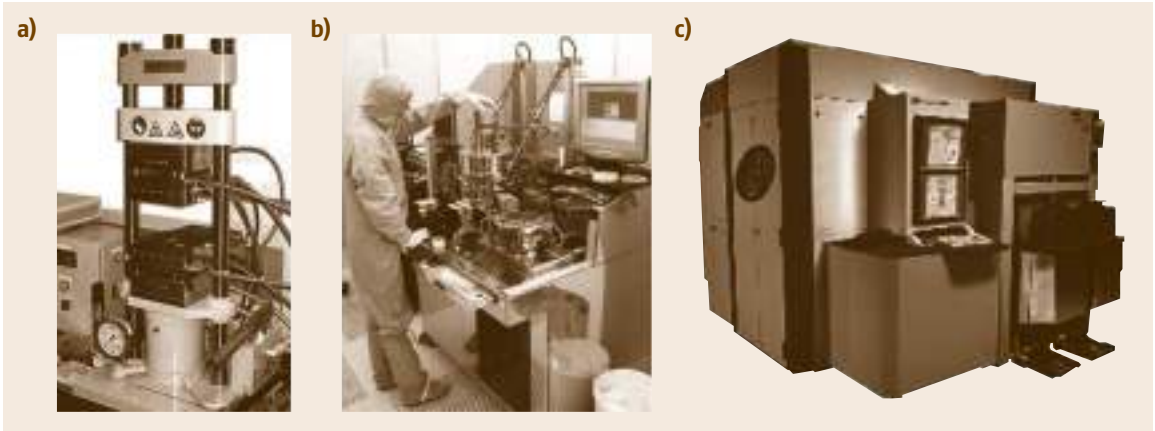

Fig. 5.14a–c Three examples of NIL presses. **(a)** Simple hydraulic press, with temperature-controlled pressing plates. **(b)** Semiautomated, hydraulic full-wafer NIL press, based on an anodic bonder. **(c)** Automated jet-and-flash UV-NIL production tool

of the piston behind the stamp leads to a local thinning of the polymer under the stamp protrusions, which is possible because the polymer is moved from squeezed areas into voids in the stamp. This movement can be generated using pneumatic, hydraulic, or motor-driven pistons. The pressure must be maintained during the whole molding process, until the voids are filled, and the molded structures are *fixed* during the cooling or curing step, depending on the method used. However, under normal process conditions, an imprint with a hard master does not work without a cushioning mechanism. This cushion balances both thickness variations due to tolerances of the setup and due to the nature of the molding process. The latter is caused by the fact that the size and shape of the stamp surface relief leads to a local pressure variation during the squeeze flow and, if the stamp can bend, to a local difference in sinking velocity. When using thick polymer plates, where the molding leads to a surface modulation of a bulky material, the cushion is formed by the viscous material itself. However, in NIL, a thickness profile has to be generated in a resist of which the thickness is often lower than the thickness tolerances of the substrates and mechanical setup used. Furthermore, height defects in the range up to some μm, such as dust particles, have to be equilibrated. Therefore the cushioning has to be achieved by the pressing mechanism and its ability to compensate has to be larger than the defects and tolerances of stamps and substrates. A lateral spreading and dispersion of the applied pressure can be achieved by using a spring mechanism, which can consist of an additional plastic or elastic layer. For example, a mattress made of rubber, Teflon or elastic graphite can be used. Due to the high pressure used in NIL, a compensation of small wedges, i. e., nonparallel alignment, is not needed. An even better pressure homogeneity can be obtained, when the cushion effect is generated by compressed air or liquid. This can be realized by constituting a pressure chamber, which is sealed against the backside of the stamp. In practice this is realized by placing a metallic or polymeric membrane between the pressure chamber and the stamp, which deforms around the stamp and substrate, and which is sealed with the counterforce of the stamper. Such tools are particularly well suited for soft stamps and UV-curable liquid resists, which can be imprinted at low pressure. The advantage of this soft stamping method is that a very gentle contact between stamp and substrate can be achieved by adjusting the air pressure, so that the surface can assume parallel alignment before the molding starts, and even local progression and retraction of the stamp can be programmed (e.g., in the so-called substrate conformal imprint lithography, SCIL [5.68]. During molding the pressure is equilibrated without delay, which assures a constant press force in all areas of the stamp only limited by the bending of the stamp.

All press concepts can be realized with heating elements for NIL, or with a UV exposure tool that enables exposure of the resist during molding. Furthermore, combinations of thermoplastic molding and UV exposure are possible. The main difference between thermoplastic molding and UV imprint are the pressures needed for imprint. Pressures from 1 to 100 bar are used in NIL, while less than 1 bar (0.1 MPa, 14.5 psi) is sufficient in UV-NIL.

Step-and-Repeat NIL

In PL, stepping was needed because of the limitation of the maximum field size to be exposed, and because the continuous reduction of structure sizes and diffraction effects is only possible by optical reduction of the masking structures into the resist by high-resolution optics. In contrast to this, step-and-repeat (S&R) NIL machines are physically identical to single-step NIL machines. They pattern a smaller area of a wafer at a time, and then move to an unpatterned area, where the process is repeated. The process is continued until the whole wafer is patterned. Many applications, e.g., with chip-based designs, enable the enlargement of the imprinted area by repeated printing with a smaller stamp, as long as the following imprints do not affect adjacent patterned areas. While this setup enables the use of smaller and more cost-effective molds, with which higher alignment accuracy can be achieved, higher process times and stitching errors at the borders of the patterned fields have to be taken into account. In the case of NIL heating and cooling times can be reduced because of the lower thermal mass, and in the case of UV-NIL illumination schemes can be simplified for smaller exposure fields; see Fig. 5.16.

In thermal NIL the thermal mass of the parts being thermally cycled should be minimized, in order to reduce the obtainable process time. This problem is readily addressed in S&R and in roll-to-roll NIL approaches, but has also found a solution in the concept of heatable stamps [5.69] or by surface heating by means of pulsed laser light [5.70]. The most advanced system is JFIL, which is directed towards high-volume manufacturing using 1 : 1 stepping of $26 \times 33\,\mathrm{mm}^2$ stamps. Apart from this, stamp fabrication and area enlargement, similar to recombination in counterfeit hologram production, is the most attractive field for S and R processes.

Roll-to-Roll NIL

Roll-to-roll (R2R) processing, also known as web processing, or reel-to-reel processing, involves the patterning of flexible materials such as plastics or metal foils (*web*), which are transferred from a roll (or reel) to another roll. If surface topographies are transferred to the foil, the term *roll embossing* is often used, which is here – in accordance with the scope of the chapter – named R2R-NIL [5.67, 71, 72]. To ensure continuous patterning of a resist on the foil, it is fed into the gap between two cylinders (*rolls*) from which one is patterned and the pattern is transferred. The area of highest pressure in which displacement of material is possible, is – due to the flexibility of either cylinders or web – in a *widened line*, or length of the web, which is called *nip*. This nip, from a few millimeters to centimeters, defines, combined with the speed of feeding, the process time available for pattering. For this, often bendable stamps are needed, which are wrapped around the cylinder.

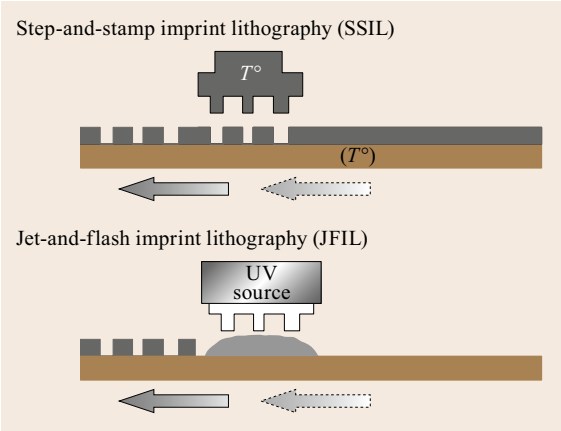

Fig. 5.16a,b Step-and-repeat processes. **(a)** In NIL: step-and-stamp imprinting lithography (SSIL), and **(b)** in UV-NIL: step and flash, aka jet and flash, imprint lithography (SFIL/JFIL). While in SFIL the liquid resin is cured locally by exposure through the stamp, in SSIL the resist is locally heated above its glass transition temperature by the hot stamp ($T°$ denotes a temperature often set above room temperature)

Continuous processing techniques are considered to have cost and processing advantages and are typically employed if speed and throughput have to be increased, but also if a constant quality over a large quantity of devices has to be achieved. However, they are physically identical to noncontinuous (sequential and stationary) processing techniques and require similar processing times for pattern formation and transfer. Therefore, apart from R2R, hybrid processes such as roll-to-plate (R2P) and plate-to-roll (P2R) sometimes have specific advantages over R2R. In R2P a pattern from a bent stamp can be imprinted or a resist transferred from a foil onto a flat substrate, and in P2R a flat stamp can be printed on a continuous foil in S&R semi-continuous mode.

In general, the advantage of roll processing is that once the process is stabilized, it can be run as long as contamination does not accumulate, antistiction layers (ASL) are preserved and processes are kept within a narrow process window. The disadvantage is that sometimes long optimization runs are needed before stability is achieved, causing waste of material, and the difficulty to interrupt processes for process control.

5.4 Applications

5.4.1 Types of Nanoimprint Applications

NIL applications can be divided into two main categories. In the first category, pattern transfer applications, the imprinted resist structure is used as a temporary masking layer for a subsequent pattern-transfer step. In the second category, polymer devices, the imprinted pattern adds functionality to the polymer film, which is the end product.

In many pattern-transfer applications, the main issue is high throughput at nanoscale resolution. Disregarding this issue, it is of minor importance whether the resist film is patterned by means of electromagnetic radiation, electrons, or by mechanical deformation. Only a few steps in the process flow are different, for example the dry etch step to remove the 10–100 nm-thick residual polymer layer after the imprint. Both additive and subtractive pattern transfer processes have been demonstrated, such as lift-off, electroplating and etching [5.73–76].

The advantages of NIL come into play if high resolution is needed over a large area. For such applications, NIL is a cost-effective alternative to current cutting-edge lithography techniques such as deep ultraviolet (DUV) lithography, dedicated to CMOS chip manufacturing [5.12, 77]. Examples of such products are bit-patterned media (BPM) for hard-disk drives (HDDs) [5.78, 79], patterned sapphire substrates (PSS) for enhanced light extraction from light-emitting diodes (LEDs [5.80] and subwavelength wire grid polarizers for high-definition television (HDTV) projectors [5.81].

The NIL process offers new possibilities to form polymer devices with microscale to nanoscale features. Nanoscale patterned polymer films find a wide range of applications within optics, electronics and nanobiotechnology. The capability to form 3-D polymer structures, with curved surfaces and high aspect ratio, paves the way for new classes of polymer-based passive optical devices, such as lenses and zone plates [5.46], photonic crystals (PhCs) [5.82] and integrated polymer optics [5.83]. The NIL technique allows for the choosing of a wide range of polymers with optimized optical properties, and allows for the patterning of thin films of organic light-emitting materials and polymers doped with laser dyes to create organic light-emitting devices (OLEDs) [5.84, 85] and lasers [5.86]. NIL is also suitable for nanoscale patterning of conducting organic films for cost-effective organic electronics [5.87].

Also within the rapidly growing field of lab-on-a-chip applications [5.88], NIL offers an attractive, cost-effective method for molding of complex structures, integrating micro- and nanofluidics, optics, mechanics and electronics on a single chip [5.89]. For example, the micro- to nanoscale fabrication capabilities are used to create single-use polymer devices containing nanopillar arrays [5.90] and nanofluidic channels [5.91] for DNA separation and sequencing.

In this section we will give an overview of different fields of applications. We start with two examples of pattern-transfer applications, which are close to production: bit-patterned media for HDD, and subwavelength metal wire gratings for HDTV projectors. We then discuss a few examples of laboratory-scale potential high-impact applications of NIL. These examples were selected from a large number of NIL applications. The number of laboratory-scale NIL applications is rapidly growing, reflecting a wealth of new possible device architectures becoming feasible by NIL. Some of the applications are directly relevant for industrial production, and others are directed towards research. Even in research the nanostructuring capability of replication processes are needed. Further insight into this field is given in Sect. 5.1.2 about pattern transfer and in Sect. 5.5 about commercialization aspects of NIL.

5.4.2 Semiconductor Memory Chips

The semiconductor industry is currently (2016) considering NIL as possible NGL to deliver the 14 nm node and beyond for the manufacturing of advanced devices such as NAND (negative AND logic) flash memory [5.13, 92]. The requirements for single-substrate patterning with moderate defect density and for chip manufacturing with 50 aligned masking levels are quite different from single-layer devices. One-step patterning at 15 nm half-pitch was achieved with JFIL, eliminating the need for complicated and expensive self-aligned multiple patterning. In addition, patterns are not limited to repeating structures such as lines and spaces. For chip manufacturing not only are the resolution issue and cost of masks important, but more and more the defectivity rate, which was until now considered as prohibitive because NIL – as a mechanical contact-based technology – is prone to contamination and wear. As an example, for a 16 nm NAND flash device, a 3σ overlay of approximately 5 nm, and less than 5 defect/cm^2 are required at a throughput of 20 wph (wafers per hour). While NIL is here mostly considered as the replacement of individual lithographic steps (pattern transfer applications), its 3-D capability, e.g., for the dual-damascene patterning of the interconnect (metalization) layer on top of the CMOS transistors, is still an option for future devices (Sect. 5.2.7). Here a functional material

is patterned, which after exposure remains as dielectric between the electroplated metal interconnects.

5.4.3 Bit-Patterned (Magnetic) Media (BPM) for Hard Disk Drives

Since the first demonstration of NIL, patterned magnetic media for HDD has been a key application for NIL technology [5.93]. After invention of the HDD in 1957, the storage capacity, quantified in areal density of bits, has increased to the current (2017) level exceeding 1 Tb/in^2. The size and density of the individual bits, defined by local magnetization of a homogeneous, or unpatterned thin magnetic film, was reduced by application of multilayer magnetic films as recording media, the sensitivity of the read-head was increased by exploiting the giant-magnetoresistance effect in multilayer thin-film conductors [5.94], and the magnetization was applied perpendicular to the surface of the recording media, while MEMS technology for the mechanical parts has been developed to a rather extreme level. In current HDDs the read-write head flies at a height of 2–3 nm above the surface of the disk plate. An overview of HDD technology is given in [5.95].

The possibilities to increase the bit density with the current technology, where bits are written by local magnetization of an unpatterned thin magnetic film, are mainly limited by the read-write width, the positioning of the magnetic head, and by thermal instability, induced by superparamagnetism in the grains of the magnetic film. These challenges are addressed by patterning the magnetic film, first implemented by discrete track recording (DTR) media [5.96], where the magnetic film is patterned with a spiral land, and groove tracks have been developed to overcome the problems associated with the read-write width and positioning of the magnetic head.

The magnetic film consists of small, weakly coupled magnetic grains, which behave as single-domain magnetic particles. Each bit consists of the order of 100 grains to obtain a reasonable signal-to-noise ratio. In order to keep this ratio of grains per bit, the grain size must be reduced with bit size. Now, with BPM, it is even increased to cover a single bit. The magnetic energy of a single grain scales with the volume of the grain. This implies that the bit can be erased thermally, when the grain size becomes sufficiently small and weakly coupled to neighboring grains. This is referred to as the superparamagnetic limit.

The superparamagnetic limit can be overcome by lithographically defining each bit as a magnetic nanoparticle or *nanomagnet*. In such a *quantized magnetic disk* [5.97, 98] each magnetic nanoparticle is a single magnetic domain with a well-defined shape, with a uniaxial magnetic anisotropy, so the magnetization only has two possible stable states, equal in magnitude but opposite in direction, as illustrated in Fig. 5.17. Such defined bits can be thermally stable for sizes down below 10 nm.

The feasibility of NIL for fabrication of patterns of magnetic nanostructures for quantized magnetic disks has been investigated by several research groups as reviewed in [5.78, 79]; see Fig. 5.18. While extensive research has been performed by enterprises such as Western Digital, Seagate and Toshiba during the last years, introduction of BPM has been postponed.

5.4.4 Subwavelength Metal-Strip Gratings and Transparent Electrodes for Displays

Metallic wire gratings with a period below 200 nm can be used to create polarizers, polarization beam splitters and optical isolators in the visible range. Such devices have many applications in compact and integrated optics, and not the least for liquid-crystal flat panel displays.

The polarizing functionality of subwavelength wire gratings is based on form-birefringence, an optical anisotropy that appears when isotropic material is structured on a length scale much smaller than the wavelength of light, λ. In this limit, the description of light propagation based on the laws of diffraction, refraction and reflection is not valid, and a rigorous solution of Maxwell's equations with the relevant boundary conditions must be applied. For a review on subwavelength optics, see [5.99]. The subwavelength linear grating of period $d < \lambda/2$, line width a, and height h, as illustrated in Fig. 5.19, will behave as a film of bire-

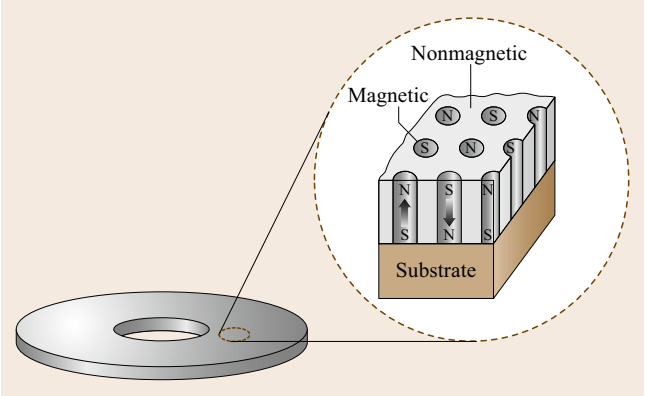

Fig. 5.17 Outline of a patterned magnetic disk for high-density data storage. Each bit is a lithographically defined, single-domain magnetic nanostructure, embedded in a nonmagnetic matrix (after [5.79])

The *top panel* shows SEM, atomic-force microscope (AFM) and magnetic-force microscope (MFM) micrographs at the different stages of the process. The MFM micrograph shows quantized up and down magnetization of isolated domains (after [5.79])

fringent material with the refractive indices n_s and n_p for the s-polarized (E-field parallel to the grating) and p-polarized (E-field perpendicular to the grating) light

$$n_p^2 = \frac{d}{a} n_1^2 + \left(1 - \frac{d}{a}\right) n_2^2 ,$$

$$n_s^2 = \frac{n_1^2 n_2^2}{\frac{d}{a} n_2^2 + \left(1 - \frac{d}{a}\right) n_1^2} ,$$

where n_1 and n_2 are the refractive indices of the isotropic grating and fill materials respectively.

For applications in liquid-crystal display (LCD) and liquid crystal on silicon (LCoS) projection devices, it is a key challenge to obtain a sufficiently high extinction ratio, larger than 2000, at the shorter wavelengths, i. e., for blue light ($\lambda \approx 450\,\text{nm}$). This requires a pitch d of 100 nm or smaller, which is not practical for production with conventional photolithography. *Yu* et al. [5.100], demonstrated a large-area ($100 \times 100\,\text{mm}^2$), $d = 100\,\text{nm}$ by NIL. The stamp gratings were formed by interference lithography using an Ar-ion laser ($\lambda = 351.1\,\text{nm}$) to achieve a pitch around 200 nm, which was transferred into a SiO_2 film by reactive-ion etching (RIE). The pitch was subsequently halved by *spatial frequency doubling*: conformal CVD deposition of Si_3N_4, and anisotropic trifluormethan/oxygen (CHF_3/O_2) RIE. Researchers at LG electronics have realized $d = 100\,\text{nm}$ Al wire grating polarizers by thermal NIL. The process is outlined in Fig. 5.20. The large-area grating stamp is fabricated by laser interference lithography in photoresist, and transferred into the underlying 200 nm-thick SiO_2 film using CF_4 and O_2 RIE [5.81]. The $50 \times 50\,\text{mm}^2$ devices (Fig. 5.21) have an extinction ratio over 2000 and a transmittance above 85% in the blue, at $\lambda = 450\,\text{nm}$. Large-area wire grid polarizers with extinction ratios larger than 1000 were fabricated by a roll-based JFIL process [5.101].

Metal films patterned as wire grids by nanoimprint lithography also have potential for transparent electrodes [5.102], for plasmonic devices [5.103] and the generation of plasmonic colors and color filters [5.104].

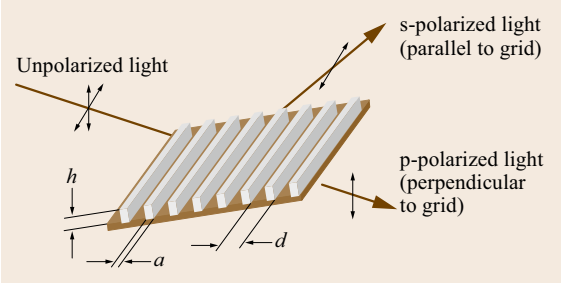

Fig. 5.19 Subwavelength wire grid polarizer. By application of subwavelength gratings, with a pitch below 100 nm for visible light, first-order diffraction with a high acceptance angle and low dispersion birefringence is obtained (after [5.81])

5.4.5 High Brightness Light-Emitting Diodes

GaN-based light-emitting diodes (LEDs) have large potential as energy efficient, long lifetime, environmentally friendly and stable light sources, and are currently entering a range of applications, such as full-color displays and projectors, traffic lights, and automotive and architectural lighting. Due to a high refractive index of the semiconductor material, the emitted light is easily trapped in waveguide modes inside the device, which strongly reduces external efficiency of the light source. The light extraction from the device can be significantly enhanced by nanopatterning the surface [5.105]. *Kim* et al. [5.106] applied a 2-D photonic crystal – an array of holes – with a photonic bandgap that prohibits propagation of photons of frequencies within the bandgap, leading to an enhanced extraction of photons through the surface of the device, and demonstrated a ninefold enhancement of the photoluminescence intensity of GaN-based green LEDs by means of 2-D PhC struc-

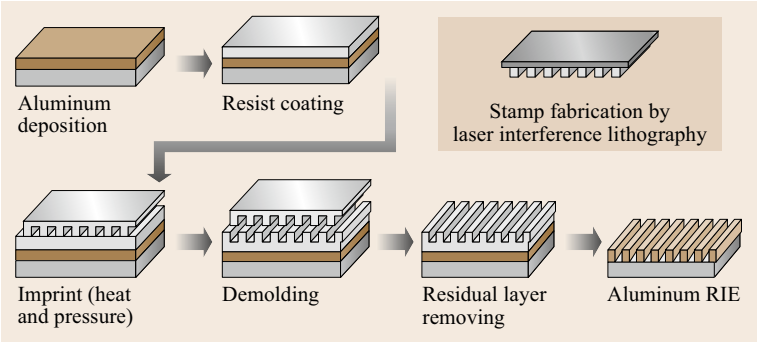

Fig. 5.20 Outline of the NIL process to fabricate $d = 100\,\text{nm}$ pitch aluminum wire grating polarizers

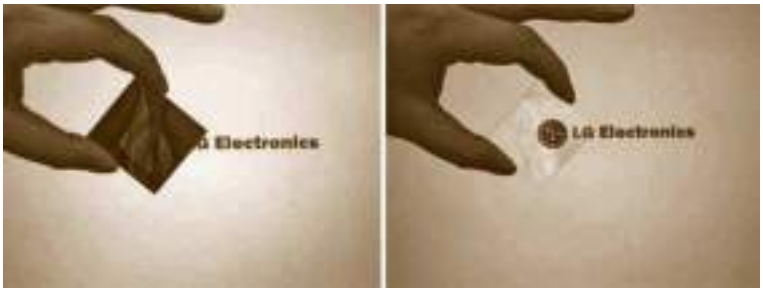

Fig. 5.21 Large-area 100 nm pitch wire grid polarizer with 85% transmission and extinction ratio larger than 2000 at wavelength $\lambda = 450\,\text{nm}$ (blue light)

tures of 180 nm-diameter, 100 nm-deep holes arranged in a square lattice with a period of 295 nm. The PhC pattern was defined by thermal NIL and RIE through a Cr mask. The NIL stamp was patterned by laser interference lithography.

Apart from such PhC surface patterns, which have also have the potential to enhance the efficiency of solar cells, NIL is used to create prepatterned substrates for semiconductor film growth, e.g., patterned sapphire (PSS) [5.107], which has been widely adopted in the industry because the epitaxial quality and light extraction efficiency can be improved simultaneously. This is done by patterning a resist and etching a regular microtopography (e.g., an orthogonal pattern with about 3 μm period) into a sapphire substrate. This pattern can be transferred into sapphire by (wet or dry) etching. After etching, the rectangular shape of the resist results in square pyramids, cones or domes, with sizes of about 3 μm and 1.0–2.0 μm height, due to the crystalline orientation of sapphire. The same principle can be employed by patterning to top of vertical-cavity surface-emitting lasers (VCSEL) [5.68] and entire photovoltaic cells [5.108].

5.4.6 Polymer Optics

NIL is ideally suited for the fabrication of polymer nanophotonics and waveguide devices with submicron critical dimensions, defined over large areas. It is also compatible with many polymer materials, giving large freedom to choose a material with specific optical properties [5.109–111].

In Fig. 5.22 we show a polymer microring resonator fabricated by NIL [5.83]. This type of device has been realized in PMMA, PC (polycarbonate), and PS (polystyrene) on SiO_2 substrates. The resonator consists of a planar waveguide and an adjacent microring waveguide. The waveguide and microring are coupled through the evanescent field in the coupling region. Resonant dips in the transmission through the waveguide occur when the phase pick-up in a trip round the microring is equal to $2\pi m$, where m is an integer. The device works as a narrow bandwidth filter, and finds applications within integrated optics and for biosensing [5.112].

The evanescent coupling coefficient between the waveguide and microring depend exponentially on the size of the gap. The devices are realized with 1.5 μm-high waveguides, and a coupling air-gap of 100–200 nm. The process flow is outlined in Fig. 5.22c. A thin initial polymer layer is spin cast onto a SiO_2 substrate layer. The stamp has a very large fill factor and large protrusion areas, implying that a large polymer flow is needed to fill the stamp cavities. A thin residual polymer layer is obtained by combining a high imprint pressure, a high process temperature and a long imprint time. The mode confinement in the PS waveguides is enhanced by etching the substrate oxide layer isotropically in hydrofluoric acid (HF), to create a pedestal structure. The Q-factor of

the resonator device depends critically on the surface scattering losses in the waveguides. The surface roughness of the polymer waveguides can be reduced by a controlled thermal reflow. The device is heated to 10–20 °C below the glass transition, and the surface reflows under the action of surface tension. A loss reduction of more than 70 dB/cm was achieved by this approach [5.113].

Apart from integrated micro- and nano-optics, antireflection gratings and subwavelength polarizers, NIL is particularly interesting for the fabrication of polymer devices such as light guides used for backlight illumination of displays and organic solar cells. For those applications, NIL is not only an easy way to patterns surfaces, but because it provides the ability to use R2R processes for upscaling and low-cost fabrication.

5.4.7 Biological Applications

Micro- and nanofabrication technology has enabled methods to manipulate and probe individual molecules and cells on a chip [5.114–117]. This type of application often requires a large area covered with nanostructures. Sometimes a large number of identical devices are needed for statistical evaluation, or to give redundancy, e.g., against clogging of nanofluidic channels. With these requirements, NIL is advantageous, or sometimes the only viable lithography method, even for laboratory-scale experiments and prototyping. Another example is devices for investigation of cell response to nanostructured surface topography, which requires nanometer-scale patterned surface areas in the mm^2 to cm^2 range.

Nanofluidic channels can be used to stretch DNA [5.118–120] for high-throughput, linear analysis. It enables measuring the length L of individual DNA molecules, or possibly sequencing by detection of fluorescent labels attached to the specific DNA sequences [5.121]; see Fig. 5.23. The linear analysis relies on a uniform stretching of the DNA molecules without coiling, as they are driven through the narrow channel. This implies that the nanofluidic channel should have cross-sectional dimensions D close to or smaller than the persistence length of the DNA, $L_p \approx 50$ nm [5.121]. The assumption of uniform stretching of the molecule also puts strong requirements to the channel sidewall smoothness.

Cell growth and adhesion can be strongly influenced by surface topography on the micrometer to nanometer length scale [5.122], and antibacterial nanotextured surfaces can be applied to minimize biofilm formation [5.123].

Gadegaard et al. [5.124] created a three-dimensional tubular scaffold for tissue engineering of blood vessels, which reproduces the basic structure of natural blood vessels: a layer of smooth muscle cells – fibroblasts – coaxially embedded between an outer collagen mesh and an inner linen of endothelial cells. Such artificially grown blood vessels with tight control of cellular attachment, migration and growth are expected to reduce problems with cellular debris and inflammation.

5.5 Conclusion and Outlook

Technological development is much based on so-called enabling techniques. For example, Gutenberg's book printing with movable metal letters was based on a combination of different existing techniques (large wine presses and metallurgy for letter casting), solving throughput and flexibility problems, and was developed at a time of globalization when information needed to be multiplied and spread (e.g., books, leaflets and maps) (1455 AD) [5.125]. In a similar way, a new lithographic technique with micro- and nanopatterning capability, such as NIL, is not entirely new, but based on patterning techniques coming from silicon micromachining and compact disc molding. In a time of technological dynamics it will lead to advances in different fields:

- In research, as long as machines are affordable and reliable enough that they can replace or complement standard lithographic techniques. In the case of thermal NIL it is advantageous that nanostructures can be replicated with simple molding tools, e.g., hot presses without alignment, thus making it possible to integrate nanopatterning by NIL into device manufacturing. Standard mask aligners can be upgraded to perform UV-NIL with moderate pressures.
- In industry, if they help to cross technological barriers, they can reduce cost and enable expansion into fields that until now have been reserved to high-volume manufacturing (HVM). Success will also depend on whether they fit into the process chain already established in a semiconductor cleanroom environment. Furthermore, substrate sizes, throughput and yield have to correspond to production requirements. As in research, many of the machines already available can be used for moderate-scale production. They can be scaled up to substrate sizes of 300 mm and higher in combination with batch-mode operation (wafer track systems) and by combining imprint tools into clusters.

In semiconductor manufacturing, NIL is currently seen as an alternative to established high-end photolithographies, enabling the replace of single or multiple mask patterning steps by a 1X imprint step – this is mostly owing to the efforts in reducing defectivity and increasing throughput. Introduction has been postponed several times, but should be – at least for NAND memory chips – in 2017 [5.13, 92]. However, NIL has other capabilities, as demonstrated in Sect. 5.4, even if not all requirements of the ITRS roadmap are met at once. Most of the other applications are based on single layers covered with nanostructures, mostly regular high-resolution gratings and dot arrays, and need single-step wafer-scale replication tools for large areas. However, CoO has become the driving force for integration of new techniques, since both 193 nm DUV- and 13.6 nm EUV-lithography have been pushing the limits of photolithography towards single-digit resolution.

NIL has now passed a barrier from a laboratory scale to industrial preproduction and is now used in patterning of PSS and for optical microdevices. Although it seems that room-temperature processes based on UV exposure have an advantage over processes based on thermocycles, even after 20 yr of development it is difficult to say which process will become a standard process and make it to the production line [5.126]. For example, isothermal processes at elevated temperatures using hybrid processes have been established that use both thermal NIL and hardening by UV curing [5.127]. With state-of-the-art UV-NIL equipment [5.125], more than 20 wph with a diameter of 300 mm can now be achieved in a step-and-repeat mode (using a stamp area of $26 \times 33\,mm^2$). Single-step wafer-scale hot imprint

has similar capabilities, and can even push throughput further if heatable stamps with low thermal mass are used. However, NIL is currently such a fast-moving field that preclusion about the final success of one technique is not possible and advisable. Innovative solutions are still needed to solve process and stamp lifetime issues for many different applications. Probably not just a single NIL process will be successfully implemented, but many variants of NIL. This includes hybrid approaches, e.g., NIL in combination with other lithographic processes, or the fabrication and copying of stamps using NIL.

6. Stamping Techniques for Micro- and Nanofabrication

John A. Rogers, Etienne Menard

Soft-lithographic techniques that use rubber stamps and molds provide simple means to generate patterns with lateral dimensions that can be much smaller than 1 μm and can even extend into the single nanometer regime. These methods rely on the use of soft elastomeric elements typically made out of the polymer poly(dimethylsiloxane). The first section of this chapter presents the fabrication techniques for these elements together with data and experiments that provide insights into the fundamental resolution limits. Next, several representative soft-lithography techniques based on the use of these elements are presented:

1. Microcontact printing, which uses molecular *inks* that form self-assembled monolayers.
2. Near- and proximity-field photolithography for producing two- and three-dimensional structures with subwavelength resolution features.
3. Nanotransfer printing, where soft or hard stamps print single or multiple layers of solid inks with feature sizes down to 100 nm.

The chapter concludes with descriptions of some device-level applications that highlight the patterning capabilities and potential commercial uses of these techniques.

There is considerable interest in methods that can be used to build structures that have micron or nanometer dimensions. Historically, research and development in this area has been driven mainly by the needs of the microelectronics industry. The spectacularly successful techniques that have emerged from those efforts – such as photolithography and electron beam lithography – are extremely well suited to the tasks for which they were principally designed: forming structures of radiation-sensitive materials (including photoresists or electron beam resists) on ultraflat glass or semiconductor surfaces. Significant challenges exist in adapting these methods for new emerging applications and areas of research that require patterning of unusual systems and materials, (including those in biotechnology and plastic electronics), structures with nanometer dimensions (below 50–100 nm), large areas in a single step (larger than a few square centimeters), or nonplanar (rough or curved) surfaces. These established techniques also have the disadvantage of high capital and operational costs. As a result, some of the oldest and conceptually simplest forms of lithography – embossing, molding, stamping, writing, and so on – are now being reexamined for their potential to serve as the basis for nanofabrication techniques that can avoid these limitations [6.1]. Considerable progress has been made in the last few years, mainly by combining these approaches or variants of them with new materials, chemistries, and processing techniques. This chapter highlights some recent advances in high-resolution printing methods, in which a *stamp* forms a pattern of *ink* on a surface that it contacts. It focuses on approaches whose capabilities, level of development, and demonstrated applications indicate a strong potential for widespread use, especially in areas where conventional methods are unsuitable.

Contact printing involves the use of an element with surface relief (the *stamp*) to transfer material applied to its surface (the *ink*) to locations on a substrate that it contacts. The printing press, one of the earliest manufacturable implementations of this approach, was introduced by Gutenberg in the fifteenth century. Since

then, this general approach has been used almost exclusively for producing printed text or images with features that are 100 μm or larger in their smallest dimension. The resolution is determined by the nature of the ink and its interaction with the stamp and/or substrate, the resolution of the stamp, and the processing conditions that are used for printing or to convert the pattern of ink into a pattern of functional material. This chapter focuses on (1) printing techniques that are capable of micron and nanometer resolution, and (2) their use for fabricating key elements of active electronic or optical devices and subsystems. It begins with an overview of some methods for fabricating high-resolution stamps and then illustrates two different ways that these stamps can be used to print patterns of functional materials. Applications that highlight the capabilities of these techniques and the performances of systems that are constructed with them are also presented.

6.1 High-Resolution Stamps

The printing process can be separated into two parts: fabrication of the stamp and the use of this stamp to pattern features defined by the relief on its surface. These two processes are typically quite different, although it is possible in some cases to use patterns generated by a stamp to produce a replica of that stamp. The structure from which the stamp is derived, which is known as the *master*, can be fabricated with any technique that is capable of producing well-defined structures of relief on a surface. This master can then be used directly as the stamp, or to produce stamps via molding or printing procedures. It is important to note that the technique for producing the master does not need to be fast or low in cost. It also does not need to possess many other characteristics that might be desirable for a given patterning task: it is used just once to produce a master, which is directly or indirectly used to fabricate stamps. Each one of these stamps can then be used many times for printing.

In a common approach for the high-resolution techniques that are the focus of this chapter, an established lithographic technique, such as one of those developed for the microelectronics industry, defines the master. Figure 6.1 schematically illustrates typical processes. Here, photolithography patterns a thin layer of resist onto a silicon wafer. Stamps are generated from this structure in one of two ways: by casting against this master, or by etching the substrate with the patterned resist as a mask. In the first approach, the master itself can be used multiple times to produce many stamps, typically using a light or heat-curable prepolymer. In the second, the etched substrate serves as the stamp. Additional stamps can be generated either by repeating the lithography and etching, or by using the original stamp to print replica stamps. For minimum lateral feature sizes that are greater than ≈ 1–2 μm, contact- or proximity-mode photolithography with a mask produced by direct write photolithography represents a convenient method of fabricating the master. For features smaller than ≈ 2 μm, several different techniques can be used [6.2], including:

1. Projection mode photolithography [6.3]
2. Direct write electron beam (or focused ion beam) lithography [6.4, 5]

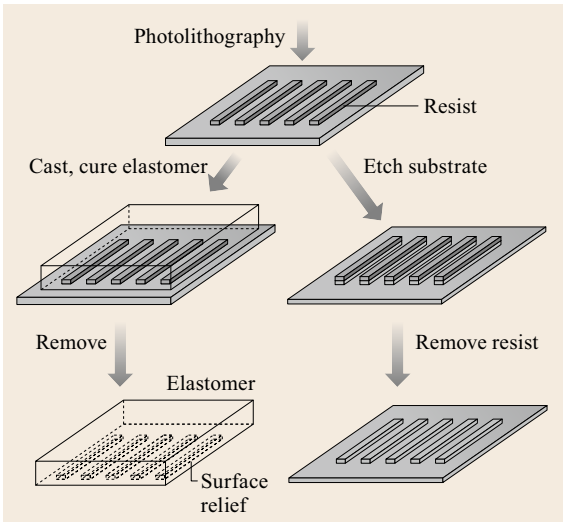

Fig. 6.1 Schematic illustration of two methods for producing high-resolution stamps. The first step involves patterning a thin layer of some radiation-sensitive material, known as the resist, on a flat substrate, such as a silicon wafer. It is convenient to use an established technique, such as photolithography or electron beam lithography, for this purpose. This structure, known as the *master*, is converted to a stamp either by etching or by molding. In the first case, the resist acts as a mask for etching the underlying substrate. Removing the resist yields a stamp. This structure can be used directly as a stamp to print patterns or to produce additional stamps. In the molding approach, a prepolymer is cast against the relief structure formed by the patterned resist on the substrate. Curing (thermally or optically) and then peeling the resulting polymer away from the substrate yields a stamp. In this approach, many stamps can be made with a single *master* and each stamp can be used many times

3. Scanning probe lithography [6.6–9]
4. Laser interference lithography [6.10].

The first approach requires a photomask generated by some other method, such as direct write photolithography or electron beam lithography. The reduction (typically 4×) provided by the projection optics relaxes the resolution requirements on the mask and enables features as small as ≈ 90 nm when deep ultraviolet radiation and phase shifting masks are used. The costs for these systems are, however, very high and their availability for general research purposes is limited. The second method is flexible in the geometry of patterns that can be produced, and the writing systems are highly developed: 30–50 nm features can be achieved with commercial systems [6.11], and < 10 nm features are possible with research tools, as first demonstrated more than 25 years ago by *Broers* [6.12]. The main drawbacks of this method are that it is relatively slow and it is difficult to pattern large areas. Like projection-mode photolithography, it can be expensive. The third

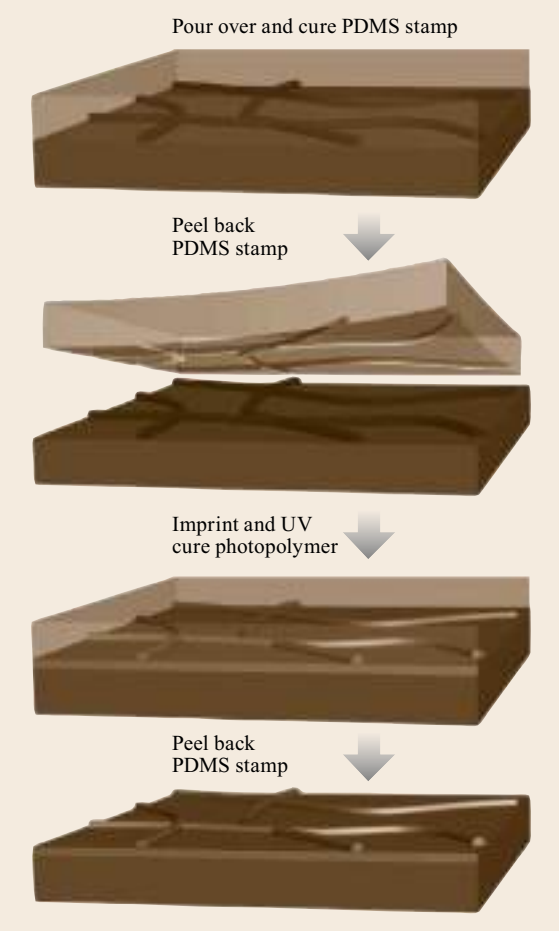

Fig. 6.2 Schematically illustrates a process for examining the ultimate limits in resolution of soft lithographic methods. The approach uses a SWNT master to create a PDMS mold with nanoscale relief features. Soft nanoimprint lithography transfers the relief on the PDMS to that on the surface of an ultraviolet curable photopolymer film

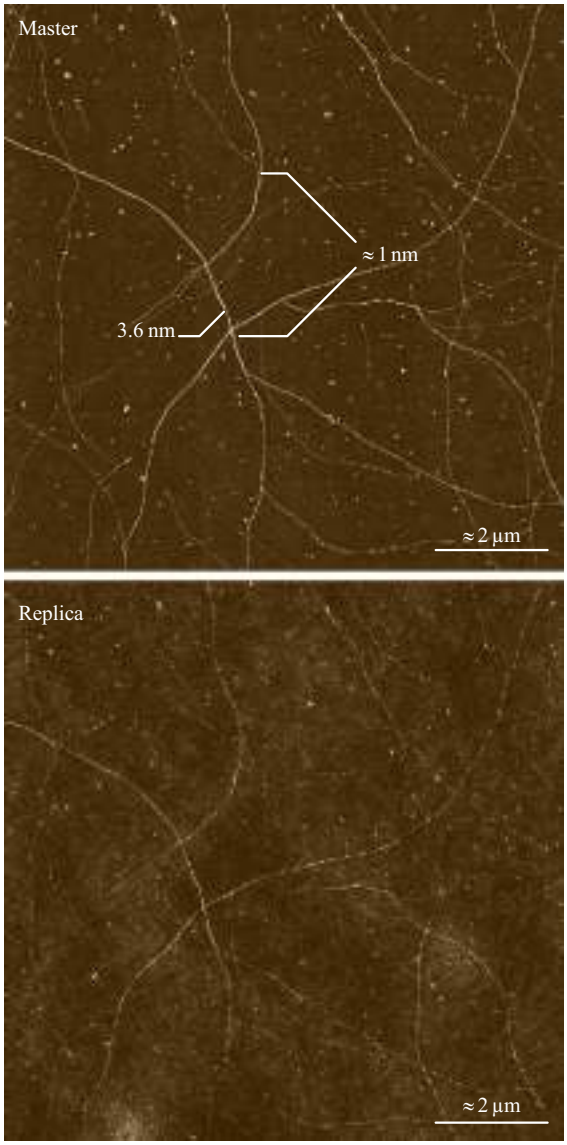

Fig. 6.3 Atomic force micrographs (*top* picture) of a *master* that consists of a submonolayer of single-walled carbon nanotubes (SWNTs; diameter between 0.5 and 5 nm) grown on a SiO_2/Si wafer. The *bottom* atomic force micrograph shows a replica of the relief structures in poly(urethane). These results indicate effective operation of a PDMS stamp for soft imprint lithography at the single nanometer scale

method, scanning probe lithography, is quite powerful in principle, but the tools are not as well established as those for other approaches. This technique has atomic resolution, but its writing speed can be lower and the areas that can be patterned are smaller than electron beam systems. Interference lithography provides a powerful, low-cost tool for generating periodic arrays of features with dimensions down to 100–200 nm; smaller sizes demand ultraviolet lasers, and patterns with aperiodic or nonregular features are difficult to produce.

In order to evaluate the ultimate resolution limit of the soft lithography methods, masters with relief structures in the single nanometer range must be fabricated. A simple method, presented in Fig. 6.2, uses submonolayer coverage of single-walled carbon nanotubes (SWNT) grown, by established chemical vapor deposition techniques, on an ultraflat silicon wafer. The SWNT, which have diameters (heights and widths) in the 0.5–5 nm range, are molded on the bottom surface of a poly(dimethylsiloxane) (PDMS) stamp generated by casting and curing against this master. Such a mold can be used to replicate the relief structure into a variety of photocurable polymers in a kind of soft nanoimprinting technique [6.13–15]. A single mold can give exceedingly high resolution, approaching the single nanometer scale range (comparable to a few bond lengths in the polymer backbone), as can be seen in Fig. 6.3 [6.16]. These results demonstrate the extreme efficiency of the basic soft lithographic procedure for generating and using elastomeric elements. The ultimate limits are difficult to predict, due to substantial uncertainties surrounding the polymer physics and chemistry that dominates in the nanometer regime.

6.2 Microcontact Printing

Microcontact printing (μCP) [6.17] is one of several soft lithographic techniques – replica molding, micromolding in capillaries, microtransfer molding, near-field conformal photolithography using an elastomeric phase-shifting mask, and so on – that have been developed as alternatives to established methods for micro- and nanofabrication [6.18–22]. μCP uses an elastomeric element (usually poly(dimethylsiloxane) – PDMS) with high-resolution features of relief as a stamp to print patterns of chemical inks. It was mainly developed for use with inks that form self-assembled monolayers (SAMs) of alkanethiolates on gold and silver. The procedure for carrying out μCP in these systems is remarkably simple: a stamp, inked with a solution of alkanethiol, is brought into contact with the surface of a substrate in order to transfer ink molecules to regions where the stamp and substrate contact. The resolution and effectiveness of μCP rely on conformal contact between the stamp and the surface of the substrate, rapid formation of highly ordered monolayers [6.23], and the autophobicity of the SAM, which effectively blocks the reactive spreading of the ink across the surface [6.24]. It can pattern SAMs over relatively large areas (≈ up to 0.25 ft^2 has been demonstrated in prototype electronic devices) in a single impression [6.25]. The edge resolution of SAMs printed onto thermally evaporated gold films is on the order of 50 nm, as determined by lateral force microscopy [6.26]. Microcontact printing has been used with a range of different SAMs on various substrates [6.18]. Of these, alkanethiolates on gold, silver, and palladium [6.27] presently give the highest resolution. In many cases, the mechanical properties of the stamp limit the sizes of the smallest features that can be achieved: the most commonly used elastomer (Sylgard 184, Dow Corning) has a low modulus, which can lead to mechanical collapse or sagging for features of relief with aspect ratios greater than ≈ 2 or less than ≈ 0.05. Stamps fabricated with high modulus elastomers avoid some of these problems [6.28, 29]. Conventional stamps are also susceptible to in-plane mechanical strains that can cause distortions in the printed patterns. Composite stamps that use thin elastomer layers on stiff supports are effective at minimizing this source of distortion [6.30]. Methods for printing that avoid direct mechanical manipulation of the stamp can reduce distortions with conventional and composite stamps [6.25]. This approach has proven effective in large-area flexible circuit applications that require accurate multilevel registration.

The patterned SAM can be used either as a resist in selective wet etching or as a template in selective deposition to form structures of a variety of materials: metals, silicon, liquids, organic polymers and even biological species. Figure 6.4 schematically illustrates the use of μCP and wet etching to pattern a thin film of Au. Figure 6.5 shows scanning electron micrograph (SEM) images of nanostructures of gold (20 nm thick, thermally evaporated with a 2.5 nm layer of Ti as an adhesion promoter) and silver (≈ 100 nm thick formed by electroless deposition using commercially available plating baths) [6.31] that were

fabricated using this approach. In the first and second examples, the masters for the stamps consisted of photoresist patterned on silicon wafers with projection and contact mode photolithography, respectively. Placing these masters in a desiccator for ≈ 1 h with a few drops of tridecafluoro-1,1,2,2-tetrahydrooctyl-1-trichlorosilane forms a silane monolayer on the exposed native oxide of the silicon. This monolayer prevents adhesion of the master to PDMS (Sylgard 184), which is cast and cured from a 10 : 1 mixture of prepolymer and curing agent. Placing a few drops of a ≈ 1 mM solution of hexadecanethiol (HDT) in ethanol on the surface of the stamps and then blowing them dry with a stream of nitrogen prepares them for printing. Contacting the metal film for a few seconds with the stamp produces a patterned self-assembled monolayer (SAM) of HDT. An aqueous etchant (1 mM $K_4Fe(CN)_6$, 10 mM $K_3Fe(CN)_6$, and 0.1 M $Na_2S_2O_3$) removes the unprinted regions of the silver [6.32]. A similar solution (1 mM $K_4Fe(CN)_6$, 10 mM $K_3Fe(CN)_6$, 1.0 M KOH, and 0.1 M $Na_2S_2O_3$) can be used to etch the bare gold [6.33]. The results in Fig. 6.5 show that the roughness on the edges of the patterns is ≈ 50–100 nm. The resolution is determined by the grain size of the metal films, the isotropic etching process, slight reactive spreading of the inks, and edge disorder in the patterned SAMs.

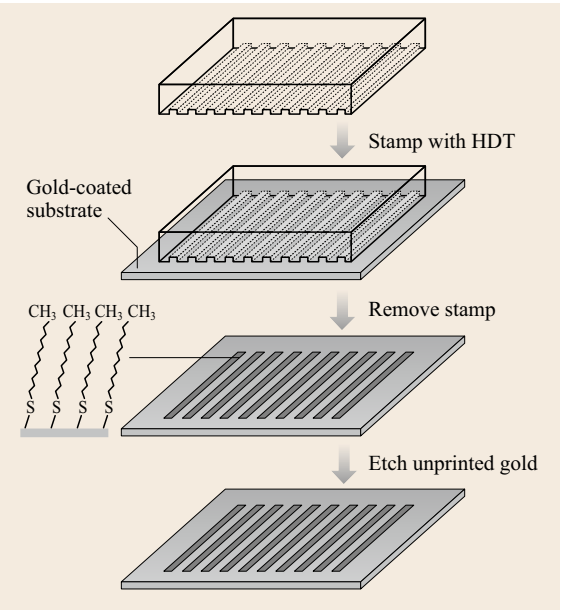

Fig. 6.4 Schematic illustration of microcontact printing. The first step involves *inking* a *stamp* with a solution of a material that is capable of forming a self-assembled monolayer (SAM) on a substrate that will be printed. In the case illustrated here, the ink is a millimolar concentration of hexadecanethiol (HDT) in ethanol. Directly applying the ink to the surface of the stamp with a pipette prepares the stamp for printing. Blowing the surface of the stamp dry and contacting it to a substrate delivers the ink to areas where the stamp contacts the substrate. The substrate consists of a thin layer of Au on a flat support. Removing the stamp after a few seconds of contact leaves a patterned SAM of HDT on the surface of the Au film. The printed SAM can act as a resist for the aqueous-based wet etching of the exposed regions of the Au. The resulting pattern of conducting gold can be used to build devices of various types

The structures of Fig. 6.5 were formed on the flat surfaces of silicon wafers (left image) and glass slides (right image). An attractive feature of μCP and certain other contact printing techniques is their ability to pattern features with high resolution on highly curved or rough surfaces [6.22, 34, 35]. This type of patterning task is difficult or impossible to accomplish with photolithography due to its limited depth of focus and the difficulty involved with casting uniform films of photoresist on nonflat surfaces. Figure 6.6 shows, as an example, a straightforward approach for high-resolution printing on the highly curved surfaces of optical fibers. Here, simply rolling the fiber over an inked stamp prints a pattern on the entire outer surface of the fiber. Simple staging systems allow alignment of features to the fiber axis; they also ensure registration of the pattern from one side of the fiber to the other [6.20]. Figure 6.7 shows 3 μm wide lines and spaces printed onto the surface of a single mode optical fiber (diameter 125 μm). The bottom frame shows a freestanding metallic struc-

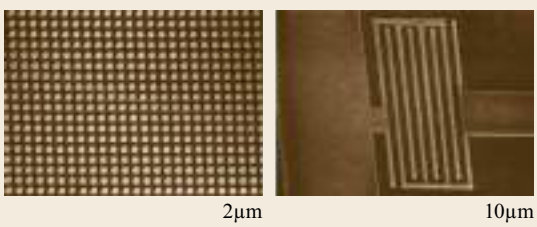

Fig. 6.5 Scanning electron micrographs of typical structures formed by microcontact printing a self-assembled monolayer ink of hexadecanethiol onto a thin metal film followed by etching of the unprinted areas of the film. The *left frame* shows an array of Au dots (20 nm thick) with ≈ 500 nm diameters. The *right frame* shows a printed structure of Ag (100 nm thick) in the geometry of interdigitated source/drain electrodes for a transistor in a simple inverter circuit. The edge resolution of patterns that can be easily achieved with microcontact printing is 50–100 nm

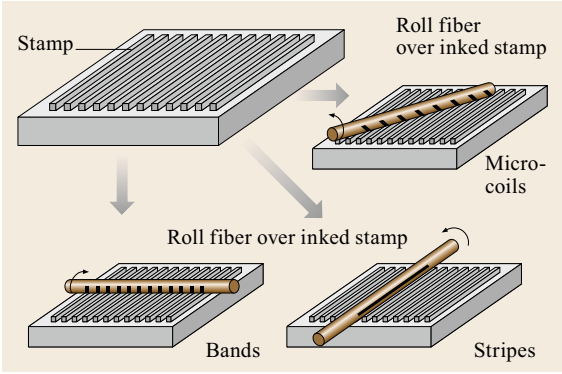

Fig. 6.6 Schematic illustration of a simple method to print lines on the surfaces of optical fibers. Rolling a fiber over the inked stamp prints a pattern onto the fiber surface. Depending on the orientation of the fiber axis with the line stamp illustrated here, it is possible, in a single rotation of the fiber, to produce a continuous microcoil, or arrays of bands or stripes

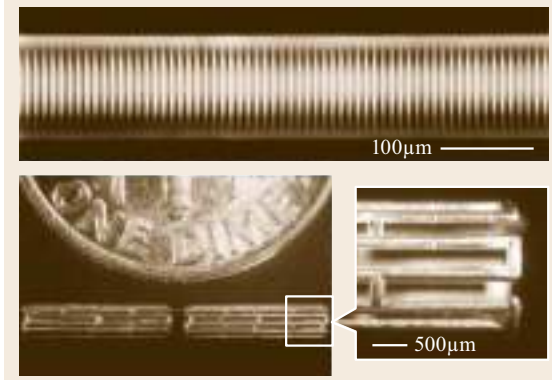

Fig. 6.7 Optical micrographs of some three-dimensional microstructures formed by microcontact printing on curved surfaces. The *top* frame shows an array of 3 μm lines of Au (20 nm)/Ti (1.5 nm) printed onto the surface of an optical fiber. This type of structure can be used as an integrated photomask for producing mode-coupling gratings in the core of the fiber. The *bottom* frames show a free-standing metallic microstructure formed by (a) microcontact printing and etching a thin film (100 nm thick) of Ag on the surface of a glass microcapillary tube, (b) electroplating the Ag to increase its thickness (to tens of micrometer) and (c) etching away the glass microcapillary with concentrated hydrofluoric acid. The structure shown here has the geometry and mechanical properties of an intravascular stent, which is a biomedical device commonly used in balloon angioplasty

ture with the geometry and mechanical properties of an intravascular stent, which is a biomedical device that is commonly used in balloon angioplasty procedures. In this latter case μCP followed by electroplating generated the Ag microstructure on a sacrificial glass cylinder that was subsequently etched away with concentrated hydrofluoric acid [6.36]. Other examples of microcontact printing on nonflat surfaces (low cost plastic sheets and optical ridge waveguides) appear in the Sect. 6.4.

6.3 Nanotransfer Printing

Nanotransfer printing (nTP) is a more recent high-resolution printing technique, which uses surface chemistries as interfacial *glues* and *release* layers (rather than *inks*, as in μCP) to control the transfer of solid material layers from relief features on a stamp to a substrate [6.37–39]. This approach is purely additive (material is only deposited in locations where it is needed), and it can generate complex patterns of single or multiple layers of materials with nanometer resolution over large areas in a single process step. It does not suffer from surface diffusion or edge disorder in the patterned inks of μCP, nor does it require post-printing etching or deposition steps to produce structures of functional materials. The method involves four components:

1. A stamp (rigid, flexible, or elastomeric) with relief features in the geometry of the desired pattern.
2. A method for depositing a thin layer of solid material onto the raised features of this stamp.
3. A means of bringing the stamp into intimate physical contact with a substrate.
4. Surface chemistries that prevent adhesion of the deposited material to the stamp and promote its strong adhesion to the substrate.

nTP has been demonstrated with SAMs and other surface chemistries for printing onto flexible and rigid substrates with hard inorganic and soft polymer stamps. Figure 6.8 presents a set of procedures for using nTP to pattern a thin metal bilayer of Au/Ti with a surface transfer chemistry that relies on a dehydration reaction [6.37]. The process begins with fabrication of a suitable stamp. Elastomeric stamps can be built using the same casting and curing procedures described for μCP. Rigid stamps can be fabricated by (1) patterning resist (such as electron beam resist or photoresist) on a substrate (such as Si or GaAs), (2) etching the exposed regions of the substrate with an anisotropic reactive ion etch, and (3) removing the resist, as illustrated in

Fig. 6.1. For both types of stamps, careful control of the lithography and the etching steps yields features of relief with nearly vertical or slightly reentrant sidewalls. The stamps typically have depths of relief $> 0.2\,\mu m$ for patterning metal films with thicknesses $< 50\,nm$.

Electron beam evaporation of Au (20 nm; 1 nm/s) and Ti (5 nm; 0.3 nm/s) generates uniform metal bilayers on the surfaces of the stamp. A vertical, collimated flux of metal from the source ensures uniform deposition only on the raised and recessed regions of relief. The gold adheres poorly to the surfaces of stamps made of GaAs, PDMS, glass, or Si. In the process of Fig. 6.8, a fluorinated silane monolayer acts to reduce the adhesion further when a Si stamp (with native oxide) is used. The Ti layer serves two purposes: (1) it promotes adhesion between the Au layer and the substrate after pattern transfer, and (2) it readily forms a ≈ 3 nm oxide layer at ambient conditions, which provides a surface where the dehydration reaction can take place. Exposing the titanium oxide (TiO_x) surface to an oxygen plasma breaks bridging oxygen bonds, thus creating defect sites where water molecules can adsorb. The result is a titanium oxide surface with some fractional coverage of hydroxyl (−OH) groups (titanol).

In the case of Fig. 6.8, the substrate is a thin film of PDMS (10–50 μm thick) cast onto a sheet of poly(ethylene terephthalate) (PET; 175 μm thick). Exposing the PDMS to an oxygen plasma produces surface (−OH) groups (silanol). Placing the plasma-oxidized, Au/Ti-coated stamp on top of these substrates leads to intimate, conformal contact between the raised regions of the stamp and the substrate, without the application of any external pressure. (The soft, conformable PDMS is important in this regard.) It is likely that a dehydration reaction takes place at the (−OH)-bearing interfaces during contact; this reaction results in permanent Ti−O−Si bonds that produce strong adhesion between the two surfaces. Peeling the substrate and stamp apart transfers the Au/Ti bilayer from the raised regions of the stamp (to which the metal has extremely poor adhesion) to the substrate. Complete pattern transfer from an elastomeric stamp to a thin elastomeric substrate occurs readily at room temperature in open air with contact times of less than 15 s. When a rigid stamp is employed, slight heating is needed to induce transfer. While the origin of this difference is unclear, it may reflect the comparatively poor contact when rigid stamps are used; similar differences are also observed in cold welding of gold films [6.40].

Figure 6.9 shows scanning electron micrographs of a pattern produced using a GaAs stamp generated by electron beam lithography and etching. The frames on the right show images of the metal-coated stamp before printing (top) and the transferred pattern (bottom).

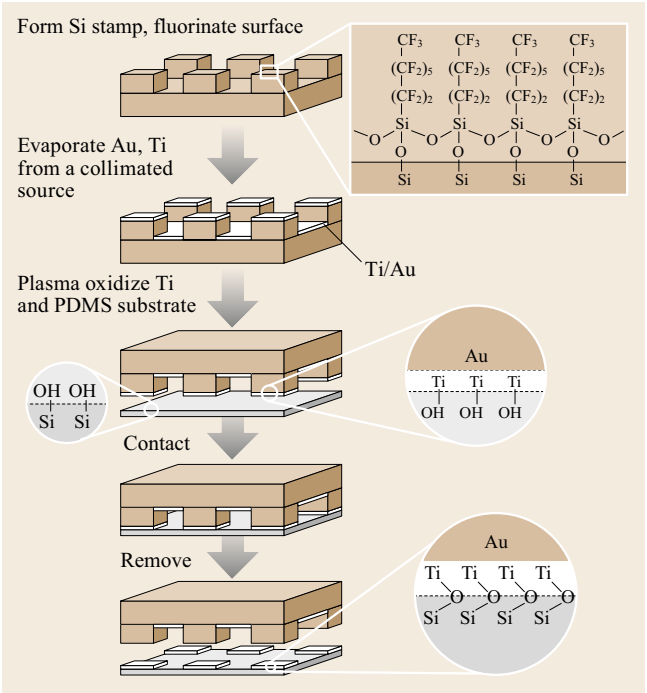

Fig. 6.8 Schematic illustration of nanotransfer printing procedure. Here, interfacial dehydration chemistries control the transfer of a thin metal film from a hard inorganic stamp to a conformable elastomeric substrate (thin film of poly(dimethylsiloxane) (PDMS) on a plastic sheet). The process begins with fabrication of a silicon stamp (by conventional lithography and etching) followed by surface functionalization of the native oxide with a fluorinated silane monolayer. This layer ensures poor adhesion between the stamp and a bilayer metal film (Au and Ti) deposited by electron beam evaporation. A collimated flux of metal oriented perpendicular to the surface of the stamp avoids deposition on the sidewalls of the relief. Exposing the surface Ti layer to an oxygen plasma produces titanol groups. A similar exposure for the PDMS produces silanol groups. Contacting the metal-coated stamp to the PDMS results in a dehydration reaction that links the metal to the PDMS. Removing the stamp leaves a pattern of metal in the geometry of the relief features

The resolution appears to be limited only by the resolution of the stamp itself, and perhaps by the grain size of the metal films. Although the accuracy in multilevel registration that is possible with nTP has not yet been quantified, its performance is likely similar to that of embossing techniques when rigid stamps are used [6.41].

A wide range of surface chemistries can be used for the transfer. SAMs are particularly attractive due to their chemical flexibility. Figure 6.10 illustrates the use of a thiol-terminated SAM and nTP for forming patterns of Au on a silicon wafer [6.38]. Here, the vapor phase

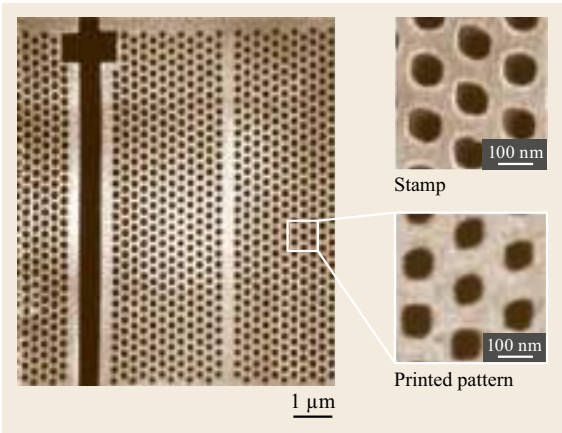

Fig. 6.9 Scanning electron micrograph (SEM) of a pattern produced by nanotransfer printing. The structure consists of a bilayer of Au (20 nm)/Ti (1 nm) (*white*) in the geometry of a photonic bandgap waveguide printed onto a thin layer of poly(dimethylsiloxane) on a sheet of plastic (*black*). Electron beam lithography and etching of a GaAs wafer produced the stamp that was used in this case. The transfer chemistry relied on condensation reactions between titanol groups on the surface of the Ti and silanol groups on the surface of the PDMS. The *frames* on the *right* show SEMs of the Au/Ti-coated stamp (*top*) before printing and on the substrate (*bottom*) after printing. The electron beam lithography and etching used to fabricate the stamp limit the minimum feature size (≈ 70 nm) and the edge resolution (≈ 5–10 nm) of this pattern

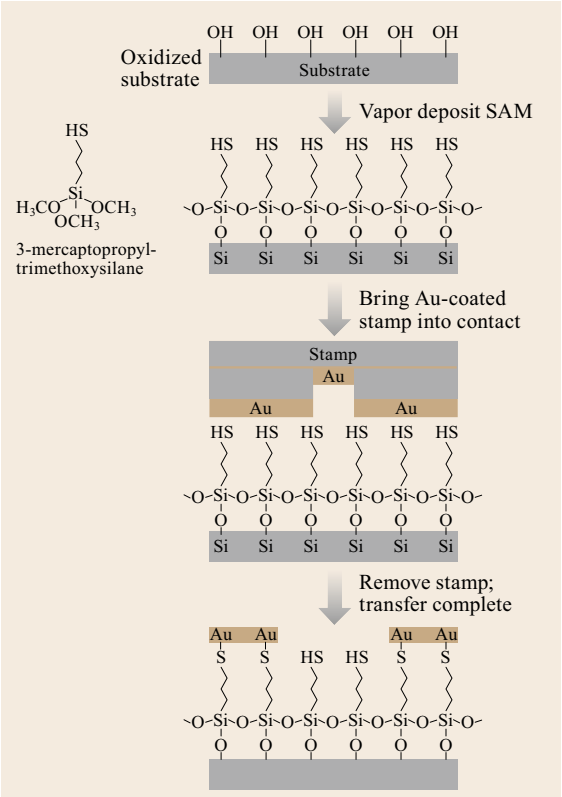

Fig. 6.10 Schematic illustration of steps involved in nanotransfer printing a pattern of a thin layer of Au onto a silicon wafer using a self-assembled monolayer (SAM) surface chemistry. Plasma oxidizing the surface of the wafer generates OH groups. Solution or vapor phase exposure of the wafer to 3-mercaptopropyltrimethoxysilane yields a SAM with exposed thiol groups. Contacting an Au-coated stamp to this surface produces thiol linkages that bond the gold to the substrate. Removing the stamp completes the transfer printing process

cocondensation of the methoxy groups of molecules of 3-mercaptopropyltrimethoxysilane (MPTMS) with the –OH-terminated surface of the wafer produces a SAM of MPTMS with exposed thiol (–SH) groups. PDMS stamps can be prepared for printing on this surface by coating them with a thin film (≈ 15 nm) of Au using conditions (thermal evaporation 1.0 nm/s; ≈ 10^{-7} Torr base pressure) that yield optically smooth, uniform films without the buckling that has been observed in the past with similar systems [6.42]. Nanocracking that sometimes occurs in the films deposited in this way can be reduced or eliminated by evaporating a small amount of Ti onto the PDMS before Au deposition and/or by exposing the PDMS surface briefly to an oxygen plasma. Bringing this coated stamp into contact with the MPTMS SAM leads to the formation of sulfur–gold bonds in the regions of contact. Removing the stamp after a few seconds efficiently transfers the gold from the raised regions of the stamp (Au does not adhere to the PDMS) to the substrate. Covalent bonding of the SAM glue to both the substrate and the gold leads to good adhesion of the printed patterns: They easily pass Scotch tape adhesion tests. Similar results can be obtained with other substrates containing surface –OH groups. For example, Au patterns can be printed onto ≈ 250 µm-thick sheets of poly(ethylene terephthalate) (PET) by first spin-casting and curing (130 °C for 24 h) a thin film of an organosilsesquioxane on the PET. Exposing the cured film (≈ 1 µm thick) to an oxygen plasma and then to air produces the necessary surface (–OH) groups. Figure 6.11 shows some optical micrographs of typical printed patterns in this case [6.38].

Similar surface chemistries can guide transfer to other substrates. Alkanedithiols, for example, are useful for printing Au onto GaAs wafers [6.39]. Immersing these substrates (freshly etched with 37% HCl for

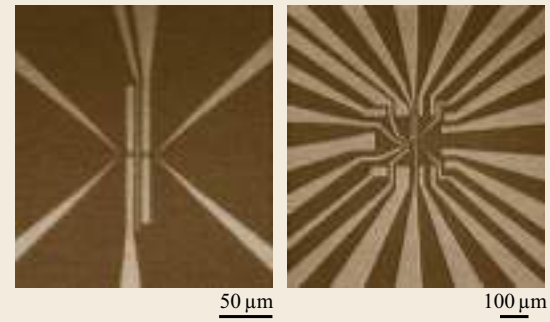

Fig. 6.11 Optical micrographs of patterns of Au (15 nm thick) formed on plastic (*left frame*) and silicon (*right frame*) substrates with nanotransfer printing. The transfer chemistries in both cases rely on self-assembled monolayers with exposed thiol groups. The minimum feature sizes and the edge resolution are both limited by the photolithography used to fabricate the stamps

≈ 2 min to remove the surface oxide) in a 0.05 M solution of 1,8-octanedithiol in ethanol for 3 h produces a monolayer of dithiol on the surface. Although the chemistry of this system is not completely clear, it is generally believed that the thiol end groups bond chemically to the surface. Surface spectroscopy suggests the formation of Ga−S and As−S bonds. Contacting an Au-coated PDMS stamp with the treated substrate causes the exposed thiol endgroups to react with Au in the regions of contact. This reaction produces permanent Au−S bonds at the stamp/substrate interface (see insets in Fig. 6.4 for idealized chemical reaction schemes). Figure 6.12 schematically illustrates how this procedure can generate continuous three-dimensional (3-D) metal patterns using stamps with nonvertical side walls. Several layers can be transferred on top of each other by successively cold-welding the different gold metal layers. Figure 6.13 shows high- and low-magnification scanning electron microscope images of nanotransfer printed single- and multilayer 3-D metal structures [6.43, 44]. The integrity of these free-standing 3-D metal structures is remarkable but depends critically on the careful optimization of the metal evaporation conditions and stamp & substrate surface chemistries.

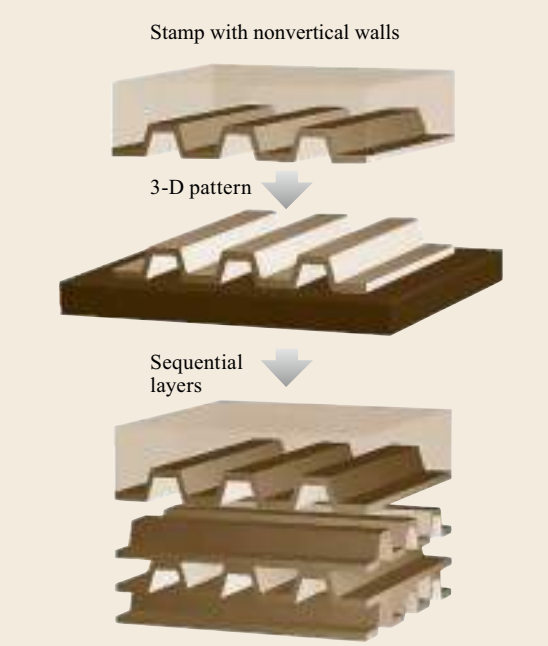

Fig. 6.12 Schematic illustration of the nanotransfer printing (nTP) process for generating continuous 3-D structures when the stamp relief side walls are not vertical. Successive transfer by cold welding the gold films on top of each other yields complex multilayer structures

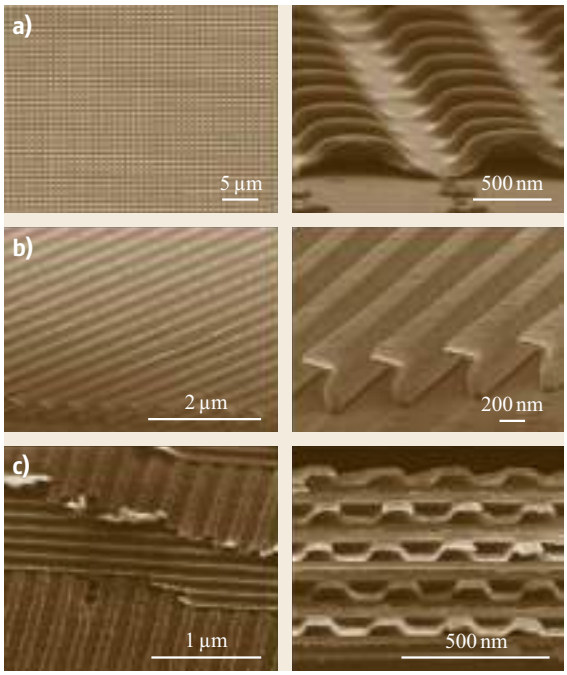

Fig. 6.13a–c Scanning electron micrographs of three-dimensional metal structures obtained by nanotransfer printing gold metal films. Part **(a)** shows closed gold nanocapsules. Part **(b)** shows free-standing L structures obtained using a stamp coated with a steeply angled flux of metal. Part **(c)** shows a multilayer 3-D structure obtained by the successive transfer and cold welding of continuous gold nanocorrugated films

6.4 Applications

Although conventional patterning techniques, such as photolithography or electron beam lithography, have the required resolution, they are not appropriate because they are expensive and generally require multiple processing steps with resists, solvents and developers that can be difficult to use with organic active materials and plastic substrates. Microcontact and nanotransfer printing are both particularly well suited for this application. They can be combined and matched with other techniques, such as ink-jet or screen printing, to form a complete system for patterning all layers in practical plastic electronic devices [6.45]. We have focused our efforts partly on unusual electronic systems such as flexible plastic circuits and devices that rely on electrodes patterned on curved objects such as microcapillaries and optical fibers. We have also explored photonic systems such as distributed feedback structures for lasers and other integrated optical elements that demand submicron features. The sections below highlight several examples in each of these areas.

6.4.1 Unconventional Electronic Systems

A relatively new direction in electronics research seeks to establish low-cost plastic materials, substrates and printing techniques for large-area flexible electronic devices, such as paperlike displays. These types of novel devices can complement those (including high-density memories and high-speed microprocessors) that are well suited to existing inorganic (such as silicon) electronics technologies. High-resolution patterning methods for defining the separation between the source and drain electrodes (the channel length) of transistors in these plastic circuits are particularly important because this dimension determines current output and other important characteristics [6.46].

Figure 6.14 illustrates schematically a cross-sectional view of a typical organic transistor. The frame on the right shows the electrical switching characteristics of a device that uses source/drain electrodes of Au patterned by μCP, a dielectric layer of an organosilsesquioxane, a gate of indium tin oxide (ITO), and a PET substrate. The effective semiconductor mobility extracted from these data is comparable to those measured in devices that use the same semiconductor (pentacene in this case) with inorganic substrates and dielectrics, and gold source/drain electrodes defined by photolithography. Our recent work [6.1, 31, 47] with μCP in the area of plastic electronics demonstrates:

1. Methods for using cylindrical *roller* stamps mounted on fixed axles for printing in a continuous reel-to-reel fashion, high-resolution source/drain electrodes in ultrathin gold and silver deposited from solution at room temperature using electroless deposition.
2. Techniques for performing registration and alignment of the printed features with other elements of a circuit over large areas.
3. Strategies for achieving densities of defects that are as good as those observed with photolithography when the patterning is performed outside of clean room facilities.
4. Methods for removing the printed SAMs to allow good electrical contact of the electrodes with organic semiconductors deposited on top of them.
5. Materials and fabrication sequences that can efficiently exploit these printed electrodes for working organic TFTs in large-scale circuits.

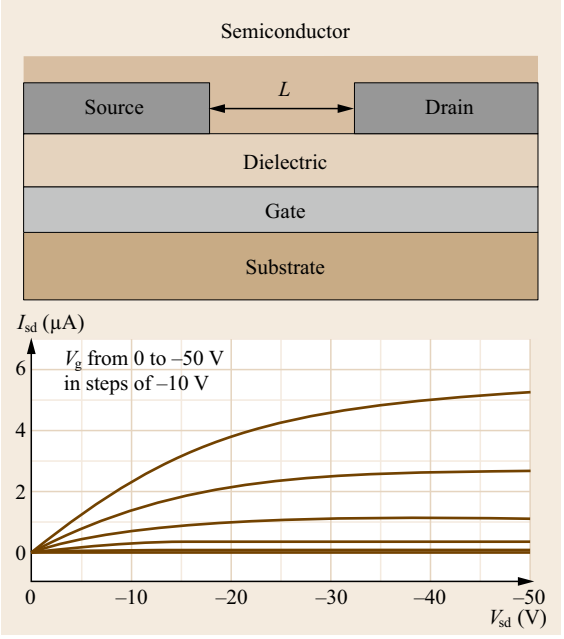

Fig. 6.14 Schematic cross-sectional view (*top*) and electrical performance (*bottom*) of an organic thin film transistor with microcontact printed source and drain electrodes. The structure consists of a substrate (PET), a gate electrode (indium tin oxide), a gate dielectric (spin-cast layer of organosilsesquioxane), source and drain electrodes (20 nm Au and 1.5 nm Ti), and a layer of the organic semiconductor pentacene. The electrical properties of this device are comparable to or better than those that use pentacene with photolithographically defined source/drain electrodes and inorganic dielectrics, gates and substrates

Figure 6.15 provides an image of a large-area plastic circuit with critical features defined by μCP. This circuit is a flexible active matrix backplane for a display. It consists of a square array of interconnected transistors, each of which serves as a switching element that controls the color of a display pixel [6.25, 48]. The transistors themselves have the layout illustrated in Fig. 6.11, and they use similar materials. The semiconductor in this image is blue (pentacene), the source/drain level is Au, the ITO appears green in the optical micrograph in the inset. Part of the circuit rests on the stamp that was used for μCP. The smallest features are the source and drain electrodes (≈ 15 μm lines), the interconnecting lines (≈ 15 μm lines), and the channel length of the transistor (≈ 15 μm). This circuit incorporates five layers of material patterned with good registration of the source/drain, gate, and semiconductor levels. The simple printing approach is illustrated in Fig. 6.16 [6.25]. Just before use, the surface of the stamp is cleaned using a conventional adhesive roller lint remover; this procedure removes dust from the stamp in such a way that does not contaminate or damage its surface. Inking the stamp and placing it face-up on a flat surface prepares it for printing. Matching the cross-hair alignment marks on the corners of one edge of the stamp with those patterned in the ITO brings the substrate into registration with the stamp. During this alignment, features on the stamp are viewed directly through the semitransparent substrate. By bending the PET sheet, contact with the stamp is initiated on the edge of the substrate that contains the cross-hair marks. Gradually unbending the sheet allows contact to progress across the rest of the surface. This printing procedure is attractive because it avoids distortions that can arise when directly manipulating the flexible rubber stamp. It also minimizes the number and size of trapped air pockets

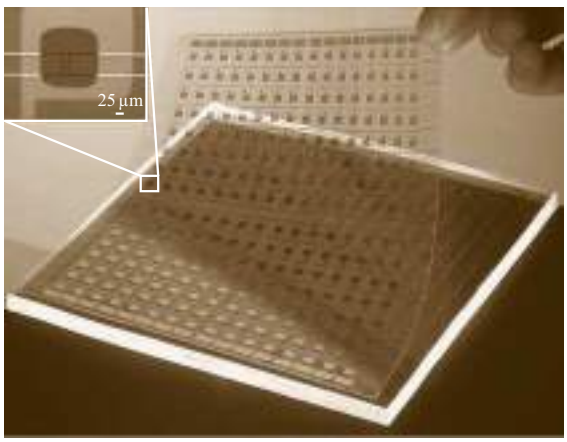

Fig. 6.15 Image of a flexible plastic active matrix backplane circuit whose finest features (transistor source/drain electrodes and related interconnects) are patterned by microcontact printing. The circuit rests partly on the elastomeric stamp that was used for printing. The circuit consists of a square array of interconnected organic transistors, each of which acts locally as a voltage-controlled switch to control the color of an element in the display. The *inset* shows an optical micrograph of one of the transistors

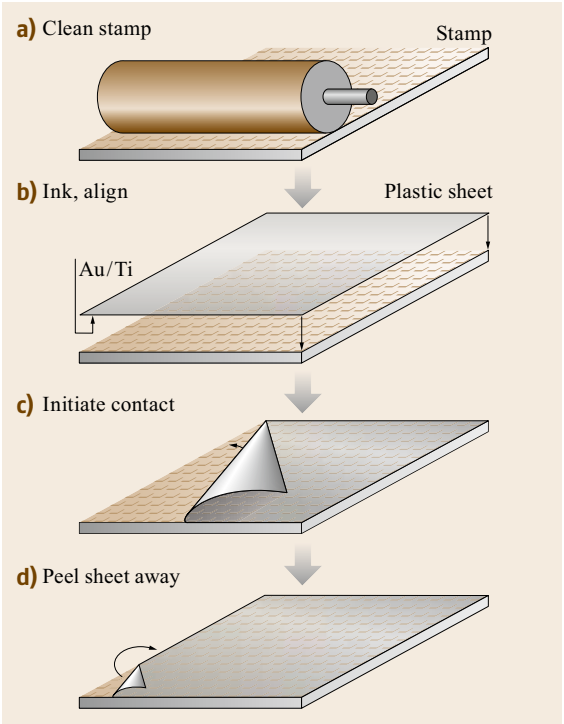

Fig. 6.16a–d Schematic illustration of fabrication steps for microcontact printing over large areas onto plastic sheets. The process begins **(a)** with cleaning the stamp using a conventional adhesive roller lint remover. This procedure effectively removes dust particles. To minimize distortions, the stamp rests face-up on a flat surface and it is not manipulated directly during the printing. Alignment and registration **(b)** are achieved with alignment marks on one side of the substrate and the stamp. By bending the plastic sheet, contact is initiated **(c)** on one side of the stamp; the contact line is then allowed to progress gradually across the stamp. This approach avoids formation of air bubbles that can frustrate good contact. After the substrate is in contact with the stamp for a few seconds, the plastic substrate is separated from the stamp **(d)** by peeling it away beginning in one corner. Good registration (maximum cumulative distortions of less than 50 μm over an area of 130 cm^2) and low defect density can be achieved with this simple approach. It is also well suited for use with rigid composite stamps designed to reduce the level of distortions even further

that can form between the stamp and substrate. Careful measurements performed after etching the unprinted areas of the gold show that over the entire $6'' \times 6''$ area of the circuit, (1) the overall alignment accuracy for positioning the stamp relative to the substrate (the offset of the center of the distribution of registration errors) is $\approx 50-100\,\mu m$, even with the simple approach used here, and (2) the distortion in the positions of features in the source/drain level, when referenced to the gate level, can be as small as $\approx 50\,\mu m$ (the full width at half maximum of the distribution of registration errors). These distortions represent the cumulative effects of deformations in the stamp and distortions in the gate and column electrodes that may arise during the patterning and processing of the flexible PET sheet. The density of defects in the printed patterns is comparable to (or smaller than) that in resist patterned by contact-mode photolithography when both procedures are performed outside of a clean-room facility (when dust is the dominant source of defects).

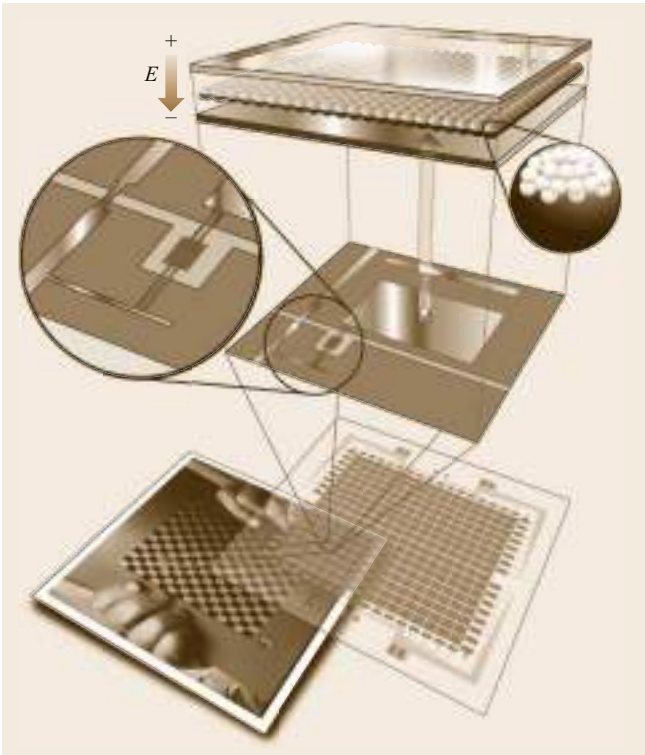

Fig. 6.17 Schematic exploded view of the components of a pixel in an electronic paperlike display (*bottom frame*) that uses a microcontact printed flexible active matrix backplane circuit (illustration near the *bottom frame*). The circuit is laminated against an unpatterned thin sheet of electronic ink (*top frame*) that consists of a monolayer of transparent polymer microcapsules (diameter $\approx 100\,\mu m$). These capsules contain a heavily dyed black fluid and a suspension of charged white pigment particles (see *right inset*). When one of the transistors turns on, electric fields develop between an unpatterned transparent frontplane electrode (indium tin oxide) and a backplane electrode that connects to the transistor. Electrophoretic flow drives the pigment particles to the front or the back of the display, depending on the polarity of the field. This flow changes the color of the pixel, as viewed from the front of the display, from black to white or vica versa

Figure 6.17 shows an *exploded* view of a paperlike display that consists of a printed flexible plastic backplane circuit, like the one illustrated in Fig. 6.16, laminated against a thin layer of *electronic ink* [6.25, 49]. The electronic ink is composed of a monolayer of transparent polymer microcapsules that contain a suspension of charged white pigment particles suspended in a black liquid. The printed transistors in the backplane circuit act as local switches, which control electric fields that drive the pigments to the front or back of the display. When the particles flow to the front of a microcapsule, it appears white; when they flow to the back, it appears black. Figure 6.18 shows a working sheet of active matrix electronic paper that uses this design. This prototype display has several hundred pixels and an optical contrast that is both independent of the viewing angle and significantly better than newsprint. The device is ≈ 1 mm thick, is mechanically flexible, and weighs $\approx 80\%$ less than a conventional liquid crystal display of similar size. Although these displays have only a relatively coarse resolution, all of the processing techniques, the μCP method, the materials, and the electronic inks, are suitable for the large numbers of pixels required for high-information content electronic newspapers and other systems.

Like μCP, nTP is well suited to forming high-resolution source/drain electrodes for plastic electronics. nTP of Au/Ti features in the geometry of the drain and source level of organic transistors, and with appropriate interconnects on a thin layer of PDMS on PET it yields a substrate that can be used in an unusual but powerful way for building circuits: soft, room temperature lamination of such a structure against a plastic substrate that supports the semiconductor, gate dielectric, and gate levels yields a high performance circuit embedded between two plastic sheets [6.37, 50]. (Details of this lamination procedure are presented elsewhere.) The left frame of Fig. 6.19 shows the current–voltage characteristics of a laminated n-channel transistor that uses the organic semiconductor copper hexadecafluorophthalocyanine (n-type) and source/drain electrodes patterned with nTP. The inset shows an optical micrograph of the printed interdigitated source/drain electrodes of this device. The bottom frame of Fig. 6.16 shows the transfer characteristics of a laminated complementary organic inverter circuit whose electrodes

Fig. 6.18 Electronic paperlike display showing two different images. The device consists of several hundred pixels controlled by a flexible active matrix backplane circuit formed by microcontact printing. The relatively coarse resolution of the display is not limited by material properties or by the printing techniques. Instead, it is set by practical considerations for achieving high pixel yields in the relatively uncontrolled environment of the chemistry laboratory in which the circuits were fabricated

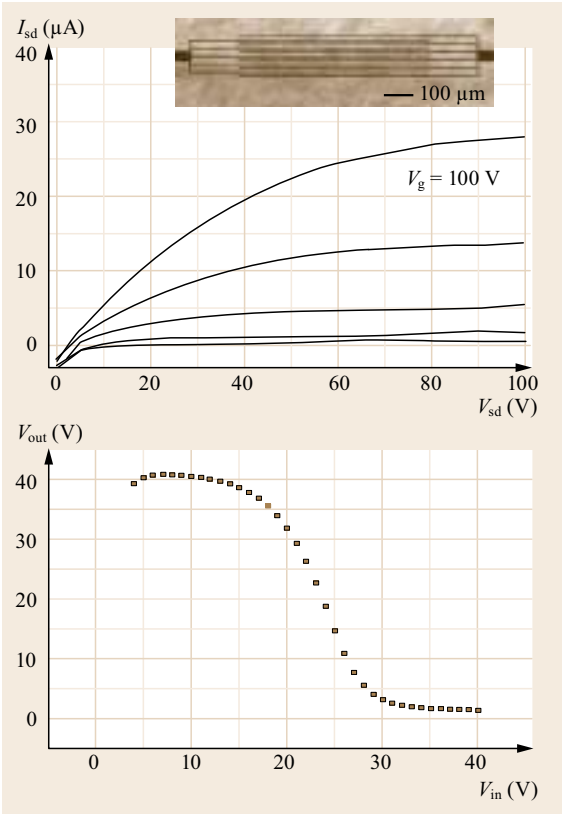

Fig. 6.19 The *upper* frame shows current–voltage characteristics of an n-channel transistor formed with electrodes patterned by nanotransfer printing that are laminated against a substrate that supports an organic semiconductor, a gate dielectric and a gate. The *inset* shows an optical micrograph of the interdigitated electrodes. The *lower* frame shows the transfer characteristics of a simple CMOS inverter circuit that uses this device and a similar one for the p-channel transistor

and connecting lines are defined by nTP. The p-channel transistor in this circuit used pentacene for the semiconductor [6.37].

In addition to high-resolution source/drain electrodes, it is possible to use nTP to form complex multilayer devices with electrical functionality on plastic substrates [6.38]. Figure 6.20 shows a metal/insulator/metal (MIM) structure of Au (50 nm), SiN_x (100 nm; by plasma enhanced vapor deposition, PECVD), Ti (5 nm) and Au (50 nm) formed by transfer printing with a silicon stamp that is coated sequentially with these layers. In this case, a short reactive ion etch (with CF_4) after the second Au deposition removes the SiN_x from the sidewalls of the stamp. nTP transfers these layers in a patterned geometry to a substrate of Au (15 nm)/Ti (1 nm)-coated PDMS (50 μm)/PET (250 μm). Interfacial cold-welding between the Au on the surfaces of the stamp and substrate bonds the multilayers to the substrate. Figure 6.8 illustrates the procedures, the structures (lateral dimensions of $250 \times 250\,\mu m^2$, for ease of electrical probing), and their electrical characteristics. These MIM capacitors have performances similar to devices fabricated on silicon wafers by photolithography and lift-off. This example illustrates the ability of nTP to print patterns of materials whose growth conditions (high-temperature SiN_x by PECVD, in this case) prevent their direct deposition or processing on the substrate of interest (PET, in this case). The cold-welding transfer approach has also been exploited in other ways for patterning components for plastic electronics [6.51, 52].

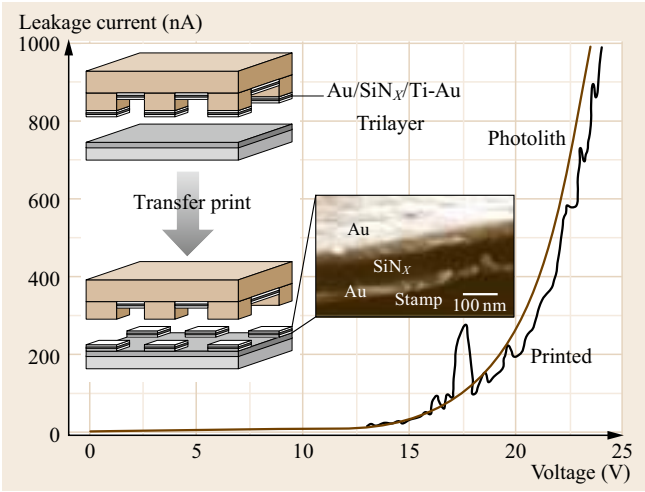

Fig. 6.20 Multilayer thin film capacitor structure printed in a single step onto a plastic substrate using the nanotransfer printing technique. A multilayer of Au/SiN_x/Ti/Au was first deposited onto a silicon stamp formed by photolithography and etching. Contacting this stamp to a substrate of Au/PDMS/PET forms a cold weld that bonds the exposed Au on the stamp to the Au-coating on the substrate. Removing the stamp produces arrays of square ($250 \times 250\,mm^2$) metal/insulator/metal capacitors on the plastic support. The *black line* shows the measured current–voltage characteristics of one of these printed capacitors. The *brown line* corresponds to a similar structure formed on a rigid glass substrate using conventional photolithographic procedures. The characteristics are the same for these two cases. The slightly higher level of noise in the printed devices results, at least partly, from the difficulties involved with making good electrical contacts to structures on the flexible plastic substrate

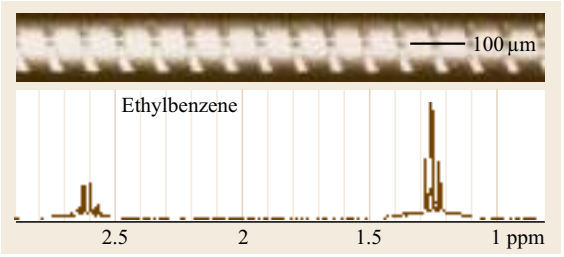

Fig. 6.21 The *top frame* shows an optical micrograph of a continuous conducting microcoil formed by microcontact printing onto a microcapillary tube. This type of printed microcoil is well suited for excitation and detection of nuclear magnetic resonance spectra from nanoliter volumes of fluid housed in the bore of the microcapillary. The *bottom frame* shows a spectra trace collected from an $\approx 8\,nL$ volume of ethyl benzene using a structure similar to the one shown in the *top frame*

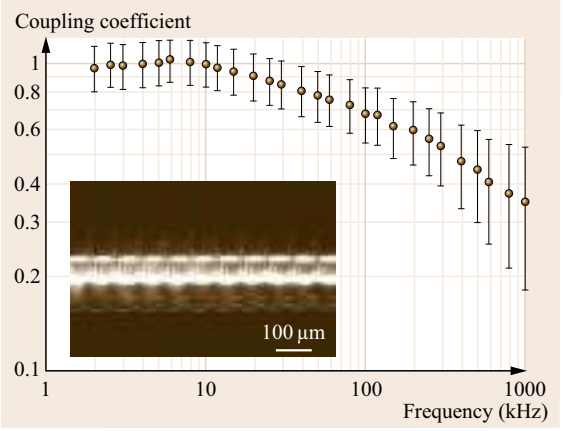

Fig. 6.22 The *inset* shows a concentric microtransformer formed using microcoils printed onto two different microcapillary tubes. The smaller of the tubes (outer diameter 135 µm) has a ferromagnetic wire threaded through its core. The larger one (outer diameter 350 µm) has the smaller tube threaded through its core. The resulting structure is a microtransformer that shows good coupling coefficients at frequencies up to $\approx 1\,MHz$. The *graph* shows its performance

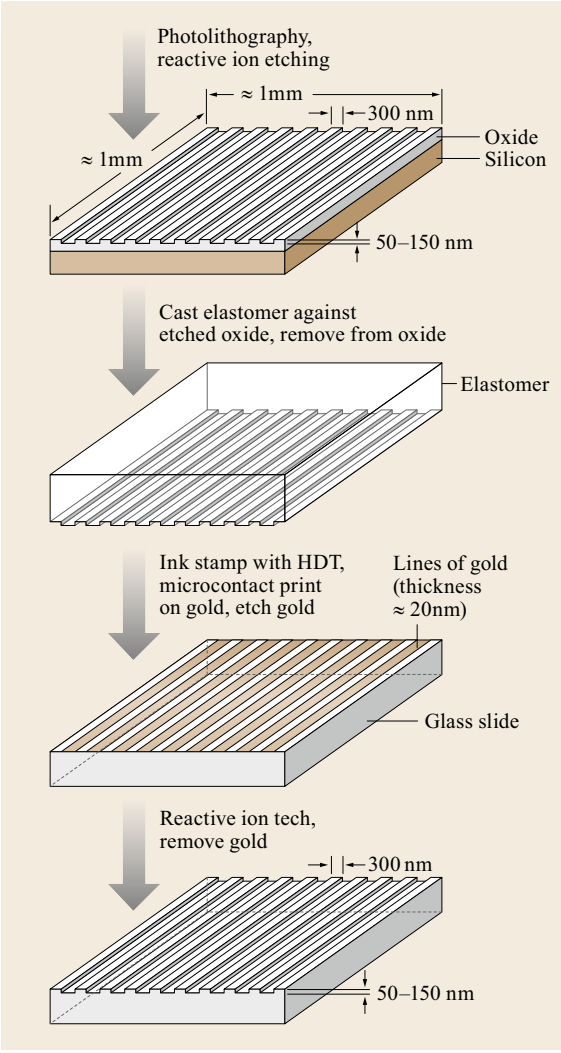
Another class of unusual electronic/optoelectronic devices relies on circuits or circuit elements on curved surfaces. This emerging area of research was stimulated primarily by the ability of µCP to print high-resolution features on fibers and cylinders. Figure 6.21 shows a conducting microcoil printed with µCP on a microcapillary tube using the approach illustrated in Fig. 6.4. The coil serves as the excitation and detection element for high-resolution proton nuclear magnetic resonance of nanoliter volumes of fluid that are housed in the bore of the microcapillary [6.53]. The high fill factor and other considerations lead to extremely high sensitivity with such printed coils. The bottom frame of Fig. 6.21 shows the spectrum of an $\approx 8\,nL$ volume of ethylbenzene. The narrow lines demonstrate the high resolution that is possible with this approach. Similar coils can be used as magnets [6.54], springs [6.36], and electrical transformers [6.55]. Figure 6.22 shows an optical micrograph and the electrical measurements from a concentric cylindrical microtransformer that uses a microcoil printed on a microcapillary tube with a ferromagnetic wire threaded through its core. Inserting this structure into the core of a larger microcapillary that also supports a printed microcoil completes the transformer [6.55]. This type of device shows good coupling coefficients up to relatively high frequencies. Examples of other optoelectronic components appear in fiber optics where microfabricated on-fiber structures serve as integrated photomasks [6.20] and distributed thermal actuators [6.22].

6.4.2 Lasers and Waveguide Structures

In addition to integral components of unconventional electronic systems, useful structures for integrated optics can be built by using μCP and nTP to print sacrificial resist layers for etching glass waveguides. These printing techniques offer the most significant potential value for this area when they are used to pattern features that are smaller than those that can be achieved with contact mode photolithography. Mode coupling gratings and distributed laser resonators are two such classes of structures. We have demonstrated μCP for forming distributed feedback (DFB) and distributed Bragg reflector (DBR) lasers that have narrow emission line widths [6.56]. This challenging fabrication demonstrates the suitability of μCP for building structures that have (1) feature sizes of significantly less than 1 μm (≈ 300 nm), *and* (2) long-range spatial coherence (≈ 1 mm). The lasers employ optically pumped gain material deposited onto DFB or DBR resonators formed from periodic relief on a transparent substrate. The gain media confines light to the surface of the structure; its thickness is chosen to support a single transverse mode. To generate the required relief, lines of gold formed by μCP on a glass slide act as resists for reactive ion etching of the glass. Removing the gold leaves a periodic pattern of relief (600 nm period, 50 nm depth) on the surface of the glass (Fig. 6.23). Figure 6.24 shows the performance of plastic lasers that use printed DFB and DBR resonators with gain media consisting of thin films of PBD doped with 1 wt% of coumarin 490 and DCMII, photopumped with 2 ns pulses from a nitrogen laser with intensities $> 5\,\mathrm{kW/cm^2}$ [6.56]. Multimode lasing at resolution-limited line widths was observed at wavelengths corresponding to the third harmonic of the gratings. These characteristics are similar to those observed in lasers that use resonators generated with photolithography and are better than those that use imprinted polymers [6.57].

Contact printing not only provides a route to low-cost equivalents of gratings fabricated with other approaches, but also allows the fabrication of structures that would be difficult or impossible to generate with photolithography. For example, μCP can be used to form DFB resonators directly on the top surfaces of ridge waveguides [6.58]. Figure 6.25 illustrates the procedures. The bottom left frame shows an optical micrograph of the printed gold lines. Sublimation of a ≈ 200 nm film of tris(8-hydroxyquinoline) aluminum (Al) doped with 0.5–5.0 wt% of the laser dye DCMII onto the resonators produces waveguide DFB lasers. The layer of gain material itself provides a planar waveguide with air and polymer as the cladding layers. The relief waveguide provides lateral confinement of the light. Photopumping these devices with the output of a pulsed nitrogen laser (≈ 2 ns, 337 nm) causes lasing due to Bragg reflections induced by the DFB structures on the top surfaces of the ridge waveguides. Some of the laser emission scatters out of the plane of the waveguide at an angle allowed by phase matching conditions. In this way, the grating also functions as an output coupler and offers a convenient way to characterize the laser emission. The bottom right frame of Fig. 6.22 shows the emission profile.



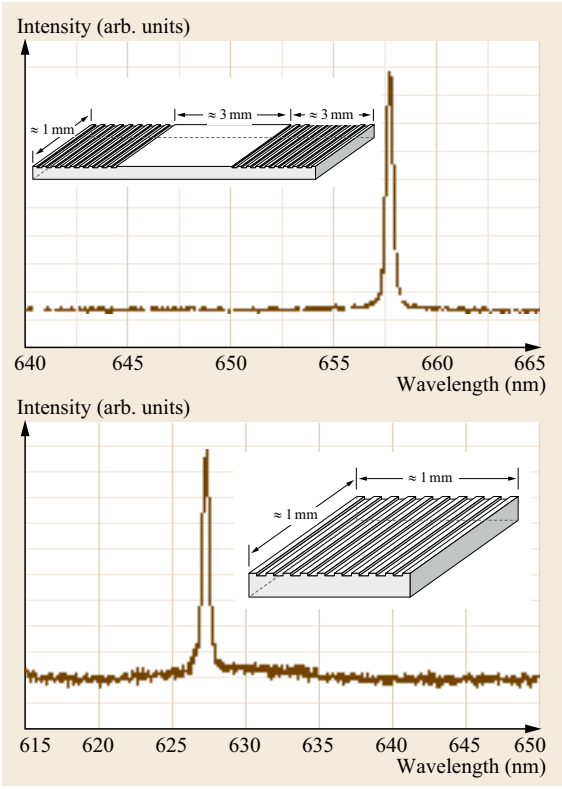


Fig. 6.23 Schematic illustration of the use of microcontact printing (μCP) for fabricating high-resolution gratings that can be incorporated into distributed planar laser structures or other components for integrated optics. The geometries illustrated here are suitable for third-order distributed feedback (DFB) lasers that operate in the red

Fig. 6.24 The *top frames* gives a schematic illustration of steps for microcontact printing high-resolution gratings directly onto the top surfaces of ridge waveguides. The printing defines a sacrificial etch mask of gold which is subsequently removed. Producing this type of structure with photolithography is difficult because of severe thickness nonuniformities that appear in photoresist spin-cast on this type of nonplanar substrate. The *upper bottom* frame shows a top view optical micrograph of printed gold lines on the ridge waveguides. The *lower bottom* frame shows the emission output of a plastic photopumped laser that uses the printed structure and a thin evaporated layer of gain media ►

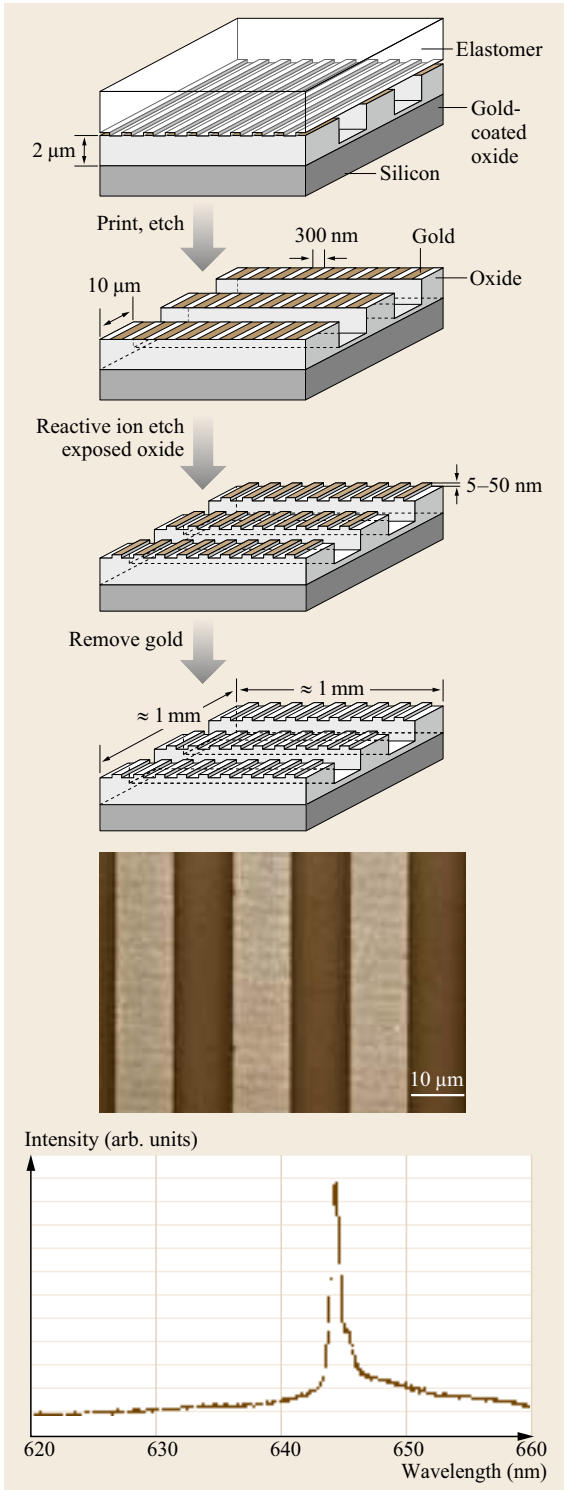

Fig. 6.25 Schematic illustrations and lasing spectra of plastic lasers that use microcontact printed resonators based on surface relief distributed Bragg reflectors (DBRs) and distributed feedback gratings (DFBs) on glass substrates. The grating periods are ≈ 600 nm in both cases. The lasers use thin film plastic gain media deposited onto the printed gratings. This layer forms a planar waveguide that confines the light to the surface of the substrate. The laser shows emission over a narrow wavelength range, with a width that is limited by the resolution of the spectrometer used to characterize the output. In both cases, the emission profiles, the lasing thresholds and other characteristics of the devices are comparable to similar lasers that use resonators formed by high-resolution projection-mode photolithography

6.5 Conclusions

This chapter provides an overview of two contact printing techniques that are capable of micrometer and submicrometer resolution. It also illustrates some applications of these methods that may provide attractive alternatives to more established lithographic methods. The growing interest in nanoscience and technology makes it crucial to develop new methods for fabricating the relevant test structures and devices. The simplicity of these techniques together with the interesting and subtle materials science, chemistry, and physics associated with them make this a promising area for basic and applied study.

Acknowledgments. The authors extend their deepest thanks to all of the collaborators who contributed the work described here.

7. Materials Aspects of Micro- and Nanoelectromechanical Systems

Christian A. Zorman

One of the more significant technological achievements during the last twenty years has been the development of the field of microelectromechanical systems (MEMS) and its offshoot, nanoelectromechanical systems (NEMS). These developments were made possible by significant advancements in the materials and processing technologies used in the fabrication of MEMS and NEMS devices. While initial developments capitalized on a mature Si infrastructure built for the integrated circuit (IC) industry, recent advances have come about using materials and processes not typically associated with IC fabrication, a trend that is likely to continue as new application areas emerge.

A well-rounded understanding of MEMS and NEMS technology requires a basic knowledge of the materials used to construct the devices, since material properties often govern device performance and dictate fabrication approaches. An understanding of the materials used in MEMS and NEMS involves an understanding of material systems, since such devices are rarely constructed of a single material, but rather a collection of materials working in conjunction with each other to provide critical functions. It is from this perspective that the following chapter is constructed. This chapter is not a summary of all materials used in MEMS and NEMS, as such a work would itself constitute a single text of significant size. It does, however, present a selection of some of the more popular materials, as well as those that illustrate the importance of viewing MEMS and NEMS in terms of material systems.

7.1 Silicon and its Commonly-Used Derivatives

The use of silicon (Si) as a material for microfabricated sensors dates back to the middle of the last century when the piezoresistive effect in germanium (Ge) and Si was first identified [7.1]. It was discovered that the piezoresistive coefficients of Si were significantly higher than those associated with metals used in conventional strain gages; this finding initiated the development of Si-based strain gage devices, and, along

with Si bulk micromachining techniques, piezoresistive Si pressure sensors during the 1960s and 1970s. The subsequent development of Si surface micromachining techniques along with the recognition that micromachined Si structures could be integrated with Si IC devices marked the advent of MEMS with Si firmly positioned as the primary MEMS material.

7.1.1 Single-Crystal Silicon

For MEMS applications, single-crystal Si serves several key functions. Single-crystal Si is one of the most versatile materials for bulk micromachining, due to the availability of anisotropic etching processes in conjunction with good mechanical properties. Single-crystal Si has favorable mechanical properties (i. e., a Young's modulus of about 190 GPa), enabling its use as a material for membranes, bridges, cantilevers and other popular micromachined structures. For surface micromachining applications, single-crystal Si substrates are used primarily as mechanical platforms on which device structures are fabricated, although the advent of silicon-on-insulator (SOI) substrates enables the fabrication of single-crystal Si surface-micromachined structures by using the buried oxide as a sacrificial layer. The use of high-quality single-crystal wafers enables the fabrication of integrated MEMS devices, at least for materials and processes that are compatible with Si ICs.

From the materials perspective, single-crystal Si is a relatively easy material to bulk micromachine, due to the availability of anisotropic etchants such as potassium hydroxide (KOH) and tetramethyl-aluminum hydroxide (TMAH) that attack the (100) and (110) Si crystal planes significantly faster than the (111) crystal planes. For example, the etching rate ratio of (100) to (111) planes in Si is about 400:1 for a typical KOH/water solution. Silicon dioxide (SiO_2), silicon nitride (Si_3N_4), and some metallic thin films (e.g., Cr, Au, etc.) provide good etch masks for most Si anisotropic etchants. Heavily boron-doped Si is an effective etch stop for some liquid reagents. Boron-doped etch stops are often less than 10 μm thick, since the boron concentration in Si must exceed 7×10^{19} cm^3 for the etch stop to be effective and the doping is done by thermal

Table 7.1 Distinguishing characteristics and application examples of selected materials for MEMS and NEMS

Material	Distinguishing Characteristics	Application Examples
Single-crystal silicon (Si)	High quality electronic material, selective anisotropic etching	Bulk micromachining, piezoresistive sensing
Polycrystalline Si (polysilicon)	Doped Si films on sacrificial layers	Surface micromachining, electrostatic actuation
Silicon dioxide (SiO_2)	Insulating, etched by HF, compatible with polysilicon	Sacrificial layer in polysilicon surface micromachining, passivation layer for devices
Silicon nitride (Si_3N_4, Si_xN_y)	Insulating, chemically resistant, mechanically durable	Isolation layer for electrostatic devices, membrane and bridge material
Polycrystalline germanium (polyGe), Polycrystalline silicon-germanium (poly-Si-Ge)	Deposited at low temperatures	Integrated surface micromachined MEMS
Gold (Au), aluminum (Al)	Conductive thin films, flexible deposition techniques	Interconnect layers, masking layers, electromechanical switches
Nickel-iron (NiFe)	Magnetic alloy	Magnetic actuation
Titanium-nickel (TiNi)	Shape-memory alloy	Thermal actuation
Silicon carbide (SiC) Diamond	Electrically and mechanically stable at high temperatures, chemically inert, high Young's modulus to density ratio	Harsh-environment MEMS, high-frequency MEMS/NEMS
Gallium arsenide (GaAs), indium phosphide (InP), indium arsenide (InAs) and related materials	Wide bandgap, epitaxial growth on related ternary compounds	Radio-frequency MEMS, optoelectronic devices, single-crystal bulk and surface micromachining
Lead zirconate titanate (PZT), aluminum nitride, gallium nitride	Piezoelectric materials	Mechanical sensors and actuators
Polyimide	Chemically resistant, high-temperature polymer	Mechanically flexible MEMS, bioMEMS
SU-8	Thick, photodefinable resist	Micromolding, High-aspect-ratio structures.
Parylene	Biocompatible polymer, deposited at room temperature by CVD	Protective coatings, molded polymer structures

diffusion. Ion implantation can be used to create a subsurface etch stop layer; however, the practical limit is a few microns.

In contrast to anisotropic etching, isotropic etching exhibits no selectivity to the various crystal planes. Commonly used isotropic Si etchants consist of hydrofluoric (HF) and nitric (HNO_3) acid mixtures in water or acetic acid (CH_3COOH), with the etch rate dependent on the ratio of HF to HNO_3. From a processing perspective, isotropic etching of Si is commonly used for removal of work-damaged surfaces, creation of structures in single-crystal slices, and patterning of single-crystal or polycrystalline films.

Well-established dry etching processes are routinely used to pattern single-crystal Si. The process spectrum ranges from physical techniques such as sputtering and ion milling to chemical techniques such as plasma etching. Reactive ion etching (RIE) is the most commonly used dry etching technique for Si patterning. By combining both physical and chemical processes, RIE is a highly effective anisotropic Si etching technique that can be used to generate patterns that are independent of crystalline orientation. Fluorinated compounds such as CF_4, SF_6, and NF_3, or chlorinated compounds such as CCl_4 or Cl_2, sometimes mixed with He, O_2 or H_2, are commonly used in Si RIE. The RIE process is highly directional, which enables direct lateral pattern transfer from an overlying masking material to the etched Si surface. SiO_2 thin films are often used as masking and sacrificial layers, owing to the material's chemical durability under these plasma conditions. Process limitations (i. e., etch rates) restrict the etch depths of conventional Si RIE to less than 10 μm, however, a process called deep reactive ion etching (DRIE) has extended the use of anisotropic dry etching to depths well beyond several hundred microns.

Using the aforementioned processes and techniques, a wide variety of microfabricated devices have been made from single-crystal Si, such as piezoresistive pressure sensors, accelerometers, and mechanical resonators to name a few. Using nearly the same approaches but on a smaller scale, *top-down* nanomachining techniques have been used to fabricate nanoelectromechanical devices from single-crystal Si. Single-crystal Si is particularly well suited for nanofabrication because high crystal quality substrates with very smooth surfaces are readily available. By coupling electron-beam (e-beam) lithographic techniques with conventional Si etching, device structures with submicron dimensions have been fabricated. Submicron, single-crystal Si nanomechanical structures have been successfully micromachined from bulk Si wafers [7.2] and silicon-on-insulator (SOI) wafers [7.3]. In the former case, an isotropic Si etch was performed to release the device structures, whereas in the latter case, the 50–200 nm structures were released by dissolving the underlying oxide layer in HF. An example of nanoelectromechanical beam structures fabricated from a single-crystal Si substrate is shown in Fig. 7.1.

7.1.2 Polycrystalline and Amorphous Silicon

Surface micromachining is a process where a sequence of thin films, often of different materials, is deposited and selectively etched to form the desired micromechanical (or microelectromechanical) structure. In contrast to bulk micromachining, the substrate serves primarily as a device-supporting platform. For Si-based surface micromachined MEMS, polycrystalline Si (polysilicon) is most often used as the structural material, SiO_2 as the sacrificial material, silicon nitride (Si_3N_4) for electrical isolation of device structures, and single-crystal Si as the substrate. Like single-crystal Si, polysilicon can be doped during or after film deposition. SiO_2 can be thermally grown or deposited on polysilicon over a broad temperature range (e.g., 200–1150 °C) to meet various process and material requirements. SiO_2 is readily dissolvable in hydrofluoric acid (HF), which does not etch polysilicon and thus can be used to dissolve SiO_2 sacrificial layers. Si_3N_4 is an insulating film that is highly resistant to oxide etchants. The polysilicon micromotor shown in Fig. 7.2 was surface micromachined using a process that included these materials.

For MEMS and IC applications, polysilicon films are commonly deposited using a process known as low-pressure chemical vapor deposition (LPCVD). The

Fig. 7.1 A collection of Si nanoelectromechanical beam resonators fabricated from a single-crystal Si substrate (courtesy M. Roukes, Caltech)

Fig. 7.2 Scanning electron microscope (SEM) micrograph of a surface micromachined polysilicon micromotor fabricated using a SiO_2 sacrificial layer

typical polysilicon LPCVD reactor is based on a hot-wall, resistance-heated furnace. Typical processes are performed at temperatures ranging from 580 to 650 °C and pressures from 100 to 400 mtorr. The most commonly used source gas is silane (SiH_4). The microstructure of polysilicon thin films consists of a collection of small grains whose microstructure and orientation is a function of the deposition conditions [7.4]. For typical LPCVD processes (e.g., 200 mtorr), the amorphous-to-polycrystalline transition temperature is about 570 °C, with polycrystalline films deposited above the transition temperature. At 600 °C, the grains are small and equiaxed, while at 625 °C, the grains are large and columnar [7.4]. The crystal orientation is predominantly (110) Si for temperatures between 600–650 °C, while the (100) orientation is dominant for temperatures between 650–700 °C.

The resistivity of polysilicon can be modified using the doping methods developed for single-crystal Si. Diffusion is an effective method for doping polysilicon films, especially for heavy doping of thick films. Phosphorous, which is the most commonly used dopant in polysilicon MEMS, diffuses significantly faster in polysilicon than in single-crystal Si due primarily to enhanced diffusion rates along grain boundaries. The diffusivity of phosphorus in polysilicon thin films with small equiaxed grains is about $1 \times 10^{12}\,cm^2/s$. Ion implantation is also used to dope polysilicon films. A high-temperature annealing step is usually required to electrically activate the implanted dopants as well as to repair implant-related damage in the polysilicon films. In general, the conductivity of implanted polysilicon films is not as high as films doped by diffusion.

In-situ doping of polysilicon is performed by simply including a dopant gas, usually diborane (B_2H_6) or phosphine (PH_3), in the CVD process. The addition of dopants during the deposition process not only modifies the conductivity, but also affects the deposition rate of the polysilicon films. As shown in Fig. 7.3, the inclusion of boron generally increases the deposition rate of polysilicon relative to undoped films [7.5], while phosphorus (not shown) reduces the rate. In situ doping can be used to produce conductive films with uniform doping profiles without requiring the high-temperature steps commonly associated with diffusion or ion implantation. Although commonly used to produce doped polysilicon for electrostatic devices, *Cao* et al. [7.6] have used in situ phosphorus doped polysilicon films in piezoresistive strain gages, achieving gage factors as high as 15 for a single strip sensor.

The thermal conductivity of polysilicon is a strong function of its microstructure, and therefore the conditions used during deposition [7.4]. For fine-grain films, the thermal conductivity is about 25% of the value of single-crystal Si. For thick films with large grains, the thermal conductivity ranges from 50–85% of the single-crystal value.

Like the electrical and thermal properties of polysilicon, the as-deposited residual stress in polysilicon films depends on microstructure. For films deposited under typical conditions (200 mtorr, 625 °C), the as-deposited polysilicon films have compressive residual stresses. The highest compressive stresses are found in amorphous Si films and polysilicon films with a strong, columnar (110) texture. For films with fine-grained microstructures, the stress tends to be tensile. Annealing can be used to reduce the compressive stress in as-deposited polysilicon films. For instance, compressive residual stresses on the order of 500 MPa can be reduced to less than 10 MPa by annealing the as-deposited films at 1000 °C in ambient N_2 [7.7, 8]. Rapid thermal annealing (RTA) provides an effective method of stress reduction in polysilicon films on temperature-sensitive substrates. *Zhang* et al. [7.9] reported that a 10 s anneal at 1100 °C was sufficient to completely relieve the stress in films that originally had a compressive stress of about 340 MPa. RTA is particularly attractive in situations where the process parameters require a low thermal budget.

As an alternative to high temperature annealing, *Yang* et al. [7.10] have developed an approach that actually utilizes the residual stress characteristics of polysilicon deposited under various conditions to construct polysilicon multilayers that have the desired thickness and stress values. The multilayers are composed of alternating tensile and compressive polysilicon layers that are deposited in a sequential manner. The tensile layers consist of fine-grained polysilicon grown at a temperature of 570 °C, while the compressive layers are made

up of columnar polysilicon deposited at 615 °C. The overall stress in the composite film depends on the number of alternating layers and the thickness of each layer. With the proper set of parameters, a composite polysilicon multilayer can be deposited with near zero residual stress and no stress gradient. The process achieves stress reduction without high-temperature annealing; a considerable advantage for integrated MEMS processes.

Along similar lines, *Kang* et al. [7.11] reported a method that uses nickel silicides (Ni_xSi_y) to compensate for residual stress gradients in polysilicon thin films. Silicides are used in complementary metal-oxide-semiconductor (CMOS) technology to reduce sheet and contact resistances in polysilicon gates and thus would be available in an integrated polysilicon MEMS process. Ni_xSi_y films were formed on polysilicon surfaces by first depositing a Ni film by thermal evaporation, followed by a low-temperature (< 400 °C) thermal anneal. The researchers found that the sheet resistance of the resulting film can be reduced from 20 000 to 10 Ω/□ and the stress gradient, as determined by vertical deflection of surface micromachined, 2 μm-thick micromachined cantilevers, can be completely relaxed at an annealing temperature of 290 °C. The cantilevers were fabricated using a tetraethoxysilane-based silicon dioxide sacrificial layer. Release of the beams required that a direct current (DC) bias be placed on the Ni_xSi_y layer to suppress electrochemical corrosion of the layer in the HF release solution.

Many device designs require polysilicon thicknesses that are not readily achievable using conventional LPCVD polysilicon due to the low deposition rates associated with such systems. For these applications, epitaxial Si reactors can be used to grow polysilicon films. Unlike conventional LPCVD processes, which typically have deposition rates of less than 10 nm/min, epitaxial processes have deposition rates on the order of 1 μm/min [7.12]. The high deposition rates result from the much higher substrate temperatures (> 1000 °C) and deposition pressures (> 50 torr) used in these processes. The polysilicon films are usually deposited on SiO_2 sacrificial layers to enable surface micromachining. An LPCVD polysilicon seed layer is sometimes used in order to control nucleation, grain size, and surface roughness. As with conventional polysilicon, the microstructure and residual stress of the epipoly films, as they are known, is related to deposition conditions. Compressive films generally have a mixture of [110] and [311] grains [7.13, 14] while tensile films have a random mix of [110], [100], [111], and [311] grains [7.13]. The Young's modulus of epipoly measured from micromachined test structures is comparable with LPCVD polysilicon [7.14]. Mechanical

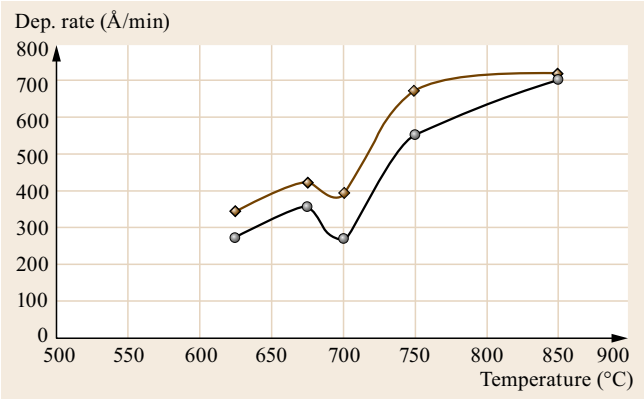

Fig. 7.3 Deposition rate versus substrate temperature for in situ boron doped (◇) and undoped (●) polysilicon films grown by atmospheric pressure chemical vapor deposition (after [7.5])

test structures [7.12–14], thermal actuators [7.12], electrostatically actuated accelerometers [7.12] and gyroscopes [7.15] have been fabricated from these films.

As a low-temperature alternative to LPCVD polysilicon, physical vapor deposition (PVD) techniques have been developed to produce Si thin films on temperature-sensitive substrates. *Abe* et al. [7.16] and *Honer* et al. [7.17] have developed sputtering processes for polysilicon. Early work [7.16] emphasized the ability to deposit very smooth (2.5 nm) polysilicon films on thermally oxidized wafers at reasonable deposition rates (19 nm/min) and with low residual compressive stresses. The process involved DC magnetron sputtering from a Si target using an Ar sputtering gas, a chamber pressure of 5 mtorr, and a power of 100 W. The authors reported that a postdeposition anneal at 700 °C in N_2 for 2 h was needed to crystallize the deposited film and perhaps lower the stress. *Honer* et al. [7.17] sought to develop a polymer-friendly, Si-based surface micromachining process based on polysilicon sputtered onto polyimide and phosphosilicate glass (PSG) sacrificial layers. To improve the conductivity of the micromachined Si structures, the sputtered Si films were sandwiched between two TiW cladding layers. The device structures on polyimide were released using oxygen plasma etching. The processing step with the highest temperature was in fact the polyimide cure at 350 °C. To test the robustness of the process, sputter-deposited Si microstructures were fabricated on substrates containing CMOS devices. As expected from thermal budget considerations, the authors reported no measurable degradation of device performance.

Plasma-enhanced chemical vapor deposition (PECVD) has emerged as an alternative to LPCVD for the production of Si-based surface micromachined structures on temperature-sensitive substrates. *Gaspar*

et al. [7.18], reported on the development of surface micromachined microresonators fabricated from hydrogenated amorphous Si (a-Si:H) thin films deposited by PECVD. The vertically actuated resonators consisted of doubly clamped microbridges suspended over fixed Al electrodes. The a-Si:H films were deposited using SiH_4 and H_2 precursors and PH_3 as a doping gas. The substrate temperature was held to around 100 °C, which enabled the use of photoresist as a sacrificial layer. The microbridges consisted of a large paddle suspended by two thin paddle supports, with the paddle providing a large reflective surface for optical detection of resonant frequency. The megahertz-frequency resonators exhibited quality factors in the 1×10^5 range when tested in vacuum. This work has since been extended to using polynorbornene as a sacrificial layer material [7.19]. A polynorbornene known as Unity 4011 thermally decomposes into vapor at 425 °C, enabling a dry, nonplasma-based release process. Surface micromachined resonators were successfully fabricated from a-Si:H films deposited by PECVD using this method. Cracking was observed near the anchor points of some structures and was attributed to differences in thermal expansion coefficients, an issue that is likely resolvable by modifying the design of the anchor regions.

7.1.3 Porous Silicon

Porous Si is produced by room-temperature electrochemical etching of Si in HF. If configured as an electrode in an HF-based electrochemical circuit, positive charge carriers (holes) at the Si surface facilitate the exchange of F atoms with H atoms that terminate the Si surface. The exchange continues in the subsurface region, leading to the eventual removal of the fluorinated Si. The quality of the etched surface is related to the density of holes at the surface, which is controlled by the applied current density. For high current densities, the density of holes is high and the etched surface is smooth. For low current densities, the hole density is low and clustered in highly localized regions associated with surface defects. Surface defects become enlarged by etching, which leads to the formation of pores. Pore size and density are related to the type of Si used and the conditions of the electrochemical cell. Both single-crystal and polycrystalline Si can be converted to porous Si.

The large surface-to-volume ratios make porous Si attractive for gaseous and liquid applications, including filter membranes and absorbing layers for chemical and mass sensing [7.20]. When single-crystal substrates are used, the unetched porous layer remains single crystalline and is suitable for epitaxial Si growth. It has been shown that CVD coatings do not generally penetrate the porous regions, but rather overcoat the pores at the surface of the substrate [7.21]. The formation of localized Si-on-insulator structures is therefore possible by simply combining pore formation with epitaxial growth, followed by dry etching to create access holes to the porous region, and thermal oxidation of the underlying porous region. A third application uses porous Si as a sacrificial layer for polysilicon and single-crystalline Si surface micromachining. As shown by *Lang* et al. [7.21], the process involves the electrical isolation of the solid structural Si layer by either pn-junction formation through selective doping, or use of electrically insulating thin films since the formation of pores only occurs on electrically charged surfaces. A weak Si etchant will aggressively attack the porous regions with little damage to the structural Si layers, and can be used to release the devices.

Porous polysilicon is also being developed as a structural material for chip-level vacuum packaging [7.22]. In this example, a 1.5 μm-thick polysilicon is deposited deposited onto a supporting PSG sacrificial layer, electrochemically etched in an HF solution to render it porous and then annealed by RTA to reduce stress in the porous layer. When fabricated locally over a prefabricated device structure (prior to release), the porous Si forms a localized shell, which will serve as a mechanical support for the main packaging structure. The porous structure enables an HF etch to remove the supporting PSG layer as well as any sacrificial oxide layers associated with the prefabricated MEMS device. After the sacrificial etch, the packaging sequence is completed by depositing a polysilicon film by LPCVD at 179 mtorr on the porous shell, thus fully encapsulating the device under vacuum conditions. This technique was used to package a microfabricated Pirani vacuum gage, which enabled an in situ measurement of pressure versus time. The authors found no detectable change in pressure over a three-month period. This process has matured to the point where it has successfully been incorporated into the well-known multiuser MEMS process (MUMPS) foundry service for polysilicon surface micromachining [7.23].

7.1.4 Silicon Dioxide

Silicon dioxide (SiO_2) is one of the most widely used materials in the fabrication of MEMS. In polysilicon surface micromachining, SiO_2 is used as a sacrificial material since it can be easily dissolved using etchants that do not attack polysilicon. SiO_2 is widely used as an etch mask for dry etching of thick polysilicon films, since it is chemically resistant to dry etching processes for polysilicon. SiO_2 films are also used as passivation

layers on the surfaces of environmentally sensitive devices.

The most common processes used to produce SiO_2 films for polysilicon surface micromachining are thermal oxidation and LPCVD. Thermal oxidation of Si is performed at temperatures of 900 to 1200 °C in the presence of oxygen or steam. Since thermal oxidation is a self-limiting process, the maximum practical film thickness that can be obtained is about 2 μm, which is sufficient for many sacrificial applications. As noted by its name, thermal oxidation of Si can only be performed on Si surfaces.

SiO_2 films can be deposited on a wide variety of substrate materials by LPCVD. In general, LPCVD provides a means for depositing thick (> 2 μm) SiO_2 films at temperatures much lower than thermal oxidation. Known as low-temperature oxides or LTOs for short, these films have a higher etch rate in HF than thermal oxides, which translates to significantly faster release times when LTO films are used as sacrificial layers. Phosphosilicate glass (PSG) can be formed using nearly the same deposition process as LTO by adding a phosphorus-containing gas to the precursor flows. PSG films are useful as sacrificial layers since they generally have higher etching rates in HF than LTO films.

PSG and LTO films are deposited in hot-wall, low-pressure, fused silica furnaces in systems similar to those described previously for polysilicon. Precursor gases include SiH_4 as a Si source, O_2 as an oxygen source, and, in the case of PSG, PH_3 as a source of phosphorus. LTO and PSG films are typically deposited at temperatures of 425–450 °C and pressures ranging from 200 to 400 mtorr. The low deposition temperatures result in LTO and PSG films that are slightly less dense than thermal oxides due to the incorporation of hydrogen in the films. LTO films can, however, be densified by an annealing step at high temperature (1000 °C). The low density of LTO and PSG films is partially responsible for the increased etch rate in HF.

Thermal SiO_2 and LTO are electrical insulators used in numerous MEMS applications. The dielectric constants of thermal oxide and LTO are 3.9 and 4.3 respectively. The dielectric strength of thermal SiO_2 is 1.1×10^6 V/cm, and for LTO it is about 80% of that value [7.24]. The stress in thermal SiO_2 is compressive with magnitude of about 300 MPa [7.24]. For LTO, however, the typical as-deposited residual stress is tensile, with a magnitude of about 100–400 MPa [7.24]. The addition of phosphorous to LTO decreases the tensile residual stress to about 10 MPa for phosphorus concentrations of 8% [7.25]. As with polysilicon, the properties of LTO and PSG are dependent on processing conditions.

Plasma-enhanced chemical vapor deposition (PECVD) is another common method to produce oxides of silicon. Using a plasma to dissociate the gaseous precursors, the deposition temperatures needed to deposit PECVD oxide films is lower than for LPCVD films. For this reason, PECVD oxides are quite commonly used as masking, passivation, and protective layers especially on devices that have been coated with metals.

Quartz is the crystalline form of SiO_2 and has interesting properties for MEMS. Quartz is optically transparent, piezoelectric, and electrically insulating. Like single-crystal Si, quartz substrates are available as high-quality, large-area wafers that can be bulk micromachined using anisotropic etchants. A short review of the basics of quartz etching was written by *Danel* et al. [7.26] and is recommended for those interested in the subject. Quartz is a popular substrate material for microfluidic devices due to its optical, electronic and chemical properties.

Another SiO_2-related material that has found uses in MEMS is spin-on-glass (SOG). SOG is a polymeric material with a viscosity suitable for spin coating. Two recent publications illustrate the potential for SOG in MEMS fabrication. In the first example, *Yasseen* et al. [7.27] detailed the development of SOG as a thick-film sacrificial molding material for thick polysilicon films. The authors reported a process to deposit, polish and etch SOG films that were 20 μm thick. The thick SOG films were patterned into molds and filled with 10 μm-thick LPCVD polysilicon films, planarized by selective chemical mechanical polishing (CMP), and subsequently dissolved in a wet etchant containing HCl, HF, and H_2O to reveal the patterned polysilicon structures. The cured SOG films were completely compatible with the polysilicon deposition process. In the second example, *Liu* et al. [7.28] fabricated high aspect ratio channel plate microstructures from SOG. Electroplated nickel (Ni) was used as a molding material, with Ni channel plate molds fabricated using a conventional Lithography, Galvanoforming, and Abformung (LIGA) process. The Ni molds were then filled with SOG, and the sacrificial Ni molds were removed in a reverse electroplating process. In this case, the fabricated SOG structures (over 100 μm tall) were micromachined glass structures fabricated using a molding material more commonly used for structural components.

7.1.5 Silicon Nitride

Silicon nitride (Si_3N_4) is widely used in MEMS for electrical isolation, surface passivation, etch masking, and as a mechanical material typically for membranes and other suspended structures. Two deposition meth-

ods are commonly used to deposit Si_3N_4 thin films, LPCVD and PECVD. PECVD silicon nitride is generally nonstoichiometric (sometimes denoted as Si_xN_y:H) and may contain significant concentrations of hydrogen. The use of PECVD silicon nitride in micromachining applications is somewhat limited because it has a high etch rate in HF (e.g., often higher than that of thermally grown SiO_2). However, PECVD offers the ability to deposit nearly stress-free silicon nitride films, an attractive property for encapsulation and packaging. Recent experiments using bulk micromachined square and rectangular membranes have shown that Si_xN_y:H thin films ($\approx$ 300–700 nm) deposited by PECVD have a Young's modulus that increases with increasing deposition temperature, from 79 GPa at 125 °C to 151 at 205 °C [7.29]. The residual stresses in these films are below 30 MPa for each deposition temperature.

Unlike its PECVD counterpart, LPCVD Si_3N_4 is extremely resistant to chemical attack, thereby making it the material of choice for many Si bulk and surface micromachining applications. LPCVD Si_3N_4 is commonly used as an insulating layer because it has a resistivity of 10^{16} Ω cm and field breakdown limit of 10^7 V/cm. LPCVD Si_3N_4 films are deposited in horizontal furnaces similar to those used for polysilicon deposition. Typical deposition temperatures and pressures range between 700–900 °C and 200–500 mtorr respectively. The standard source gases are dichlorosilane (SiH_2Cl_2) and ammonia (NH_3). To produce stoichiometric Si_3N_4 a NH_3 to SiH_2Cl_2 ratio 10:1 is commonly used. The microstructure of films deposited under these conditions is amorphous.

The residual stress in stoichiometric Si_3N_4 is large and tensile, with a magnitude of about 1 GPa. Such a large residual stress causes films thicker than a few hundred nanometers to crack. Nonetheless thin stoichiometric Si_3N_4 films have been used as mechanical support structures and electrical insulating layers in piezoresistive pressure sensors [7.30]. To enable the use of Si_3N_4 films for applications that require micron-thick, durable and chemically resistant membranes, Si_xN_y films can be deposited by LPCVD. These films, often referred to as Si-rich or low-stress nitride, are intentionally deposited with an excess of Si by simply decreasing the ratio of NH_3 to SiH_2Cl_2 during deposition. Nearly stress-free films can be deposited using a NH_3 to SiH_2Cl_2 ratio of 1:6, a deposition temperature of 850 °C and a pressure of 500 mtorr [7.31]. The increase in Si content not only leads to a reduction in tensile stress, but also a decrease in the etch rate in HF. Such properties have enabled the development of fabrication techniques that would otherwise not be feasible with stoichiometric Si_3N_4. For example, low-stress silicon nitride has been bulk micromachined using silicon as the sacrificial material [7.32]. In this case, Si anisotropic etchants (TMAH) were used for dissolving the sacrificial silicon. *French* et al. [7.33] used PSG as a sacrificial layer to surface micromachine low-stress nitride, capitalizing on the HF resistance of the nitride films.

7.2 Germanium-Based Materials

7.2.1 Polycrystalline Germanium

Like Si, Ge has a long history as a semiconductor device material, dating back to the development of the earliest transistors and semiconductor strain gages. Issues related to germanium oxide, however, stymied the development of Ge for microelectronic devices. Nonetheless, there is a renewed interest in using Ge in surface micromachined devices due to the relatively low processing temperatures required to deposit the material and its compatibility with Si.

Thin polycrystalline Ge (poly-Ge) films can be deposited by LPCVD at temperatures as low as 325 °C on Si, Ge and SiGe substrates [7.34]. Ge does not nucleate on SiO_2 surfaces, which prohibits the use of thermal oxides and LTO films as sacrificial layers, but enables the use of these films as sacrificial molds. Residual stress in poly-Ge films deposited on Si substrates can be reduced to nearly zero after short anneals at modest temperatures (30 s at 600 °C). Poly-Ge is essentially impervious to KOH, TMAH, and BOE, enabling the fabrication of Ge membranes on Si substrates [7.34]. The mechanical properties of poly-Ge are comparable to polysilicon, having a Young's modulus of 132 GPa and a fracture stress ranging between 1.5 GPa and 3.0 GPa [7.35]. Mixtures of HNO_3, H_2O, and HCl and H_2O, H_2O_2, and HCl, as well as the RCA SC-1 cleaning solution isotropically etch Ge. Since these mixtures do not etch Si, SiO_2, Si_3N_4 and SiN, poly-Ge can be used as a sacrificial substrate layer in polysilicon surface micromachining. Using these techniques, poly-Ge-based thermistors and Si_3N_4 membrane-based pressure sensors made using poly-Ge sacrificial layers have been fabricated [7.34]. *Franke* et al. [7.35] found no performance degradation in Si CMOS devices following the fabrication of surface micromachined poly-Ge structures, thus demonstrating the potential for on-chip integration of Ge electromechanical devices with Si circuitry.

7.2.2 Polycrystalline Silicon Germanium

Like poly-Ge, polycrystalline SiGe (poly-SiGe) is a material that can be deposited at temperatures lower than polysilicon. Deposition processes include LPCVD, APCVD, and rapid thermal CVD (RTCVD) using SiH_4 and GeH_4 as precursor gases. Deposition temperatures range between 450 °C for LPCVD [7.36] to 625 °C for RTCVD [7.37]. In general, the deposition temperature is related to the concentration of Ge in the films, with higher Ge concentrations resulting in lower deposition temperatures. Like polysilicon, poly-SiGe can be doped with boron and phosphorus to modify its conductivity. In situ boron doping can be performed at temperatures as low as 450 °C [7.36]. *Sedky* et al. [7.38] showed that the deposition temperature of conductive films doped with boron could be further reduced to 400 °C if the Ge content was kept at or above 70%. Recent work [7.39] has shown that films grown at temperatures around 400 °C exhibit a strain gradient in the range of $\approx 1\times10^{-5}/\mu m$. This strain gradient is attributed to the columnar microstructure of the films combined with a high compressive stress at the film–substrate interface. Boron doping enhances uniformity in the columnar microstructure throughout the thickness of the film and thus reduces the strain gradient. It has been reported that deposition temperatures for poly-SiGe can be reduced to 210 °C, however to achieve strain gradients on the order of $1\times10^{-6}/\mu m$, the films must be annealed following deposition [7.40]. Since the objective of this effort is to minimize thermal budget, localized annealing by way of excimer laser illumination is required.

Unlike poly-Ge, poly-SiGe can be deposited on a number of sacrificial substrates, including SiO_2 [7.37], PSG [7.35] and poly-Ge [7.35]. For Ge-rich films, a thin polysilicon seed layer is sometimes used on SiO_2 surfaces since Ge does not readily nucleate on oxide surfaces. Like many compound materials, variations in film composition can change the physical properties of the material. For instance, etching of poly-SiGe by H_2O_2 becomes significant for Ge concentrations over 70%. *Sedky* et al. [7.38] have shown that the microstructure, film conductivity, residual stress, and residual stress gradient are related to the concentration of Ge in the material. With respect to residual stress, *Franke* et al. [7.36] produced in situ boron-doped films with residual compressive stresses as low as 10 MPa.

The poly-SiGe, poly-Ge material system is particularly attractive for surface micromachining since H_2O_2 can be used as a release agent. It has been reported that poly-Ge etches at a rate of 0.4 μm/min in H_2O_2, while poly-SiGe with Ge concentrations below 80% has no observable etch rate after 40 h [7.41]. The ability to use H_2O_2 as a sacrificial etchant makes the combination of poly-SiGe and poly-Ge extremely attractive for surface micromachining from processing, safety and materials compatibility points of view. Due to the conformal nature of LPCVD processing, poly-SiGe structural elements, such as gimbal-based microactuator structures, have been made by high-aspect-ratio micromolding [7.41]. Capitalizing on the low deposition temperatures, poly-SiGe MEMS structures integrated with Si ICs have been demonstrated [7.36]. In this process, CMOS structures are first fabricated on Si wafers. Poly-SiGe mechanical structures are then surface micromachined using a poly-Ge sacrificial layer. A significant advantage of this design lies in the fact that the MEMS structure is positioned directly above the CMOS structure, thus reducing the parasitic capacitance and contact resistance characteristic of interconnects associated with side-by-side integration schemes. The use of H_2O_2 as the sacrificial etchant eliminates the need for layers to protect the underlying CMOS structure during release. In addition to its utility as a material for integrated MEMS devices, poly-SiGe has been identified as a material well suited for micromachined thermopiles [7.42] due to its lower thermal conductivity relative to Si.

7.3 Metals

It can be argued that of all the material categories associated with MEMS, metals may be among the most enabling, since metallic thin films are used in many different capacities, ranging from etch masks used in device fabrication to interconnects and structural elements in microsensors and microactuators. Metallic thin films can be deposited using a wide range of techniques, including evaporation, sputtering, CVD, and electroplating. Since a complete review of the metals used in MEMS is far beyond the scope of this chapter, the examples presented in this section were selected to represent a broad cross-section where metals have found uses in MEMS.

Aluminum (Al) and gold (Au) are among the most widely employed metals in microfabricated electronic and electromechanical devices as a result of their use as interconnect and packaging materials. In addition to these critical electrical functions, Al and Au are also de-

sirable as electromechanical materials. One such example is the use of Au micromechanical switches for radio frequency MEMS (RF MEMS. For conventional RF applications, chip-level switching is currently performed using FET- and PIN diode-based solid-state devices fabricated from gallium arsenide (GaAs) substrates (FET: field effect transistor; PIN: p-type/intrinsic/n-type). Unfortunately, these devices suffer from insertion losses and poor electrical isolation. In an effort to develop replacements for GaAs-based solid-state switches, *Hyman* et al. [7.43] reported the development of an electrostatically actuated, cantilever-based micromechanical switch fabricated on GaAs substrates. The device consisted of a silicon nitride-encased Au cantilever constructed on a sacrificial silicon dioxide layer. The silicon nitride and silicon dioxide layers were deposited by PECVD, and the Au beam was electroplated from a sodium sulfite solution inside a photoresist mold. A thin multilayer of Ti and Au was sputter deposited in the mold prior to electroplating. The trilayered cantilever structure was chosen to minimize the deleterious effects of thermal and process-related stress gradients in order to produce unbent and thermally stable beams. After deposition and pattering, the cantilevers were released in HF. The processing steps proved to be completely compatible with GaAs substrates. The released cantilevers demonstrated switching speeds of better than 50 μs at 25 V with contact lifetimes exceeding 10^9 cycles.

In a second example from RF MEMS, *Chang* et al. [7.44] reported the fabrication of an Al-based micromachined switch as an alternative to GaAs FETs and PIN diodes. In contrast to the work by *Hyman* et al. [7.43], this switch utilizes the differences in the residual stresses in Al and Cr thin films to create bent cantilever switches that capitalize on the stress differences in the materials. Each switch is comprised of a series of linked bimorph cantilevers designed in such a way that the resulting structure bends significantly out of the plane of the wafer due to the stress differences in the bimorph. The switch is drawn closed by electrostatic attraction. The bimorph consists of metals that can easily be processed with GaAs wafers, thus making integration with GaAs devices possible. The released switches were relatively slow, at 10 ms, but an actuation voltage of only 26 V was needed to close the switch.

A recent study published by *Reddy* et al. documents the use of micromachined structures to characterize the mechanical properties of thin Al and Ni films [7.45]. The structures, fabricated from sputter-deposited films, consisted of bulk micromachined suspended metal membranes and surface micromachined metal-coated lateral resonators. The researchers found that the Young's modulus for the Al films was 70 GPa and that for the Ni films was 200 GPa, values that are in agreement with bulk samples.

Direct bulk micromachining of metal substrates is being developed for MEMS applications requiring structures with the dimensional complexity associated with Si DRIE and the physical properties of metals. One such example is Ti, which has a higher fracture toughness, a greater biocompatibility, and a more stable passivating oxide than Si. A process to fabricate high-aspect-ratio, three-dimensional structures from bulk Ti substrates has been developed [7.46]. This process involves inductively coupled plasma (ICP) etching of a TiO_2-capped Ti substrate. The TiO_2 capping layer is deposited by DC reactive sputtering and photolithographically patterned using a CHF_3-based dry etch. The deep Ti etch is then performed using a Cl/Ar-based plasma that exhibits a selectivity of 40:1 with the masking TiO_2 layer. The etch process consists of a series of two-step sequences, where the first step involves Ti removal by the Cl/Ar plasma while the second step involves sidewall passivation using an oxygen plasma. After the prescribed etch period, the masking thin film can be removed by HF etching. High-aspect-ratio comb-drive actuators and other beam-based structures have been fabricated directly from bulk Ti using this method. An effort to develop Ti microneedles that incorporate microfluidic channels for drug delivery applications fabricated using this technique has been published [7.47].

Thin-film metallic alloys that exhibit the shape-memory effect are of particular interest to the MEMS community for their potential in microactuators. The shape-memory effect relies on the reversible transformation from a ductile martensite phase to a stiff austenite phase in the material with the application of heat. The reversible phase change allows the shape-memory effect to be used as an actuation mechanism since the material changes shape during the transition. It has been found that high forces and strains can be generated from shape-memory thin films at reasonable power inputs, thus enabling shape-memory actuation to be used in MEMS-based microfluidic devices such as microvalves and micropumps. Titanium-nickel (TiNi) is among the most popular of the shape-memory alloys owing to its high actuation work density, ($50\,MJ/m^3$), and large bandwidth (up to 0.1 kHz) [7.48]. TiNi is also attractive because conventional sputtering techniques can be employed to deposit thin films, as detailed in a recent report by *Shih* et al. [7.48]. In this study, TiNi films were deposited by cosputtering elemental Ti and Ni targets, and cosputtering TiNi alloy and elemental Ti targets. It was reported that cosputtering from TiNi and Ti targets produced better films due to process variations related to roughening of the

Ni target in the case of Ti and Ni cosputtering. The TiNi/Ti co-puttering process has been used to produce a shape-memory material for a silicon spring-based microvalve [7.49].

The use of thin-film metal alloys in magnetic actuator systems is another example of the versatility of metallic materials in MEMS. Magnetic actuation in microdevices generally requires the magnetic layers to be relatively thick (tens to hundreds of microns) to generate magnetic fields of sufficient strength to generate the desired actuation. To this end, magnetic materials are often deposited by thick-film methods such as electroplating. The thicknesses of these layers exceeds what can feasibly be patterned by etching, so plating is often performed in microfabricated molds made from materials such as polymethylmethacrylate (PMMA). The PMMA mold thickness can exceed several hundred microns, so x-rays are used as the exposure source during the patterning steps. When necessary, a metallic thin-film seed layer is deposited prior to plating. After plating, the mold is dissolved, which frees the metallic component. Known as LIGA (short for Lithography, Galvanoforming, and Abformung), this process has been used to produce a wide variety of high-aspect ratio structures from plateable materials, such as nickel-iron (NiFe) magnetic alloys [7.50] and Ni [7.51].

In addition to elemental metals and simple compound alloys, more complex metallic alloys commonly used in commercial macroscopic applications are finding their way into MEMS applications. One such example is an alloy of titanium known as Ti-6Al-4V. Composed of 88% titanium, 6% aluminum and 4% vanadium, this alloy is widely used in commercial aviation due to its weight, strength and temperature tolerance. *Pornsin-Sirirak* et al. [7.52] have explored the use of this alloy in the manufacture of MEMS-based winged structures for micro-aerial vehicles. The authors considered this alloy not only because of its weight and strength, but also because of its ductility and its etching rate at room temperature. The designs for the wing prototype were modeled after the wings of bats and various flying insects. For this application, Ti-alloy structures patterned from bulk (250 μm-thick) material by an $HF/HO_3/H_2O$ etching solution were used rather than thin films. Parylene-C (detailed in a later section) was deposited on the patterned alloy to serve as the wing membrane. The miniature micromachined wings were integrated into a test setup and several prototypes actually demonstrated short-duration flight.

7.4 Semiconductors for Harsh Environment Applications

7.4.1 Silicon Carbide

Silicon Carbide (SiC) has long been recognized as the leading semiconductor for use in high-temperature and high-power electronics, and is currently being developed as a material for harsh environment MEMS. SiC is a polymorphic material that exists in cubic, hexagonal, and rhombehedral polytypes. The cubic polytype, called 3C-SiC, has an electronic bandgap of 2.3 eV, which is over twice that of Si. Numerous hexagonal and rhombehedral polytypes have been identified, with the two most common being 4H-SiC and 6H-SiC. The electronic bandgaps of 4H- and 6H-SiC are even higher than 3C-SiC, being 2.9 and 3.2 eV respectively. SiC films can be doped to create n-type and p-type materials. The Young's modulus of SiC is still the subject of research, but most reported values range from 300 GPa to 450 GPa, depending on the microstructure and measurement technique. SiC is not etched in any wet Si etchants and is not attacked by XeF_2, a popular dry Si etchant used for releasing device structures [7.53]. SiC is a material that does not melt, but rather sublimes at temperatures in excess of 1800 °C. Single-crystal 4H- and 6H-SiC wafers are commercially available, but are generally smaller in diameter (3 in) and much more expensive than Si wafers.

SiC thin films can be grown or deposited using a number of different techniques. For high-quality single-crystal films, APCVD and LPCVD processes are most commonly employed. Homoepitaxial growth of 4H- and 6H-SiC yields high-quality films suitable for microelectronic applications but typically only on substrates of the same polytype. These processes usually employ dual precursors, such as SiH_4 and C_3H_8, and are performed at temperatures ranging from 1500 to 1700 °C. Epitaxial films with p-type or n-type conductivity can be grown using Al and B for p-type films and N and P for n-type films. Nitrogen is so effective at modifying the conductivity of SiC that growth of undoped SiC films is extremely challenging because the concentrations of residual nitrogen in typical deposition systems are sufficient for n-type doping.

APCVD and LPCVD can also be used to deposit 3C-SiC on Si substrates. Heteroepitaxy is possible despite a 20% lattice mismatch because 3C-SiC and Si have the same lattice structure. The growth process involves two key steps. The first step, called carbonization, converts the near-surface region of the Si

substrate to 3C-SiC by simply exposing it to a hydrocarbon/hydrogen mixture at high substrate temperatures (> 1200 °C). The carbonized layer forms a crystalline template on which a 3C-SiC film can be grown by adding a silicon-containing gas to the hydrogen/hydrocarbon mix. The lattice mismatch between Si and 3C-SiC results in the formation of crystalline defects in the 3C-SiC film, with the density being highest in the carbonization layer and decreasing with increasing thickness. The crystal quality of 3C-SiC films is nowhere near that of epitaxially grown 4H- and 6H-SiC films; however, the fact that 3C-SiC can be grown on Si substrates enables the use of Si bulk micromachining techniques for fabrication of a host of 3C-SiC-based mechanical devices. These include microfabricated pressure sensors [7.54] and nanoelectromechanical resonant structures [7.55]. For designs that require electrical isolation from the substrate, 3C-SiC devices can be made directly on SOI substrates [7.54] or by wafer bonding and etchback, such as the capacitive pressure sensor developed by *Young* et al. [7.56].

Polycrystalline SiC (poly-SiC) is a more versatile material for SiC MEMS than its single-crystal counterparts. Unlike single-crystal versions of SiC, poly-SiC can be deposited on a variety of substrate types, including common surface micromachining materials such as polysilicon, SiO_2 and Si_3N_4. Commonly used deposition techniques include LPCVD [7.53, 57, 58] and APCVD [7.59, 60]. The deposition of poly-SiC requires much lower substrate temperatures than epitaxial films, ranging from roughly 700 to 1200 °C. Amorphous SiC can be deposited at even lower temperatures (25–400 °C) by PECVD [7.61] and sputtering [7.62]. The microstructure of poly-SiC films is temperature-, substrate-, and process-dependent. For amorphous substrates such as SiO_2 and Si_3N_4, APCVD poly-SiC films deposited from SiH_4 and C_3H_8 are randomly oriented with equiaxed grains [7.60], whereas for oriented substrates such as polysilicon, the texture of the poly-SiC film matches that of the substrate itself [7.59]. By comparison, poly-SiC films deposited by LPCVD from SiH_2Cl_2 and C_2H_2 are highly textured (111) films with a columnar microstructure [7.57], while films deposited from disilabutane have a distribution of orientations [7.53]. This variation suggests that device performance can be tailored by selecting the proper substrate and deposition conditions.

SiC films deposited by AP- and LPCVD generally suffer from large residual stresses that are tensile and on the order of several 100 MPa. Moreover, the residual stress gradients in these films tend to be large, leading to significant out-of-plane bending of structures anchored at a single location. The thermal stability of SiC makes a postdeposition annealing step impractical for films deposited on Si substrates, since the temperatures needed to significantly modify the film are likely to exceed the melting temperature of the wafer. For LPCVD processes using SiH_2Cl_2 and C_2H_2 precursors, *Fu* et al. [7.63] have described a relationship between deposition pressure and residual stress that enables the deposition of undoped poly-SiC films with nearly zero residual stresses and negligible stress gradients. This work has been extended to include films doped with nitrogen [7.64].

Direct bulk micromachining of SiC is very difficult, due to its chemical inertness. Although conventional wet chemical techniques are not effective, several electrochemical etch processes have been demonstrated and used in the fabrication of 6H-SiC pressure sensors [7.65]. The etching processes are selective to the conductivity of the material, so dimensional control of the etched structures depends on the ability to form doped layers, which can only be formed by in situ, or ion implantation processes since solid source diffusion is not possible at reasonable processing temperatures. This constraint somewhat limits the geometrical complexity of the patterned structures as compared to conventional plasma-based etching. To fabricate thick (100s of microns), three-dimensional (3-D), high-aspect-ratio SiC structures, a molding technique has been developed [7.51]. The molds are fabricated from Si substrates using deep reactive ion etching and then filed with SiC using a combination of thin epitaxial and thick polycrystalline film CVD processes. The thin-film process is used to protect the mold from pitting during the more aggressive mold-filling SiC growth step. The mold-filling process coats all surfaces of the mold with a SiC film as thick as the mold is deep. To release the SiC structure, the substrate is first mechanically polished to expose sections of the Si mold, then the substrate is immersed in a Si etchant to completely dissolve the mold. This process has been used to fabricate solid SiC fuel atomizers [7.51], and a variant has been used to fabricate SiC structures for micropower systems [7.66]. *Min* et al. [7.67] reported a process to fabricate reusable glass press molds made from SiC structures that were patterned using Si molding masters. SiC was selected as the material for the glass press mold, because the application requires a hard, mechanically strong, and chemically stable material that can withstand and maintain its properties at temperatures between 600–1400 °C.

In addition to CVD processes, bulk micromachined SiC structures can be fabricated using sintered SiC powders. *Tanaka* et al. [7.68] describe a process where SiC components, such as microscale gas turbine engine rotors, can be fabricated from SiC powders using a microreaction-sintering process. The molds are mi-

crofabricated from Si using DRIE, and filled with SiC and graphite powders mixed with a phenol resin. The molds are then reaction-sintered using a hot isostatic pressing technique. The SiC components are then released from the Si mold by wet chemical etching. The authors reported that the component shrinkage was less than 3%. The bending strength and Vickers hardness of the microreaction-sintered material was roughly 70–80% of commercially available reaction-sintered SiC, the difference being attributed to the presence of unreacted Si in the microscale components.

In a related process, *Liew* et al. [7.69] detail a technique to create silicon carbon nitride (SiCN) MEMS structures by molding injectable polymer precursors. Unlike the aforementioned processes, this technique uses SU-8 photoresists for the molds. To be detailed later in this chapter, SU-8 is a versatile photodefinable polymer in which thick films (100s of microns) can be patterned using conventional ultraviolet (UV) photolithographic techniques. After patterning, the molds are filled with the SiCN-containing polymer precursor, lightly polished, and then subjected to a multistep heat-treating process. During the thermal processing steps, the SU-8 mold decomposes and the SiCN structure is released. The resulting SiCN structures retain many of the same properties of stoichiometric SiC.

Although SiC cannot be etched using conventional wet etch techniques, SiC can be patterned using conventional dry etching techniques. RIE processes using fluorinated compounds such as CHF_3 and SF_6 combined with O_2 and sometimes with an inert gas or H_2 are used to pattern thin films. The high oxygen content in these plasmas generally prohibits the use of photoresist as a masking material; therefore hard masks made of Al, Ni, and ITO are often used. RIE-based SiC surface micromachining processes with polysilicon and SiO_2 sacrificial layers have been developed for single-layer devices [7.70, 71]. ICP RIE of SiC using SF_6 plasmas and Ni or ITO etch masks has been extended to bulk micromachine SiC substrates by DRIE, with structural depths in excess of 100 µm reported [7.72]. *Sharpe* et al. reported on the use of bulk micromachined tensile specimens to characterize the tensile strength of single-crystalline SiC structures at temperatures up to 1000 °C [7.73]. The structures were made from commercially available 6H-SiC wafers and micromachined by DRIE. They found that the the testing specimens exhibited a fracture strength between 0.45 and 1.2 GPa at room temperature depending on specimen geometry, which varied only slightly with increasing temperature.

Initially, multilayer thin-film structures were very difficult to fabricate by direct RIE because the etch rates of the sacrificial layers were much higher than the SiC structural layers, making dimensional control very difficult. To address this issue, a micromolding process for patterning SiC films on sacrificial layer substrates was developed [7.74]. In essence, the micromolding technique is the thin-film analog to the molding-based, bulk micromachining technique presented earlier. The micromolding process utilizes polysilicon and SiO_2 films as both molds and sacrificial substrate layers, with SiO_2 molds used with polysilicon sacrificial layers and vice versa. These films are deposited and patterned using conventional methods, thus leveraging the well-characterized and highly selective processes developed for polysilicon MEMS. Poly-SiC films are simply deposited into the micromolds and mechanical polishing is used to remove poly-SiC from atop the molds. Appropriate etchants are then used to dissolve the molds and sacrificial layers. The micromolding method utilizes the differences in chemical properties of the three materials in this system in a way that bypasses the difficulties associated with chemical etching of SiC. This technique has been developed specifically for multilayer processing, and has been used successfully to fabricate SiC micromotors [7.74] and the lateral resonant structure shown in Fig. 7.4 [7.75].

Recent advancements in the area of SiC RIE show that significant progress has been made in developing etch recipes with selectivities to nonmetal mask and sacrificial layers that are suitable for multilayer SiC surface micromachining. For instance, *Gao* et al. [7.76] have developed a transformer coupled RIE process using a HBr-based chemistry for thin-film poly-SiC etching. The recipe exhibits a SiC-to-SiO_2 selectivity of 20:1 and a SiC-to-Si_3N_4 selectivity of 22:1, which are the highest reported thus far. In addition, the anisotropy of the etch was quite high, and micromasking, a common problem when metal masks are used, was

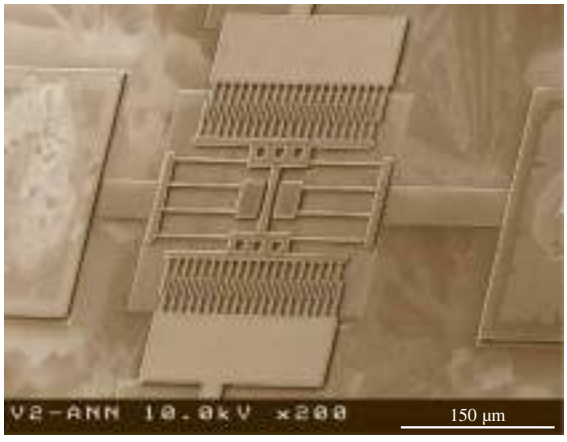

Fig. 7.4 SEM micrograph of a poly-SiC lateral resonant structure fabricated using a multilayer, micromolding-based micromachining process (after [7.75])

not an issue. This process has since been used to fabricate multilayered lateral resonant structures that utilize poly-SiC as the main structural material and polysilicon as a conducting plane that lies underneath the resonating shuttle [7.77].

Yang et al. [7.55] have shown that the chemical inertness of SiC facilitates the fabrication of NEMS devices. In this work, the authors present a fabrication method to realize SiC mechanical resonators with submicron thickness and width dimensions. The resonators were fabricated from ≈ 260 nm-thick 3C-SiC films epitaxially grown on (100) Si wafers. The films were patterned into 150 nm-wide beams ranging in length from 2 to 8 μm. The beams were etched in a $NF_3/O_2/Ar$ plasma using an evaporated Cr etch mask. After patterning, the beams were released by etching the underlying Si isotropically using a NF_3/Ar plasma. The inertness of the SiC film to the Si etchant enables the dry release of the nanomechanical beams. An example of a 3C-SiC nanomechanical beam is shown in Fig. 7.5. The first nanomechanical resonator to exhibit a fundamental resonant frequency in excess of 1 GHz was fabricated from a 3C-SiC film using the aforementioned process [7.78].

7.4.2 Diamond

Diamond is commonly known as nature's hardest material, making it ideal for high-wear environments. Diamond has a very large electronic bandgap (5.5 eV), which makes it attractive for high-temperature electronics. Undoped diamond is a high-quality insulator with a dielectric constant of 5.5; however it can be relatively easily doped with boron to create p-type conductivity. Diamond has a very high Young's modulus (1035 GPa) making it suitable for high-frequency micromachined resonators, and it is among nature's most chemically inert materials, making it well suited for harsh chemical environments.

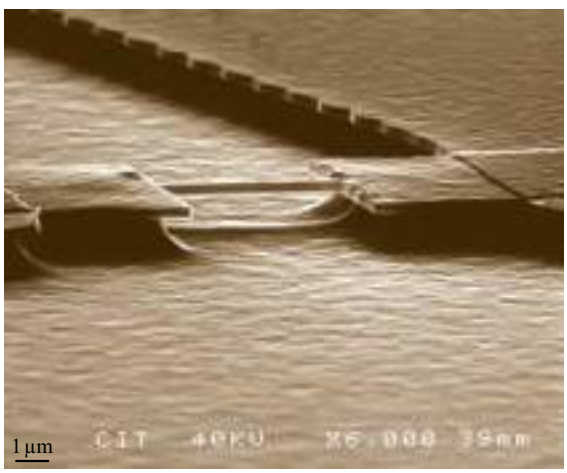

Fig. 7.5 SEM micrograph of a 3C-SiC nanomechanical beam resonator fabricated by electron-beam lithography and dry etching processes (courtesy M. Roukes, Caltech)

Unlike SiC, fabrication of diamond MEMS is currently restricted to polycrystalline and amorphous material, since single-crystal diamond wafers are not yet commercially available. Polycrystalline diamond films can be deposited on Si and SiO_2 substrates by CVD methods, but the surfaces must often be seeded by diamond powders or biased with a negative charge to initiate growth. In general, diamond nucleates much more readily on Si surfaces than on SiO_2 surfaces, an effect that has been used to selectively pattern diamond films into micromachined atomic force microscope (AFM) cantilever probes using SiO_2 molding masks [7.79].

Bulk micromachining of diamond using wet and dry etching is extremely difficult given its extreme chemical inertness. Diamond structures have nevertheless been fabricated using bulk micromachined Si molds to pattern the structures [7.80]. The Si molds were fabricated using conventional micromachining techniques and filed with polycrystalline diamond deposited by hot filament chemical vapor deposition (HFCVD). The HFCVD process uses H_2 and CH_4 precursors. The process was performed at a substrate temperature of 850–900 °C and a pressure of 50 mtorr. The Si substrate was seeded prior to deposition using a diamond particle/ethanol solution. After deposition, the top surface of the structure was polished using a hot iron plate. After polishing, the Si mold was removed in a Si etchant, leaving behind the micromachined diamond structure. This process was used to produce high-aspect-ratio capillary channels for microfluidic applications [7.81], and components for diffractive optics, laser-to-fiber alignment, and power device cooling structures [7.82].

Due to the nucleation processes associated with diamond film growth, surface micromachining of polycrystalline diamond thin films requires modifications to conventional micromachining to facilitate film growth on sacrificial substrates. Initially, conventional RIE methods were generally ineffective, so work was focused on developing selective deposition techniques. One early method used selective seeding to form patterned templates for diamond nucleation. The selective seeding process employed the lithographic patterning of photoresist that contained diamond powders [7.83]. The diamond-loaded photoresist was deposited and patterned onto a Cr-coated Si wafer. During the onset of diamond growth, the patterned photoresist rapidly evaporates, leaving behind the diamond seed particles in the desired locations. A patterned diamond film is then selectively grown on these locations.

A second process utilized selective deposition directly on sacrificial substrate layers. This processes combined conventional diamond seeding with photolithographic patterning and etching to fabricate micromachined diamond structures on SiO_2 sacrificial layers [7.84]. The process was performed in one of two ways. The first approach begins with the seeding of an oxidized Si wafer. The wafer is coated with photoresist, and photolithographically patterned. Unmasked regions of the seeded SiO_2 film are then partially etched, forming a surface unfavorable for diamond growth. The photoresist is then removed and a diamond film is deposited on the seeded regions. The second approach also begins with an oxidized Si wafer. The wafer is coated with photoresist, photolithographically patterned and then seeded with diamond particles. The photoresist is removed, leaving behind a patterned seed layer suitable for selective growth. These techniques have been successfully used to fabricate cantilever beams and bridge structures.

A third method to surface micromachine polycrystalline diamond films follows the conventional approach of film deposition, dry etching, and release. The chemical inertness of diamond renders most conventional plasma chemistries useless; however, oxygen-based ion beam plasmas can be used to etch diamond thin films [7.85]. A simple surface micromachining process begins with the deposition of a polysilicon sacrificial layer on a Si_3N_4-coated Si wafer. The polysilicon layer is seeded using diamond slurry and a diamond film is deposited by HFCVD. Since photoresist is not resistant to O_2 plasmas, an Al masking film is deposited and patterned. The diamond films are then etched in the O_2 ion beam plasma, and the structures are released by etching the polysilicon with KOH. This process has been used to create lateral resonant structures, but a significant stress gradient in the films rendered the devices inoperable.

In general, conventional HFCVD requires that the substrate be pretreated with a seeding layer prior to diamond film growth. However, a method called biased enhanced nucleation (BEN) has been developed that enables the growth of diamond on unseeded Si surfaces. *Wang* et al. [7.86] have shown that if Si substrates are masked with patterned SiO_2 films, selective diamond growth will occur primarily on the exposed Si surfaces, and a slight HF etch is sufficient to remove the adventitious diamond from the SiO_2 mask. This group was able to use this method to fabricate diamond micromotor rotors and stators on Si surfaces.

Diamond is a difficult, but not impossible material to etch using conventional RIE techniques. It is well known that diamond will be etched in oxygen plasmas, but these plasmas can be problematic for device fabrication because the etching tends to be isotropic. Fabrication of MEMS structures has been aided significantly by the development of RIE processes for diamond thin films. *Wang* et al. [7.87] describe a process to fabricate a vertically actuated, doubly clamped micromechanical diamond beam resonator using RIE. The process outlined in this paper addresses two key issues related to diamond surface micromachining, namely residual stress gradients in the diamond films and diamond patterning techniques. A microwave plasma CVD (MPCVD) reactor was used to grow the diamond films on sacrificial SiO_2 layers that were pretreated with a nanocrystalline diamond powder, resulting in a uniform nucleation density at the diamond/SiO_2 interface. The diamond films were etched in a CF_4/O_2 plasma using Al as a hard mask. Reasonably straight sidewalls were created, with roughness attributable to the surface roughness of the faceted diamond film. An Au/Cr drive electrode beneath the sacrificial oxide remained covered throughout the diamond patterning steps and thus was undamaged during the diamond etching process. This work has since been extended to develop a 1.51 GHz diamond micromechanical disk resonator [7.88]. In this instance, the nanocrystalline diamond film was deposited by MPCVD, coated with an oxide film that was patterned into an etch mask, and then etched in a O_2/CF_4 RIE plasma under conditions that yielded a fairly anisotropic etch with a diamond-to-oxide selectivity of 15:1. The disk was suspended over the substrate on a polysilicon stem using an oxide sacrificial layer. Polysilicon was also used as the drive and sense electrodes. The material mismatch between the step and the resonating disk substantially reduced anchor losses, thus allowing for very high quality factors (11 500) for 1.5 GHz resonators testing in vacuum. *Sepulveda* et al. have successfully fabricated cantilever-beam resonators by surface micromachining using silicon dioxide as a sacrificial layer material [7.89]. The diamond films were grown by MPCVD using 25 nm diamond powders as seeds for nucleation. Seeding was not done preferentially, so the diamond film was patterned by dry etching using a 300 nm-thick Ti film as an etch mask. Along similar lines, *Sekaric* et al. fabricated NEMS structures such as paddle oscillators, doubly clamped beams and mesh membranes from nanocrystalline diamond films grown on oxide-coated Si wafers by MPCVD using nanoparticle seeds [7.90].

In conjunction with recent advances in RIE and micromachining techniques, work is being performed to develop diamond deposition processes specifically for MEMS applications. Diamond films grown using conventional techniques, especially processes that require pregrowth seeding, tend to have high residual

stress gradients and roughened surface morphologies as a result of the highly faceted, large-grain polycrystalline films that are produced by these methods (Fig. 7.6). The rough surface morphology degrades the patterning process, resulting in roughened sidewalls in etched structures and roughened surfaces of films deposited over these layers. Unlike polysilicon and SiC, a postdeposition polishing process is not technically feasible for diamond due to its extreme hardness. For the fabrication of multilayer diamond devices, methods to reduce the surface roughness of the as-deposited films are highly desirable. Along these lines, *Krauss* et al. [7.91] have reported on the development of an ultrananocrystalline diamond (UNCD) film that exhibits a much smoother surface morphology than comparable diamond films grown using conventional methods. Unlike conventional CVD diamond films that are grown using a mixture of H_2 and CH_4, the ultrananocrystalline diamond films are grown from mixtures of Ar, H_2 and C_{60} or Ar, H_2 and CH_4. Films produced by this method have proven to be effective as conformal coatings on Si surfaces, and have been used successfully in several surface micromachining processes. This group has extended the UNCD deposition technology to low deposition temperatures, with high-quality nanocrystalline diamond films being deposited at rates of 0.2 μm/h at substrate temperatures of 400 °C, making these films compatible from a thermal budget perspective with Si IC technology [7.92]. A wide range of microdevice structures have been successfully fabricated using UNCD diamond films, including UNCD cantilevers that incorporate PZT piezoelectric actuators [7.93], suspended membranes [7.94], and microfabricated retinal implants [7.95]. In addition to achieving a smooth surface morphology, it has been shown using micromachined cantilevers that nanocrystalline and ultrananocrystalline diamond films to not suffer from the high stress gradients associated with their microcrystalline counterparts [7.96].

Another alternative deposition method that is proving to be well suited for diamond MEMS is based on pulsed laser deposition [7.97]. The process is performed in a high-vacuum chamber and uses a pulsed excimer laser to ablate a pyrolytic graphite target. Material from the ejection plume deposits on a substrate, which is kept at room temperature. Background gases composed of N_2, H_2 and Ar can be introduced to adjust the deposition pressure and film properties. The as-deposited films consist of tetrahedrally bonded carbon that is amorphous in microstructure, hence the name amorphous diamond. Nominally stress-free films can be deposited by proper selection of deposition parameters [7.98] or by a short postdeposition annealing step [7.97]. The amorphous diamond films exhibit many of the properties of single-crystal diamond, such as a high hardness (88 GPa) a high Young's modulus (1100 GPa) and chemical inertness. Many single-layer surface micromachined structures have been fabricated using these films; in part because the films can readily be deposited in oxide sacrificial layers and they can be etched in an oxygen plasma. Amorphous diamond films have been used as a dielectric isolation layer in vertically actuated microbridges in micromachined RF capacitive switches [7.99]. The diamond films sit atop W fixed electrodes and provide dielectric isolation from an Au microbridge that spans the fixed electrode structure. The diamond films are particularly attractive for such applications since the surfaces are hydrophobic and thus do not suffer from stiction and are highly resistant to wear over repeated use.

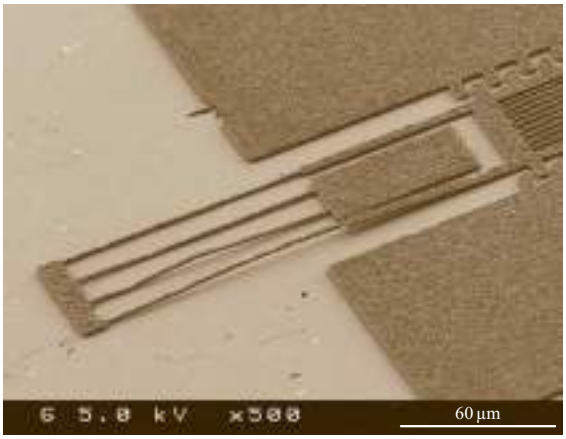

Fig. 7.6 SEM micrograph of the folded beam truss of a diamond lateral resonator. The diamond film was deposited using a seeding-based hot filament CVD process. The micrograph illustrates the challenges facing MEMS structures made from polycrystalline material, namely roughened surfaces and residual stress gradients

7.5 GaAs, InP and Related III–V Materials

Gallium arsenide (GaAs), indium phosphide (InP) and related III-V compounds have favorable piezoelectric and optoelectric properties, high piezoresistive constants and wide electronic bandgaps relative to Si, making them attractive for various sensor and optoelectronic applications. Like Si, significant research in bulk crystal growth has led to the development of GaAs and InP substrates that are commercially available as

high-quality, single-crystal wafers. Unlike compound semiconductors such as SiC, III-V materials can be deposited as ternary and quaternary alloys with lattice constants that closely match the binary compounds from which they are derived (i. e., $Al_xGa_{1-x}As$ and GaAs), thus permitting the fabrication of a wide variety of heterostructures that facilitate device performance.

Crystalline GaAs has a zinc blend crystal structure with an electronic bandgap of 1.4 eV, enabling GaAs electronic devices to function at temperatures as high as 350 °C [7.100]. High-quality, single-crystal wafers are commercially available, as are well-developed metalorganic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE) growth processes for epitaxial layers of GaAs and its alloys. GaAs does not outperform Si in terms of mechanical properties, however its stiffness and fracture toughness are still suitable for micromechanical devices.

Micromachining of GaAs is relatively straightforward, since many of its lattice-matched ternary and quaternary alloys have sufficiently different chemical properties to allow their use as sacrificial layers [7.101]. For example, the most common ternary alloy for GaAs is $Al_xGa_{1-x}As$. For values of x less than or equal to 0.5, etchants containing mixtures of HF and H_2O will etch $Al_xGa_{1-x}As$ without attacking GaAs, while etchants containing NH_4OH and H_2O_2 attack GaAs isotropically but do not etch $Al_xGa_{1-x}As$. Such selectivity enables the micromachining of GaAs wafers using lattice-matched etch stops and sacrificial layers. Devices fabricated using these methods include comb-drive lateral resonant structures [7.101], pressure sensors [7.102, 103], thermopile sensors [7.104], Fabry–Perot detectors [7.105], and cantilever-based sensors and actuators [7.106, 107]. In addition, nanoelectromechanical devices, such as suspended micromechanical resonators [7.108] and tethered membranes [7.109] have been fabricated using these techniques. An example of a nanoelectromechanical beam structure fabricated from GaAs is shown in Fig. 7.7.

In addition to using epitaxial layers as etch stops, ion implantation methods can also be used to produce etch stops in GaAs layers. *Miao* et al. [7.110] describe a process that uses electrochemical etching to selectively remove n-type GaAs layers. The process relies on the creation of a highly resistive near-surface GaAs layer on an n-type GaAs substrate by low-dose nitrogen implantation in the MeV energy range. A pulsed electrochemical etch method using a H_2PtCl_6, H_3PO_4, H_2SO_4 platinum electrolytic solution at 40 °C with 17 V, 100 ms pulses is sufficient to selectively remove n-type GaAs at about 3 µm/min. Using this method, stress-free, tethered membranes could readily be fabricated from the highly resistive GaAs layer. The high

Fig. 7.7 SEM micrograph of a GaAs nanomechanical beam resonator fabricated by epitaxial growth, electron-beam lithography and selective etching (courtesy of M. Roukes, Caltech)

implant energies enable the fabrication of membranes several microns in thickness. Moreover, the authors demonstrated that if the GaAs wafer was etched in such a way as to create an undulating surface prior to ion implantation, corrugated membranes could be fabricated. These structures can sustain much higher deflection amplitudes than flat structures.

Micromachining of InP closely resembles the techniques used for GaAs. Many of the properties of InP are similar to GaAs in terms of crystal structure, mechanical stiffness and hardness; however, the optical properties of InP make it particularly attractive for micro-optomechanical devices to be used in the 1.3−1.55 µm wavelength range [7.111]. Like GaAs, single-crystal wafers of InP are readily available and ternary and quaternary lattice-matched alloys, such as InGaAs, InAlAs, InGaAsP and InGaAlAs, can be used as either etch stop and/or sacrificial layers depending on the etch chemistry [7.101]. For instance, InP structural layers deposited on $In_{0.53}Al_{0.47}As$ sacrificial layers can be released using etchants containing $C_6H_8O_7$, H_2O_2, and H_2O. In addition, InP films and substrates can be etched in solutions containing HCl and H_2O using $In_{0.53}Ga_{0.47}As$ films as etch stops. Using InP-based micromachining techniques, multi-air gap filters [7.112], bridge structures [7.111], and torsional membranes [7.105] have been fabricated from InP and its related alloys.

In addition to GaAs and InP, materials such as indium arsenide (InAs) can be micromachined into device structures. Despite a 7% lattice mismatch between InAs and (111) GaAs, high-quality epitaxial layers can be grown on GaAs substrates. As described by *Yamaguchi*

et al. [7.113], the surface Fermi level of InAs/GaAs structures is pinned in the conduction band, enabling the fabrication of very thin conductive membranes. In fact the authors have successfully fabricated free-standing InAs structures that range in thickness from 30 to 300 nm. The thin InAs films were grown directly on GaAs substrates by MBE and etched using a solution containing H_2O, H_2O_2, and H_2SO_4. The structures, mainly doubly clamped cantilevers, were released by etching the GaAs substrate using a $H_2O/H_2O_2/NH_4OH$ solution.

Ternary III-V compounds have also been utilized in MEMS structures. *Deng* et al. report on the development of disk-type microresonators based on epitaxial AlGaAs films [7.114]. The resonator consists of a surface micromachined disk that is tethered to the substrate by four supporting beams. The disk is made from a Si-doped $Al_{0.3}Ga_{0.7}As$ layer that clads an undoped $Al_{0.3}Ga_{0.7}As$ layer. This three-layer stack is grown on a sacrificial $Al_{0.7}Ga_{0.3}As$ layer that is epitaxially grown on a commercially available GaAs wafer. Reactive ion etching is used to pattern the disk resonator and the structure is released by dissolving the sacrificial layer in HF, which is highly selective to the Al-rich AlGaAs layer. The device capitalizes on the piezoelectric properties of AlGaAs for actuation, which is realized in the suspended disk due to the excellent lattice matching between each epitaxial layer.

7.6 Piezoelectric Materials

7.6.1 Lead Zirconate Titanate

Piezoelectric materials play an important role in MEMS technology for sensing and mechanical actuation applications. In a piezoelectric material, mechanical stress produces a polarization, and conversely a voltage-induced polarization produces a mechanical stress. Many asymmetric materials, such as quartz, GaAs, and zinc oxide (ZnO), exhibit varying levels of piezoelectric behavior. Recent work in MEMS has focused on the development of ferroelectric compounds such as lead zirconate titanate, $Pb(Zr_xTi_{1-x})O_3$, or PZT for short, because such compounds have high piezoelectric constants that result in high mechanical transduction. It is relatively straightforward to fabricate a PZT structure on top of a thin free-standing structural layer (i. e., cantilever, diaphragm). Such a capability enables the piezoelectric material to be used in sensor applications or actuator applications where piezoelectric materials are particularly well suited. Like Si, PZT films can be patterned using dry etch techniques based on chlorine chemistries, such as Cl_2/CCl_4, as well as ion beam milling using inert gases like Ar.

PZT has been successfully deposited in thin-film form using cosputtering, CVD, and sol-gel processing. Sol-gel processing is particularly attractive because the composition and homogeneity of the deposited material over large surface areas can be readily controlled. The sol-gel process outlined by *Lee* et al. [7.115] uses PZT solutions made from liquid precursors containing Pb, Ti, Zr, and O. The solution is deposited by spin coating on a Si wafer that has been coated with a $Pt/Ti/SiO_2$ thin-film multilayer. The process is executed to produce a PZT film in layers, with each layer consisting of a spin-coated layer that is dried at 110 °C for 5 min and then heat treated at 600 °C for 20 min. After building up the PZT layer to the desired thickness, the multilayer was heated at 600 °C for up to 6 h. Prior to this anneal, a PbO top layer was deposited on the PZT surface. An Au/Cr electrode was then sputter deposited on the surface of the piezoelectric stack. This process was used to fabricate a PZT-based force sensor. *Xu* et al. [7.116] describe a similar sol-gel process to produce 12 μm-thick, crack-free PZT films on Pt-coated Si wafers and 5 μm-thick films on insulating ZrO_2 layers to produce micromachined MHz-range two-dimensional transducer arrays for acoustic imaging. A publication by *Hong* et al. describes the development of large-deflection circular diaphragm actuators made using a solution-cast PZT film [7.117]. The PZT film was deposited by spin casting onto a sol-gel ZrO_2 film deposited on a SiO_2-coated Si wafer. A sputter-deposited Pt film was patterned into interdigitated electrodes on the PZT film and the diaphragm was created by bulk micromachining the silicon dioxide-coated substrate by DRIE. The PZT film had a tensile residual stress of 50 to 100 MPa. For a ≈ 3 μm-thick, 800 μm-diameter membrane, a center deflection of ≈ 7 μm could be generated with an applied voltage of 100 V.

Thick-film printing techniques for PZT have been developed to produce thick films in excess of 100 μm. Such thicknesses are desired for applications that require actuation forces that cannot be achieved with the much thinner sol-gel films. *Beeby* et al. [7.118] describe a thick-film printing process whereby a PZT paste is made from a mixture of 95% PZT powder, 5% lead borosilicate powder and an organic carrier. The paste was then printed through a stainless steel screen using a thick-film printer. Printing was performed on an oxidized Si substrate that is capped with a Pt elec-

trode. After printing, the paste was dried and then fired at 850–950 °C. Printing could be repeated to achieve the desired thickness. The top electrode consisted of an evaporated Al film. The authors found that it was possible to perform plasma-based processing on the printed substrates, but that the porous nature of the printed PZT films made them unsuitable for wet chemical processing.

7.6.2 Aluminum Nitride

Aluminum nitride (AlN) has emerged as an alternative to PZT in MEMS and NEMS applications owing to its favorable piezoelectric, mechanical and thermal properties combined with its process compatibility with other MEMS materials, in particular silicon, but also other MEMS materials like SiC and GaN. To produce thin films of AlN suitable for MEMS and NEMS, both chemical and physical vapor deposition techniques can be used, with the two most common deposition techniques being metalorganic chemical vapor deposition (MOCVD) and magnetron sputtering. MOCVD is the preferred method to produce single-crystalline and high-quality polycrystalline films. The most commonly used precursor gases are trimethylaluminum (TMA) and ammonium (NH_3). Substrate temperatures are typically in excess of 1000 °C. Under these conditions, high-quality crystalline films can be produced on (111) Si substrates. In fact, one of the most common uses of AlN thin films is as a transition layer for epitaxial growth of GaN on Si, however the excessively high growth temperatures associated with AlN growth by MOCVD inhibit integration with prefabricated Si CMOS devices.

Fortunately for MEMS and NEMS applications, the piezoelectric properties of micro- and nanocrystalline AlN films produced by magnetron sputtering are sufficient for many sensor/actuator applications. *Tonish* et al. compared the d_{33} piezoelectric coefficient of AlN films deposited on (111) Si by both magnetron sputtering and MOCVD [7.119]. The sputtered films were produced by reactive sputtering of an Al target in a nitrogen environment with the substrate temperature ranging from 350 to 500 °C. The MOCVD films were grown using TMA and NH_3 at substrate temperatures of 1050 to 1190 °C. Films ranged in thickness between 130 and 250 nm. The sputtered films exhibited a nanocrystalline microstructure with a grain size of $\approx$ 20 nm while the MOCVD films were polycrystalline with a grain size of 100 nm. Of the two deposition methods, the sputtered films exhibited the highest d_{33} coefficient ($\approx$ 5 pm/V), which was attributed to the favorable microstructure of these films in supporting the piezoelectric effect in spite of the small grain size. The low substrate temperatures associated with the sputter deposition of AlN make it compatible for use as a piezoelectric actuator on structural components made from polysilicon [7.120]. Bulge testing of bulk micromachined diaphragms made from 600 nm-thick AlN films deposited by magnetron sputtering on a silicon substrate yielded a Young's modulus of $\approx$ 250 GPa and a residual stress of 350 MPa; values that are similar to other MEMS materials [7.121]. These diaphragms were fabricated by bulk micromachining the silicon substrate by conventional deep reactive ion etching.

Piazza et al. have exploited the favorable piezoelectric properties of sputter-deposited AlN films to develop a new class of vibrating contour-mode MEMS resonators [7.122]. These MHz-frequency rectangular and ring-shaped resonators consist of structural 2 µm-thick AlN films that are sandwiched between a bottom Pt electrode and a top Al electrode. These devices are fabricated on Si_3N_4-coated Si wafers by conventional sputter deposition, photolithographic patterning and chemical etching. Large area contacts for the bottom Pt electrode are etched through the AlN layer using a phosphoric acid etch at 160 °C, whereas the AlN resonators are fabricated simultaneous to the pattering of the top Al electrode in a self-aligned process using a Cl_2-based RIE etch. The device is released by an isotropic dry etch of the underlying Si in XeF_2. Testing in air revealed quality factors of 4300 and exceptionally low motional resistances ($< 700\,\Omega$), at the time the lowest ever reported for contour-mode MEMS devices.

Sputter-deposited AlN retains its favorable piezoelectric properties when scaled down to the NEMS regime. *Sinha* et al. demonstrated NEMS-based bimorph actuators based on nanometer-scale AlN films [7.123]. These NEMS-based cantilevers were comprised of a multimaterial stack consisting of two 100 nm-thick AlN layers sandwiched between three 50 nm Pt electrode layers. All the layers were deposited by physical vapor deposition, with the AlN layers deposited by alternating current (AC) reactive sputtering. To control the residual stresses in the film in situ, substrate heating during a portion of each AlN deposition was used. Cantilevers ranging in length from 5 to 18 µm were fabricated using an isotropic silicon etchant for release of doubly clamped bridges followed by focused ion beam etching to cut away one of the bridge anchors. The three-electrode configuration allowed for actuation voltages to be applied independently to each AlN layer, thus enabling bimorph-type actuation due to differing voltage-related displacements in the two piezoelectric AlN films. Vertical displacements as large as 40 nm at 2 V were realized from these devices.

Karabalin et al. also developed NEMS-based devices from sputter-deposited AlN films [7.124]. Their

devices were NEMS-based cantilevers and doubly clamped bridges consisting of a single 100 nm AlN film sandwiched between two 100 nm Mo thin-film electrodes. A thin (20 nm) AlN seed layer was sputter deposited onto the (100) Si wafer prior to the deposition of the bottom Mo electrode to ensure that the Mo film was of proper microstructure to produce highly *c*-axis AlN films. A multistep electron beam-based photolithography and etch process was used to pattern the thin-film stack into cantilevers that were nominally 6 μm in length, 900 nm in width and 320 nm in thickness. An anisotropic Ar/Cl_2 inductively couple plasma etch was used to pattern the AlN and Mo films, while an isotropic Ar/NF_3 reactive ion etch was used to selectively remove the underlying silicon and release the structures. The resonators demonstrated fundamental flexural modes up to 80 MHz, which were enabled by the AlN layers retaining a d_{31} coefficient of 2.4 pm/V.

7.6.3 Gallium Nitride

Gallium nitride is an attractive material for MEMS applications because it is a wide bandgap semiconductor ($E_g = 3.4$ eV) that also possesses piezoelectric properties that while not as strong as PZT and AlN are useful in MEMS. GaN is a binary semiconductor that belongs to a family of III-N ternary compound semiconductors of similar lattice constant but differing bandgaps, thus enabling the fabrication of single-crystal heterostructures that cannot be realized in SiC and diamond. These heterostructures enable the direct integration of GaN MEMS with AlGaN/GaN high electron mobility transistors (HEMTs) that can be used for sensing the mechanical motion of the MEMS structure in a manner that may be more straightforward than similar structures in Si. Although wafer-scale bulk GaN is not currently available, high-quality epitaxial films can readily be grown on sapphire, 4H-SiC, and Si wafers. As such, GaN has become an extremely popular semiconductor for high-frequency and optoelectronic devices.

Like AlN, the most popular method to produce device-quality GaN is by MOCVD with the most common precursors being trimethylgalium and ammonia and substrate temperatures in the neighborhood of 1000 °C. For MEMS applications, Si is the most convenient substrate owing to the compatibility of GaN to Si micromachining. Like SiC, GaN is chemically stable, which translates to a lack of viable wet chemical etchants for surface and bulk micromachining. *Ramesh* et al. describe the use of electrochemical etching techniques for the release of GaN devices [7.125]. In this case, a p-type GaN layer was grown on a sacrificial InGaN layer and photoelectrochemical etching of the sacrificial layer was performed in a KOH solution while illuminating the structure with UV radiation at a wavelength below the bandgap of GaN but above that of InGaN. Similarly, a bias-assisted dark electrochemical etch was developed to selectively remove p-type GaN. This etch requires a relatively large bias voltage (5 V) and is highly isotropic, therefore requiring proper design of anchor regions.

Like nearly all MEMS structural materials, GaN can be patterned by plasma etching. *Lv* et al. describe a surface micromachining process to fabricate GaN-based accelerometers [7.126]. The device actually consists of a 20 nm-thick AlGaN, 1 μm-thick GaN heterostructure that serves as both the structural element and sensing component, with the interface of the epitaxial layers serving as a two-dimensional (2-D) electron gas that is sensitive to the displacement of the structure; essentially a piezoresistive effect based on the piezoelectric polarization at this interface. The AlGaN/GaN layers are first grown onto a (111) Si substrate by MOCVD. The AlGaN and GaN layers are etched using inductively coupled plasma etching using Cl_2 gas, with the thinner AlGaN layer etched at a lower power than the thicker GaN film. A Ti/Al/Ni/Au stack was used for ohmic contacts. The device was released by first etching the underlying silicon using an anisotropic $SF_6/O_2/C_4F_8$ deep reactive ion etching process followed by an isotropic SF_6/O_2 etch. Assessment of residual stress by Raman spectroscopy in released and unreleased sections of the device showed a reduction in stress by 87% after release. Other plasma-based etches that are effective in patterning GaN include mixes of Cl_2 and BCl_3 mixed with Ar [7.127].

Like almost all of the other semiconductor materials used in MEMS, the mechanical properties of GaN thin films has been characterized using micromachined structures. *Amar* et al. used vibrating micromachined cantilevers comprised of AlN/GaN/AlGaN multilayers to experimentally determine the Young's modulus of GaN and AlN from resonant frequency data [7.128]. They found that the Young's modulus of their GaN to be ≈ 260 GPa while that for AlN was ≈ 340 GPa; values that compare favorably with measurements made by nanoindentation. *Zimmerman* et al. also characterized AlGaN and GaN cantilevers by static load-displacement and found the Young's modulus of GaN to be ≈ 250 GPa [7.129]. Testing to fracture yielded a fracture strength of 350 MPa.

7.7 Polymer Materials

7.7.1 Polyimide

Polyimides comprise an important class of durable polymers that are well suited for many of the techniques used in conventional MEMS processing. In general, polyimides can be acquired in bulk or deposited as thin films by spin coating. Polyimides can be patterned using conventional dry etching techniques and processed at relatively high temperatures. These attributes make polyimides an attractive group of polymers for MEMS that require polymer structural and/or substrate layers, such as microfabricated biomedical devices where inertness and flexibility are important parameters.

Shearwood et al. [7.130] explored the use of polyimide as a robust mechanical material for microfabricated audio membranes. The authors fabricated 7 μm-thick, 8 mm-diameter membranes on GaAs substrates by bulk micromachining the GaAs substrate using a NH_3/H_2O_2 solution. They realized 100% yield and despite a low Young's modulus (≈ 3 GPa), observed flat membranes to within 1 nm after fabrication.

Jiang et al. [7.131] capitalized on the strength and flexibility of polyimide to fabricate a flexible sheer-stress sensor array based on Si sensors. The sensor array consisted of a collection of Si islands linked by two polyimide layers. Each Si sensor island was 250 × 250 μm^2 in area and 80 μm in thickness. Al was used as an electrical interconnect layer. The two polyimide layers served as highly flexible hinges giving the sensor array the ability to be mounted on curved surfaces. The sensor array was successful in profiling the shear-stress distribution along the leading edge of a rounded delta wing.

Yousef et al. report on the development of MEMS-based thermopiles made from micromachined polyimide substrates [7.132]. The thermopiles consisted of vertically oriented Sb and Ni pillars traversing the thickness of the polyimide substrate. The pillars, known as thermolegs, are formed by electroplating in vias micromachined into the substrate. The vias were micromachined by selectively irradiating the polyimide substrate with 8.3 MeV Xe ions and etching the ion-damaged regions in a sodium hypochlorite solution.

The chemical and temperature durability of polyimides enables their use as a sacrificial layer for a number of commonly used materials, such as evaporated or sputter-deposited metals. *Memmi* et al. [7.133] developed a fabrication process for capacitive micromechanical ultrasonic transducers using polyimide as a sacrificial layer. The authors showed that the polyimide could withstand the conditions used to deposit silicon monoxide by evaporation and silicon nitride by PECVD at 400 °C. Recent work by *Bagolini* et al. [7.134] has shown that polyimides can even be used as sacrificial layers for micromachined devices made from PECVD SiC thin films.

In the area of microfabricated biomedical devices, polyimide is receiving attention as a substrate material for implantable devices, owing to its potential biocompatiblity and mechanical flexibility. *Stieglitz* [7.135] reported on the fabrication of multichannel microelectrodes on polyimide substrates. Instead of using polyimide sheets as starting substrates, Si carrier wafers coated with a 5 μm-thick polyimide film were used. Pt microelectrodes were then fabricated on these substrates using conventional techniques. Thin polyimide layers were deposited between various metal layers to serve as insulating layers. A capping polyimide layer was then deposited on the top of the substrates, and then the entire polyimide/metal structure was peeled off the Si carrier wafers. Backside processing was then performed on the free-standing polyimide structures to create devices that have exposed electrodes on both surfaces. In later papers, *Stieglitz* et al. [7.136, 137] describe variations of this process for advanced polyimide-based neural prostheses.

7.7.2 SU-8

SU-8 is a negative-tone epoxy-like photoresist that is receiving much attention for its versatility in MEMS processing. It is a high-aspect-ratio, UV-sensitive resist designed for applications requiring single-coat resists with thicknesses on the order of 500 μm [7.138]. SU-8 has favorable chemical properties, which enable it to be used as a molding material for high-aspect-ratio electroplated structures (as an alternative to LIGA), and as a structural material for microfluidics [7.138]. In terms of mechanical properties, *Lorenz* et al. [7.139] reported that SU-8 has a modulus of elasticity of 4.02 GPa, which compares favorably with a commonly used polyamide (3.4 GPa).

In addition to the above-mentioned conventional uses for SU-8, several interesting alternative uses are beginning to appear in the literature. *Conradie* et al. [7.140] have used SU-8 to trim the mass of silicon paddle oscillators as a means to adjust the resonant frequency of the beams. The trimming process involves the patterning of SU-8 posts on Si paddles. The process capitalizes on the relative chemical stability of the SU-8 resin in conjunction with the relatively large masses that can be patterned using standard UV exposure processes.

SU-8 is also of interest as a bonding layer material for wafer bonding processes using patterned bonding

layers. *Pan* et al. [7.141] compared several UV photodefinable polymeric materials and found that SU-8 exhibited the highest bonding strength (20.6 MPa) for layer thicknesses up to 100 μm.

7.7.3 Parylene

Parylene (poly-paraxylylene) is another emerging polymeric MEMS material due in large part to its biocompatibility. It is particularly attractive from the fabrication perspective because it can be deposited by CVD at room temperature. Moreover the deposition process is conformal, which enables parylene coatings to be applied to prefabricated structures, such as Si microneedles [7.142], low-stress silicon nitride membrane particle filters [7.143], and micromachined polyimide/Au optical scanners [7.144]. In the former cases, the parylene coating served to strengthen the microfabricated structures, while in the latter case it served to protect the structure from condensing water vapor.

In addition to its function as a protective coating, parylene can actually be bulk micromachined into free-standing components. *Noh* et al. [7.145] demonstrated a method to create bulk micromachined parylene microcolumns for miniature gas chromatographs. The structure is fabricated using a micromolding technique where Si molds are fabricated by DRIE and coated with parylene to form three sides of the microcolumn. A second wafer is coated with parylene and the two are bonded together via a fusion bonding process. After bonding, the structure is released from the Si mold by KOH etching. In a second example, *Suzuki* et al. describe a process to fabricate high-aspect-ratio parylene springs for use in low-frequency accelerometers [7.146]. The process involves the fabrication of deep trench etching into a Si substrate in locations where the parylene springs are desired. The trench walls are coated with SiO_2 by thermal oxidation. Parylene is then deposited onto the wafer, filling the trenches and coating the field areas. Unwanted parylene in the field is removed by O_2 plasma etching, leaving behind isolated parylene structures embedded into the Si wafer. Si DRIE is then used from the backside to free up the parylene springs and release the Si proof mass. The paper reports the fabrication and successful testing of a prototype device with a resonant frequency of only 37 Hz.

Like many vapor deposited materials, parylene structures can be fabricated by surface micromachining. *Yao* et al. [7.147] describe a dry release process for parylene surface micromachining. In this process, sputtered Si is used as a sacrificial layer onto which a thick sacrificial photoresist is deposited. Parylene is then deposited on the photoresist and patterned into the desired structural shape. The release procedure is a two-step process. First the photoresist is dissolved in acetone. This results in the parylene structure sticking to the sputtered Si. Next, a dry BrF_3 etch is performed, which dissolves the Si and releases the parylene structures. Parylene beams that were 1 mm long and 4.5 μm thick were successfully fabricated using this technique. The use of photoresist as a sacrificial layer for parylene surface micromachining has since been extended to fabricate parylene-based valves for microfluidic applications [7.148].

Parylene is a United States Pharmacopoeia Class IV material that is commonly used for biomedical device packaging. This attribute, combined with the fact that parylene can be deposited by highly conformal CVD, makes parylene an ideal candidate for micromachined neural prostheses. *Rodger* et al. have developed retinal prostheses based on parylene [7.149]. Their basic structure consists of parylene base and capping layers that sandwich a Pt multi-electrode (i. e., 256) array. The total thickness of the parylene layers is ≈ 13 μm, giving the structure a very high degree of mechanical flexibility. Access to the Pt electrodes is easily made by RIE. Due in part to the highly conformal nature of the coating process combined with the low substrate temperatures required for film growth, prepackaged application specific integrated circuits (ASICS) can be incorporated into the electrode structure. Devices are fabricated on Si handle wafers using photoresist as a sacrificial release layer.

Ziegler et al. describe a method to fabricate neural probes with built-in microfluidic channels for drug delivery [7.150]. The device is fabricated from two parylene layers, a base layer that supports the metal electrodes and a capping layer that forms the top of the fluidic channel and covers the electrode traces. The base layer is fabricated on a Cr/Al-coated Si wafer while the capping layer is formed on a detergent-coated glass substrate. The key processing step is the bonding step, which joins the base and capping layers forming a leak-free seal. This processing step is performed in a standard convection oven at 160 °C over 30 min with an applied pressure of only 4.9 MPa. After bonding the glass wafer is simply removed due to the weak glass-to-parylene bond as a result of the detergent coating. The Si wafer is then removed by anodic aluminum etching in a NaCl solution. Undoubtedly, the bonding process is greatly enhanced by the fact that parylene can be vapor deposited in extremely smooth Si wafers.

7.7.4 Liquid Crystal Polymer

Liquid crystal polymer (LCP) is a high-performance thermoplastic currently being used in printed circuit board and electronics packaging applications, and has

been investigated for use in MEMS applications requiring a material that is mechanically flexible, electrically insulating, chemically durable and impermeable to moisture. LCP can be bonded to itself and other substrate materials such as glass and Si by thermal lamination. It can be micromachined using an oxygen plasma and yet it is highly resistant to HF and many metal etchants [7.151]. The moisture absorption is less than 0.02% as compared with about 1% for polyimide [7.152], making it well suited as a packaging material.

Applications where LCPs have been used as a key component in a MEMS device are beginning to emerge. *Faheem* et al. [7.153] reported on the use of LCP for encapsulation of variable RF MEMS capacitors. In this example, LCP, dispensed in liquid form, was used to join and seal a glass microcap to a prefabricated, microbridge capacitor. LCP was chosen in part because in addition to the aforementioned properties, it has very low RF loss characteristics, making it very well suited as an RF MEMS packaging material. *Wang* et al. [7.151] showed that LCP is a very versatile material that is highly compatible with many standard Si-based processing techniques, and that these techniques can be used to make LCP cantilever flow sensors that incorporate metal strain gages and LCP membrane tactile sensors using NiCr strain gages. *Lee* et al. [7.152] have developed a mechanically flexible, multichannel microelectrode array structure for neural stimulation and recording using LCP as a base substrate and *Palasagaram* et al. have developed a capacitive pressure sensor from LCP [7.154]. The capacitive pressure sensor was fabricated by thermally laminating three layers of LCP. The bottom layer consisted of 30 mil-thick LCP coated 0.5 μm-thick Cu that was patterned into an electrode. The middle layer consisted of an unmetalized, 2 mil-thick LCP layer that was patterned with a through hole that forms the pressure sensor cavity. The pressure sensor membrane was formed from a 2 mil-thick LCP layer that supports a 0.5 μm-thick Cu electrode. The sensor membrane was roughly 1.6 mm in diameter. This sensor exhibited a relative capacitance change of 0.277 pF over an applied pressure range of 0–100 kPa.

7.8 Future Trends

The rapid expansion of MEMS in recent years is due in large part to the inclusion of new materials that have expanded the functionality of microfabricated devices beyond what is achievable in silicon. This trend will certainly continue as new application areas for micro- and nanofabricated devices are identified. Many of these applications will likely require both new materials and new processes to fabricate the micro- and nanomachined devices for these yet-to-be-identified applications. Currently, conventional micromachining techniques employ a *top-down* approach that begins with either bulk substrates or thin films. Future MEMS and NEMS will likely incorporate materials that are created using a *bottom-up* approach. A significant challenge facing device design and fabrication engineers alike will be how to marry top-down and bottom-up approaches to create devices and systems that cannot be made using either process alone.

Acknowledgments. Prof. Zorman thanks Prof. Mehran Mehregany of Case Western Reserve University for his numerous contributions to this manuscript.

8. Carbon Nanotubes

Marc Monthioux, Philippe Serp, Brigitte Caussat, Emmanuel Flahaut, Manitra Razafinimanana, Flavien Valensi, Christophe Laurent, Alain Peigney, David Mesguich, Alicia Weibel, Wolfgang Bacsa, Jean-Marc Broto

Carbon nanotubes (CNTs) are remarkable objects that once looked set to revolutionize the technological landscape in the near future. Since the 1990s and for twenty years thereafter, it was repeatedly claimed that tomorrow's society would be shaped by nanotube applications, just as silicon-based technologies dominate society today. Space elevators tethered by the strongest of cables, hydrogen-powered vehicles, artificial muscles: these were just a few of the technological marvels that we were told would be made possible by the science of carbon nanotubes.

Of course, this prediction is still some way from becoming reality; most often the possibilities and potential have been evaluated, but actual technological development is facing the unforgiving rule that drives the transfer of a new material or a new device to market: profitability. New materials, even more so for nanomaterials, no matter how wonderful they are, have to be cheap to produce, constant in quality, easy to handle, and nontoxic. Those are the conditions for an industry to accept a change in its production lines to make them nanocompatible. Consider the example of fullerenes – molecules closely related to nanotubes. The anticipation that surrounded these molecules, first reported in 1985, resulted in the bestowment of a Nobel Prize for their discovery in 1996. However, two decades later, very few fullerene applications have reached the market, suggesting that similarly enthusiastic predictions about nanotubes should be approached with caution, and so should it be with graphene, another member of the carbon nanoform family which joined the game in 2004, again acknowledged by a Nobel Prize in 2010.

There is no denying, however, that the expectations surrounding carbon nanotubes are still high, because of specificities that make them special compared to fullerenes and graphene: their easiness of production, their dual molecule/nano-object nature, their unique aspect ratio, their robustness, the ability of their electronic structure to be given a gap, and their wide typology etc. Therefore, carbon nanotubes may provide the building blocks for further technological progress, enhancing our standard of living.

In this chapter, we first describe the structures, syntheses, growth mechanisms, and properties of carbon nanotubes. Then we introduce nanotube-based materials, which comprise on the one hand those formed by reactions and associations of all-carbon nanotubes with foreign atoms, molecules and compounds, and on the other hand, composites, obtained by incorporating carbon nanotubes in various matrices. Finally, we will provide a list of applications currently on the market, while skipping the potentially endless and speculative list of possible applications.

8.1 **Structure of Carbon Nanotubes** 194
8.1.1 Single-Wall Nanotubes 194

Carbon nanotubes (CNTs) have long been synthesized as products of the action of a catalyst on the gaseous species originating from the thermal decomposition of hydrocarbons (Sect. 8.2) [8.1]. The first evidence that the nanofilaments produced in this way were actually nanotubes – that they exhibited an inner cavity – can be found in the transmission electron microscope micrographs published by *Radushkevich* and *Lukyanovich* in 1952 [8.2]. Since then, the interest in carbon nanofilaments/nanotubes was recurrent, though within a scientific area almost limited to the carbon material scientist community [8.3]. Worldwide enthusiasm began unexpectedly in 1991, after the catalyst-free formation of nearly perfect concentric multiwall carbon nanotubes (c-MWNTs, Sect. 8.1) was reported [8.4] as by-products of the formation of fullerenes via the electric-arc technique (Sect. 8.3). But the real breakthrough occurred two years later, when attempts to fill the nanotubes in situ with various metals (Sect. 8.5) led to the discovery – again unexpected – of single-wall carbon nanotubes (SWNTs) (Sect. 8.1) simultaneously by *Iijima* and *Ichihashi* [8.5] and *Bethune* et al. [8.6]. SWNTs were really new nano-objects with properties and behaviors that are often quite specific (Sect. 8.4). They are also beautiful objects for fundamental physics as well as unique molecules for experimental chemistry. Potential applications seem countless for such CNTs or CNTs combined with a matrix (Sect. 8.6), and some have reached the market (Sect. 8.7) yet toxicity and environmental issues should not be ignored (Sect. 8.8). Consequently, it still remains an extraordinarily active – and highly competitive – field of research, as that of fullerenes was and that of graphene now is, which, by the way, are again carbon nano-objects structurally closely related to nanotubes.

8.1 Structure of Carbon Nanotubes

It is relatively easy to imagine a single-wall carbon nanotube (SWNT). Ideally, it is enough to consider a perfect graphene sheet (graphene is a polyaromatic monoatomic layer consisting of sp^2-hybridized carbon atoms arranged in hexagons; genuine graphite consists of layers of this graphene) and to roll it into a cylinder (Fig. 8.1), making sure that the hexagonal rings placed in contact join coherently.

Then the tips of the tube are sealed by two caps, each cap being a hemifullerene with the appropriate diameter (Fig. 8.2a–c).

8.1.1 Single-Wall Nanotubes

Calculations have shown that collapsing the single-wall tube into a flattened two-layer ribbon is energetically more favorable than maintaining the tubular morphology beyond a diameter value of ≈ 2.5 nm [8.8]. Conversely, the shorter the radius of curvature, the higher the stress and the energetic cost, although SWNTs with diameters as low as 0.4 nm have been synthesized successfully [8.9]. A suitable energetic compromise is therefore reached for ≈ 1.35 nm, the most frequent di-

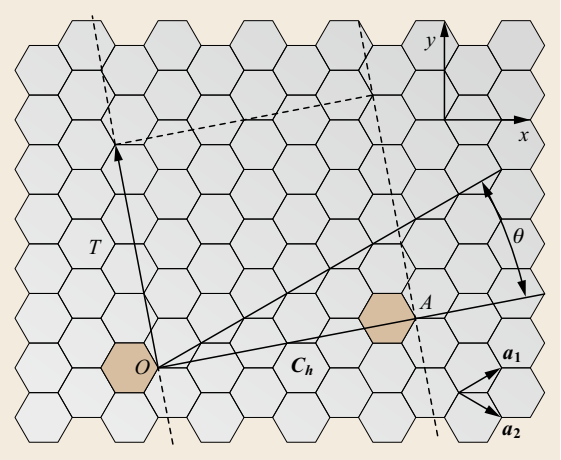

Fig. 8.1 Making an SWNT, starting from a graphene sheet (after [8.7])

ameter encountered when the growth is free from the influence of the catalytic particle size (as for the synthesis technique based on solid carbon sources) and when conditions ensuring high SWNT yields are used. Nanotube length only depends on the specific synthesis conditions (thermal gradients, residence time, and so on). Experimental data are consistent with these statements, since SWNTs wider than 2.5 nm are only rarely reported in the literature, whatever the preparation method, while the length of the SWNTs can be in the micrometer or the millimeter range. These features make SWNTs a unique example of single molecules with huge aspect ratios.

Two important consequences derive from the SWNT structure as described above:

1. All carbon atoms are involved in hexagonal aromatic rings only and are therefore in equivalent positions, except at each nanotube tip, where $6 \times 5 = 30$ atoms are involved in pentagonal rings (considering that adjacent pentagons are unlikely) as a consequence of Euler's rule that also governs the fullerene structure. For ideal SWNTs, chemical reactivity will therefore be highly favored at the tube tips, at the locations of the pentagonal rings.
2. Although carbon atoms are involved in aromatic rings, the C=C bond angles are not planar. This means that the hybridization of carbon atoms is not pure sp^2; it has some degree of sp^3 character, in a proportion that increases as the tube radius of curvature decreases. The effect is the same as for the C_{60} fullerene molecules, whose radius of curvature is 0.35 nm, and whose bonds therefore have 10% sp^3 character [8.11]. This has consequences for SWNT reactivity and electronic behavior (Sect. 8.4).

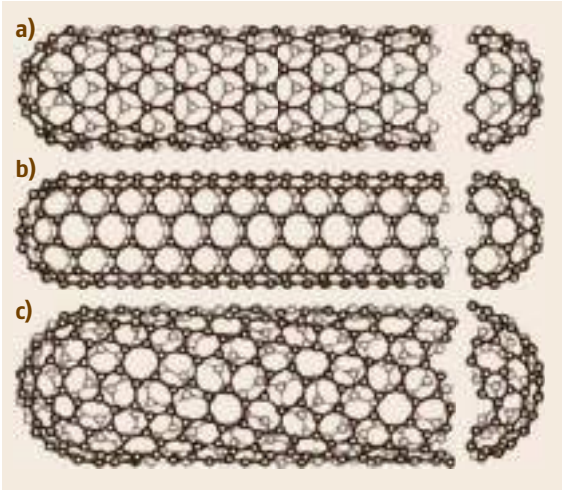

Fig. 8.2a–c Sketches of three different SWNT structures that are examples of **(a)** a zigzag-type nanotube, **(b)** an armchair-type nanotube, **(c)** a helical nanotube (after [8.10])

As illustrated by Fig. 8.2, there are many ways to roll a graphene into a single-walled nanotube, with some of the resulting nanotubes possessing planes of symmetry both parallel and perpendicular to the nanotube axis (such as the SWNTs from Fig. 8.2a,b), while others do not (such as the SWNT from Fig. 8.2c). Similar to the terms used for molecules, the latter are commonly called *chiral* nanotubes, since one cannot superimpose them on their own image in a mirror. *Helical* should however be preferred (see below). The various ways to roll graphene into tubes are therefore mathematically defined by the vector of helicity $\boldsymbol{C}_\mathrm{h}$, and the angle of helicity θ, as follows (referring to Fig. 8.1)

$$\boldsymbol{OA} = \boldsymbol{C}_\mathrm{h} = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$$

with

$$\boldsymbol{a}_1 = \frac{a\sqrt{3}}{2}\boldsymbol{x} + \frac{a}{2}\boldsymbol{y} \quad \text{and} \quad \boldsymbol{a}_2 = \frac{a\sqrt{3}}{2}\boldsymbol{x} + \frac{a}{2} - \boldsymbol{y}\,,$$

where $a = 2.46$ Å, and

$$\cos\theta = \frac{2n+m}{2\sqrt{n^2+m^2+mn}}\,,$$

where n and m are the integers of the vector $\boldsymbol{OA}$ considering the unit vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$.

The vector of helicity $\boldsymbol{C}_\mathrm{h}$ $(= \boldsymbol{OA})$ is perpendicular to the tube axis, while the angle of helicity θ is taken with respect to the so-called zigzag axis: the vector of helicity that results in nanotubes of the *zigzag* type (see below). The diameter D of the corresponding nanotube

is related to $\boldsymbol{C}_\mathrm{h}$ by the relation

$$D = \frac{|\boldsymbol{C}_\mathrm{h}|}{\pi} = \frac{a_{\mathrm{CC}}\sqrt{3(n^2+m^2+nm)}}{\pi} ,$$

where

$$\underset{\text{(graphite)}}{1.41\,\text{Å}} \leq a_{\mathrm{C=C}} \leq \underset{(\mathrm{C_{60}})}{1.44\,\text{Å}} .$$

The C−C bond length is actually elongated by the curvature imposed by the structure; the average bond length in the C_{60} fullerene molecule is a reasonable upper limit, while the bond length in flat graphene in genuine graphite is the lower limit (corresponding to an infinite radius of curvature). Since $\boldsymbol{C}_\mathrm{h}$, θ, and D are all expressed as a function of the integers n and m, they are sufficient to define any particular SWNT by denoting them (n, m). The values of n and m for a given SWNT can be simply obtained by counting the number of hexagons that separate the extremities of the $\boldsymbol{C}_\mathrm{h}$ vector following the unit vector $\boldsymbol{a}_1$ first and then $\boldsymbol{a}_2$ [8.7]. In the example of Fig. 8.1, the SWNT that is obtained by rolling the graphene so that the two shaded aromatic cycles can be superimposed exactly is a (4,2) chiral nanotube. Similarly, SWNTs from Fig. 8.2a–c are (9,0), (5,5), and (10,5) nanotubes respectively, thereby providing examples of zigzag-type SWNT (with an angle of helicity = 0°), armchair-type SWNT (with an angle of helicity of 30°), and a chiral SWNT, respectively. This also illustrates why the term *chiral* is sometimes inappropriate and should preferably be replaced with *helical*. Armchair (n, n) nanotubes, although definitely achiral from the standpoint of symmetry, exhibit a nonzero *chiral angle*. *Zigzag* and *armchair* qualifications for achiral nanotubes refer to the way that the carbon atoms are displayed at the edge of the nanotube cross section (Fig. 8.2a,b). Generally speaking, it is clear from Figs. 8.1 and 8.2a that having the vector of helicity perpendicular to any of the three overall C=C bond directions will provide zigzag-type SWNTs, denoted $(n, 0)$, while having the vector of helicity parallel to one of the three C=C bond directions will provide armchair-type SWNTs, denoted (n, n). Conversely, because of the sixfold symmetry of the graphene sheet, the angle of helicity θ for the chiral (n, m) nanotubes is such that $0 < \theta < 30°$. Figure 8.3 provides two examples of what chiral SWNTs look like, as seen via atomic force microscopy.

The graphenes in graphite have π electrons which are accommodated by the stacking of graphenes, allowing van der Waals forces to develop. Similar reasons make fullerenes gather and order into fullerite crystals and SWNTs into SWNT ropes (Fig. 8.4a). Provided the SWNT diameter distribution is narrow, the SWNTs in ropes tend to spontaneously arrange into hexagonal arrays, which correspond to the highest compactness achievable (Fig. 8.4b). This feature brings new periodicities with respect to graphite or turbostratic polyaromatic carbon crystals. Turbostratic structure corresponds to graphenes that are stacked with random rotations or translations instead of being piled up following sequential *ABAB* positions, as in graphite structure. This implies that no lattice atom plane exists other than the graphene planes themselves (corresponding to the (001) atom plane family). These new periodicities give specific diffraction patterns that are quite

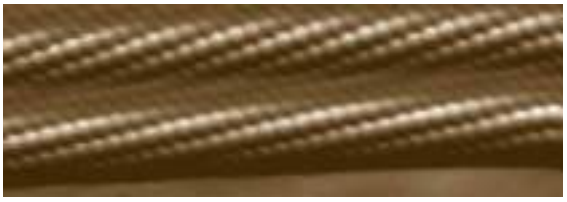

Fig. 8.3 Image of two neighboring chiral SWNTs within an SWNT bundle as seen using high-resolution scanning tunneling microscopy (courtesy of Prof. Yazdani, University of Illinois at Urbana, USA)

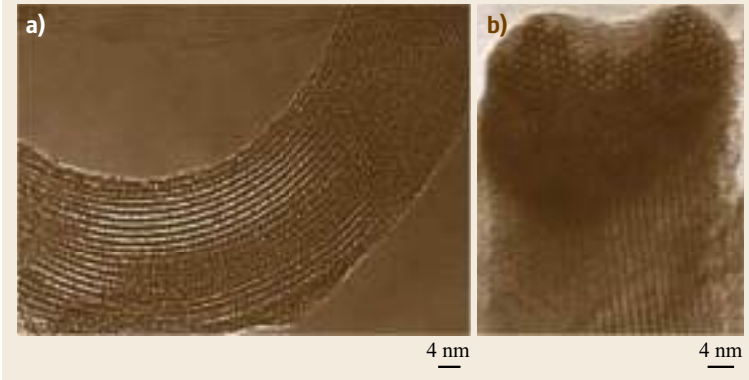

Fig. 8.4a,b High-resolution transmission microscopy (TEM) images of an SWNT rope. **(a)** Longitudinal view. An isolated single SWNT also appears at the top of the image. **(b)** Cross-sectional view (after [8.12])

different to those of other sp^2-carbon-based crystals, although *hk* reflections, which account for the hexagonal symmetry of the graphene plane, are still present. Conversely, 00*l* reflections, which account for the stacking sequence of graphenes in regular, *multilayered* polyaromatic crystals (which do not exist in SWNT ropes) are absent. This hexagonal packing of SWNTs within the ropes requires that SWNTs exhibit similar diameters, which is the usual case for SWNTs prepared by electric arc or laser vaporization processes. SWNTs prepared using these methods are actually about 1.35 nm wide (diameter of a (10,10) tube, among others), for reasons related to the energetic compromise mentioned earlier that the latter synthesis techniques allow to occur during the specific growth mechanisms taking place (Sect. 8.3).

8.1.2 Multiwall Nanotubes

Building MWNTs (multiwall carbon nanotubes) is a little bit more complex, since it involves the various ways graphenes can be displayed and mutually arranged within filamentary morphology. A similar versatility can be expected to the usual textural versatility of polyaromatic solids. Likewise, their diffraction patterns are barely differentiable from those of anisotropic polyaromatic solids. The easiest MWNT to imagine is the concentric type (c-MWNT), in which SWNTs with regularly increasing diameters are coaxially arranged (according to a Russian-doll model) into a multiwall nanotube (Fig. 8.5). Such nanotubes are generally formed either by the electric-arc technique (without the need for a catalyst), by catalyst-enhanced thermal cracking of gaseous hydrocarbons, or by CO disproportionation (Sect. 8.2). There can be any number of walls (or coaxial tubes), from two upwards. The intertube distance is approximately the same as the intergraphene distance in turbostratic, polyaromatic solids, 0.34 nm (as opposed to 0.335 nm in genuine graphite), since the increasing radius of curvature imposed on the concentric graphenes prevents the carbon atoms from being arranged according to the Bernal sequence as in graphite. However, two cases allow a nanotube to reach – totally or partially – the 3-D crystal periodicity of graphite. One is to consider a high number of concentric graphenes, where the more external concentric graphenes may have a long radius of curvature. In this case, the shift in the relative positions of carbon atoms from superimposed graphenes is so small with respect to that in graphite that some commensurability is possible over distances long enough to make Bernal stacking possible over a large enough area. This may result in MWNTs where both structures are associated; in other words they have turbostratic cores

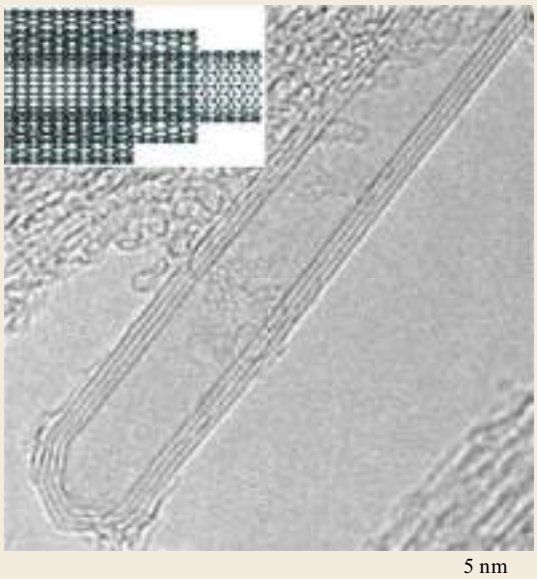

Fig. 8.5 High-resolution TEM image (longitudinal view) of a concentric MWNT (c-MWNT prepared using an electric arc). The *insert* shows a model of the related Russian doll-like arrangement of graphenes (image by M. Monthioux, CNRS. Model by I. Suarez-Martinez, Curtin University)

and graphitic outer parts [8.13]. The other case occurs for c-MWNTs exhibiting faceted morphologies, usually originating from subsequent heat treatment at high temperature (e.g., 2000 °C) in an inert atmosphere. Facets allow the graphenes to resume a flat arrangement of atoms (except at the junction between neighboring facets) which allows the specific stacking sequence of graphite to develop.

Another frequent inner texture for MWNTs is the so-called herringbone texture (h-MWNTs), in which the graphenes make an angle with respect to the nanotube axis (Fig. 8.6). The value of this angle varies with the processing conditions (such as catalyst morphology or composition of the atmosphere), from 0 (in which case the texture becomes that of a c-MWNT) to 90° (in which case the filament is no longer a tube, see below), and the inner diameter varies so that the tubular arrangement can be lost [8.15], meaning that the latter are more accurately called nanofibers rather than nanotubes. h-MWNTs are exclusively obtained by processes involving catalysts, generally catalyst-enhanced thermal cracking of hydrocarbons or CO disproportionation. One long-debated question was whether the herringbone texture, which actually describes the texture projection rather than the overall three-dimensional texture, originates from the scroll-like spiral arrange-

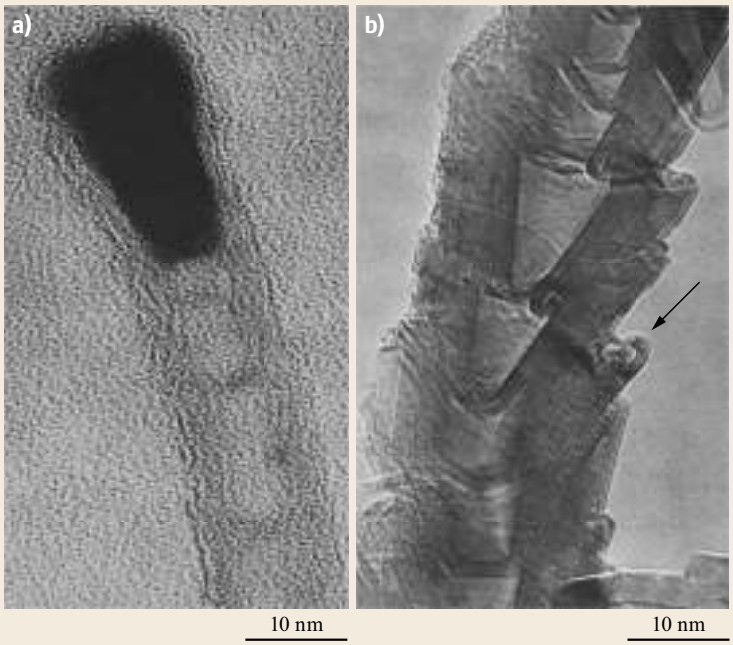

Fig. 8.6a,b Some of the earliest high-resolution TEM images of a herringbone (and bamboo) multiwall nanotube (bh-MWNT, longitudinal view) prepared by CO disproportionation on an Fe-Co catalyst. **(a)** As-grown. The nanotube surface is made of free graphene edges. **(b)** After 2900 °C heat treatment. Both the herringbone and the bamboo textures have become obvious. Graphene edges from the surface have buckled with their neighbors (*arrow*), closing off access to the intergraphene space (after [8.14])

ment of a single graphene ribbon or from the stacking of independent truncated cone-like graphenes in what is also called a *cup-stack* texture. It has now been demonstrated that both exist [8.16, 17].

Another common feature is the occurrence, to some degree, of a limited amount of graphenes oriented perpendicular to the nanotube axis, thus forming a *bamboo* texture. This is not a texture that can exist on its own; it affects either the c-MWNT (bc-MWNT) or the h-MWNT (bh-MWNT) textures (Figs. 8.6 and 8.7). The question is whether such filaments, although hollow, should still be called nanotubes, since the inner cavity is no longer open all the way along the filament as it is for a genuine tube. These are therefore sometimes also referred to as *nanofibers* in the literature.

One nanofilament that definitely cannot be called a nanotube is built from graphenes oriented perpendicular to the filament axis and stacked as piled-up plates. Such filaments are referred to as *platelet nanofibers* in the literature [8.15].

Unlike SWNTs, whose aspect ratios are so high that it is almost impossible to find the tube tips, the aspect ratios for MWNTs (and carbon nanofibers) are generally lower and often allow one to image tube ends by TEM. Aside from c-MWNTs derived from an electric arc (Fig. 8.5), which grow in a catalyst-free process, nanotube tips are frequently found to be associated with the catalyst crystals from which they were formed.

The properties of the MWNT (Sect. 8.4) will obviously largely depend on the perfection and the orientation of the graphenes in the tube (for example, the helicity angles of the nanotubes constituting c-MWNTs has little importance). Graphene orientation is a matter of texture, whereas graphene perfection is a matter of nanotexture, which both are commonly used to describe graphene-based materials [8.20], and depend on the processing conditions. While texture is a permanent fea-

Fig. 8.7a,b TEM images from bamboo multiwall nanotubes (longitudinal views). **(a)** Low magnification of a bamboo-herringbone multiwall nanotube (bh-MWNT) showing the nearly periodic nature of the texture, which occurs very frequently (after [8.18]); **(b)** high-resolution image of a bamboo-concentric multiwall nanotube (bc-MWNT) (after [8.19])

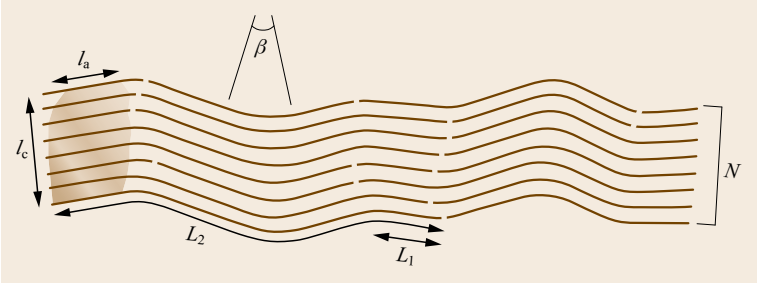

Fig. 8.8 Sketch explaining the various parameters obtained from high-resolution (lattice fringe mode) TEM, used to quantify nanotexture: L_1 is the average length of perfect (distortion-free) graphenes of coherent areas; N is the number of piled-up graphenes in coherent (distortion-free) areas; L_2 is the average length of continuous though distorted graphenes within graphene stacks; β is the average distortion angle. L_1 and N are related to the l_a and l_c values obtained from X-ray diffraction

ture (unless subjected to severe degradation), nanotexture can be quantified (Fig. 8.8), as it can be improved by subsequent thermal treatments at high temperatures (such as $> 2000\,^{\circ}\mathrm{C}$) and potentially degraded by chemical treatments (such as slightly oxidizing conditions).

To summarize, because work in the field started more than a century ago, the names of filamentous carbons have changed with time from vapor-grown carbon fibers, to nanofilaments, nanofibers, and eventually nanotubes. For all filamentous carbons, the generic name should be vapor-grown carbon nanofilaments (VGCNF). Whether or not the filaments are tubular is then a matter of inner morphology description [8.20], which can be further refined by considering textural features such as bamboo, herringbone, and concentric (see above). In the following, we will therefore use MWNTs for any hollowed nanofilament, whether they contain graphene walls oriented transversally or not. Any other nanofilament (i. e., not hollowed) will be termed a *nanofiber*.

8.2 Synthesis of Carbon Nanotubes

8.2.1 Solid Carbon Source–Based Synthesis Techniques: The DC Electric Arc

Principle

One route to produce CNTs is to vaporize a solid carbon source (usually graphite), which requires processes able to generate high temperatures ($T > 5000\,\mathrm{K}$). Various techniques have been employed for this (e.g., laser ablation, DC electric arc, solar furnace). We will focus here on the DC electric-arc technique, as the other methods have been almost abandoned for being less robust and versatile. Some information on the other techniques will be provided in Sect. 8.2.3. Further information can be found in the previous edition of this chapter [8.21].

The DC electric-arc process is based on carbon vaporization in an inert gas atmosphere at reduced pressure. The morphologies of the carbon nanostructures and the SWNT yields can differ notably with respect to the experimental conditions. It was (and still is) the first method of producing fullerenes in relatively large quantities [8.22–24]. In the course of investigating other carbon nanostructures formed along with the fullerenes, and more particularly the solid carbon deposit that formed on the cathode, *Iijima* [8.4] discovered the catalyst-free formation of perfect c-MWNT-type CNTs. Then, as mentioned above, the catalyst-promoted formation of SWNTs was accidentally discovered after amounts of transition metal were introduced into the anode in an attempt to fill the c-MWNTs with metals during growth [8.5, 6]. Since then, a lot of work has been carried out by many groups using this technique in order to understand the mechanisms of nanotube growth in the synthesis of MWNTs and/or SWNTs [8.25–36].

The different mechanisms (such as carbon molecule dissociation and atom-recombination processes) involved in this high-temperature technique take place at different time scales, from nanoseconds to microseconds and even milliseconds. The formation of nanotubes and other graphene-based products occurs afterward with a relatively long delay.

The electric-arc method is based on the energy transfer resulting from the interaction between the electrode and the plasma. This interaction causes anode erosion, leading to the formation of a plasma, i. e., an electrically neutral ionized gas, composed of neutral atoms, charged particles (molecules and ionized

species), and electrons. The ionization rate of this plasma, defined by the ratio $(n^e/(n^e + n^o))$, where n^e and n^o are the electron and the neutral atom densities respectively, highlights the importance of energy transfer between the plasma and the material. The characteristics of this plasma and notably the ranges in temperature and concentrations of the various species present in the plasma thereby depend not only on the nature and composition of the anode but also on the energy transferred.

One of the advantages of this synthesis technique is the ability to vary a large variety of parameters which modify the composition of the high-temperature medium and consequently allow the most relevant plasma characteristics to be determined so that optimal conditions for the control of CNT formation can be obtained. However, a major drawback of this technique – and of any other technique used to produce SWNTs – is that the SWNTs formed are not pure: they are associated with other carbon phases and remnants of the catalyst. Although purification processes exist, they are all based on oxidation processes (e.g., HNO_3, or heat treatments in air) that are likely to significantly affect the SWNT structure [8.12]. Subsequent thermal treatments at $\approx 1200\,^{\circ}C$ under inert atmosphere, however, succeed in somewhat recovering structural quality [8.37].

Experimental Device

Several elements such as iron, nickel, cobalt, yttrium, boron, gadolinium, or cerium can be used as catalysts, however highest yields were obtained using a bimetallic catalyst, including a transition metal (typically Ni) and a rare earth (typically yttrium); the inert gas atmosphere can be composed of argon or (preferably) helium. Some work was also performed with liquid media, such as liquid nitrogen [8.38] or water [8.39, 40], but this adaptation has remained prospective. The arc burns between the catalyst-doped graphite anode and a graphite (or copper, for instance) cathode: the plasma formed consists of the mixture of carbon vapor, inert gas, and catalyst vapors. The vaporization is the consequence of energy transfer from the arc to the anode. The importance of the anode erosion rate depends on the power of the arc and also on other experimental conditions. It is worth noting that a high anode erosion rate does not necessarily lead to a high CNT production.

An example of a reactor layout is shown in Fig. 8.9. It consists of a cylinder about 30 cm in diameter and about 1 m in height with two valves, one for performing the primary evacuation (0.1 Pa) of the chamber, the other for filling it with a rare gas up to the desired working pressure. Arc observation is possible through diametrically opposed sapphire windows facing the plasma zone. Carbon nanoforms are found in different regions of the reactor:

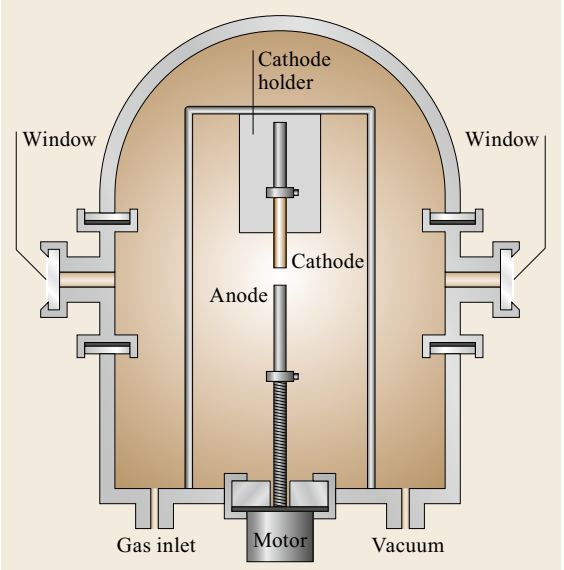

Fig. 8.9 Sketch of an electric-arc reactor

1. The collaret, which forms around the cathode
2. The weblike deposits found above the cathode
3. The soot deposited all around the reactor walls and the bottom
4. A hard deposit adherent to the cathode, whether catalysts are used or not.

SWNTs are found in the collaret and the web, yet their formation is not systematic and depends on the experimental conditions (for instance they do not form with a pressure of 40 kPa) while the cathode deposit and soot are obtained systematically. The catalyst-free growth of MWNTs occurs in the cathode deposit.

The electrode diameter is a few millimeters but varies from one author to another. In some cases, the cathode has a larger diameter than the anode in order to facilitate their alignment [8.28]. Other authors utilize electrodes of the same diameter [8.37]. The whole device can be designed horizontally [8.29, 36] or vertically [8.31–33]. The advantage of the latter is the symmetry with respect to gravity, which facilitates computer modeling (regarding convection flows, for instance).

Two types of anode can be used, a graphite rod with a coaxial hole (several centimeters in length) filled with a mixture of powdered catalyst(s), graphite, and possibly other dopants as needed, or an anode within which the catalyst(s) are homogeneously dispersed [8.41]. The former is by far the most popular, due to their ease of fabrication.

The role of synthesis parameters is studied for process optimization, in terms of nanotube yield and quality. They include the type of doped anode, the nature and concentration of the catalyst(s), the pressure and nature of the plasmagen gas, the arc current intensity, or the distance between electrodes. Experiment duration, however, is preferably short (in the range of a few minutes) in order for the synthesis not to be significantly affected by the increasing pressure rise resulting from anode vaporization. The plasma characteristics (species concentrations and temperature) constitute the link between input parameters and obtained products. Their study as a function of operating parameters is important for better understanding of the phenomena involved during nanotube formation. However, few works are dedicated to this; they are based on atomic and molecular optical emission spectroscopy [8.31–34, 36].

Results

The numerous results available in the literature regarding the synthesis of CNTs by the DC arc process show that both the morphology and yield strongly depend on the experimental conditions. It is also worth noting that the products obtained do not consist solely of CNTs. In addition to catalyst remnants found in various concentrations in all deposit areas, nontubular forms of carbon can be obtained [8.30, 32, 33]. They include nanoparticles (NPs), fullerene-like structures including C_{60}, poorly organized polyaromatic carbons, nearly amorphous nanofibers, multiwall shells, single-wall nanocapsules, and amorphous carbon. The nature, proportion, and distribution of the catalysts in the anode are particularly important. Optimized conditions for high SWNT yields (with lengths in the micrometer range and diameters typically around 1.4 nm, mostly found in the collaret (50–70%) and the web ($\approx$ 50% or less)) may correspond to a helium pressure of about 60 kPa, an arc current of 80 A, an electrode gap of 1 mm, the use of a heterogeneous anode and Ni/Y as coupled catalysts [8.5, 29, 42], and graphite powder grain size in the 1 μm range [8.43, 44]. Deviations from those conditions can have significant consequences: using Ni/Co instead of Ni/Y as catalysts may prevent the formation of SWNTs; Ni/Co catalysts in a homogeneous instead of heterogeneous anode mostly generate double-wall nanotubes (DWNTs), while decreasing the ambient pressure from 60 to 40 kPa also suppresses nanotube formation. It is worth noting that, unlike SWNTs, MWNTs are formed as a cathode deposit almost systematically, i. e., it is less sensitive to parameter variations. However, although using a rare earth as a single catalyst does not allow one to grow SWNTs, it may affect MWNT growth by promoting the closure of graphene edges, the preferred formation of telescope-like morphology, and the occurrence of nested crystals (Gd, in the paper cited) [8.31, 33]. Generally speaking, the optimized result achieved using bimetallic catalysts such as Ni+Y regarding SWNT yield was proposed once to be due to the transitory formation of an yttrium carbide coating over the nickel particles whose lattice constants were somewhat commensurable with that of graphene, thereby resulting in SWNT growth [8.45]. However, another explanation, more plasma-related, could be that the presence of yttrium increases the anode erosion rate and leads to higher plasma temperatures, which both are plasma features favorable to SWNT growth.

Surprisingly, loading heterogeneous anodes with diamond instead of graphite (with similar 1 μm range grain size) does not affect the plasma characteristics (both graphite and diamond lead to the same plasma composition once carbon is vaporized at high temperature, > 4000 K), nor the type and yield of the products formed [8.34, 35], while changing graphite grain size from 1 to 100 μm does ([8.43, 44] and Fig. 8.10a). This shows that thermal conductivity prevails over electrical conductivity as a leading parameter, and is driven by the porosity amount left when compacting the filler materials into the anode cavity. Indeed, lower grain size led to better compaction and powder homogeneity, hence to a steadier erosion of the anode, a feeding of the plasma with more constant carbon and catalyst proportions which goes along with smoother radial temperature profiles (see the previous version of this chapter in [8.21]). The consequence on the product is a lower variability in the carbon phases formed, finally resulting in an enhanced purity and yield of the SWNT phase.

Finally, the chamber volume was also shown to be an important parameter for SWNT growth [8.46]. The volume must be limited to keep convection cooling efficient and sustain a high thermal radial gradient which is favorable to SWNT growth. However, the volume has to remain sufficient to ensure recirculation of catalyst particles responsible for growing SWNTs. Therefore, Fig. 8.10 shows that lower chamber volume and smaller grain size both generate hotter plasma and higher C_2 concentration, a set of conditions found to correspond to optimized SWNT growth.

The analysis of the plasma from the anode to the cathode along the discharge axis shows a huge vertical gradient (≈ 500 K mm) close to it (probably due to convection) along with a dramatic increase of the C_2 concentration [8.21]. The latter demonstrates that C_2 moieties are secondary products resulting from the recombination of primary species formed from the anode. It also suggests that C_2 moieties may also be the building blocks for MWNTs (formed at the cathode) [8.33, 35]. A plausible reason is that the zone of

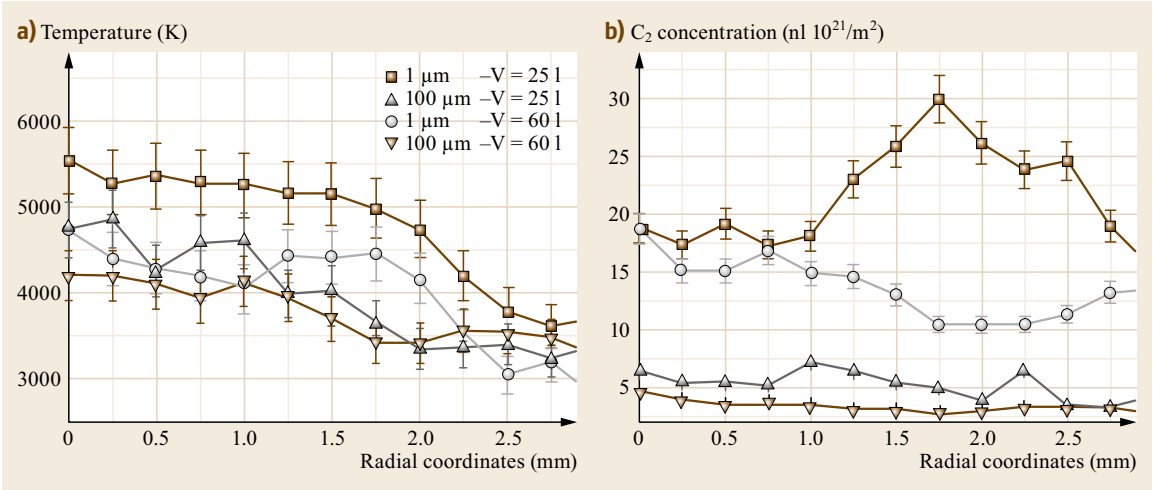

Fig. 8.10a,b Emission spectroscopy data obtained from experiments involving heterogeneous-type anodes, with two different graphite grain sizes (1 and 100 µm) and two different chamber volumes (25 and 60 l). **(a)** Radial temperature profiles; **(b)** C_2 radial concentration ratio. Smaller grain size results in better anode compaction, hence in higher anode thermal conductivity, and lower chamber volume enables more efficient convection cooling (after [8.46])

actual SWNT formation corresponds to colder areas, outside the plasma. Figure 8.11 shows an example of the evolution with time of the gas temperature in such an area.

Overall, the importance of the physical phenomena (charge and heat transfers) that occur in the anode during the arc clearly makes the characterization of the plasma indispensable, an aspect which is still neglected in many works.

Although many aspects still need to be understood, the electric-arc method is one of three methods currently used to produce SWNTs as commercial products, although it is progressively being abandoned due to the difficulty to reduce production costs down to that of chemical vapor deposition (CVD)-based processes, because of the subsequent extensive purification needed and the drawback of being a discontinuous process. For instance, Nano-lab (MA, USA) was proposing until recently (2016) 40–90%-purified SWNTs at prices ranging from 225 to 2500 US $/g.

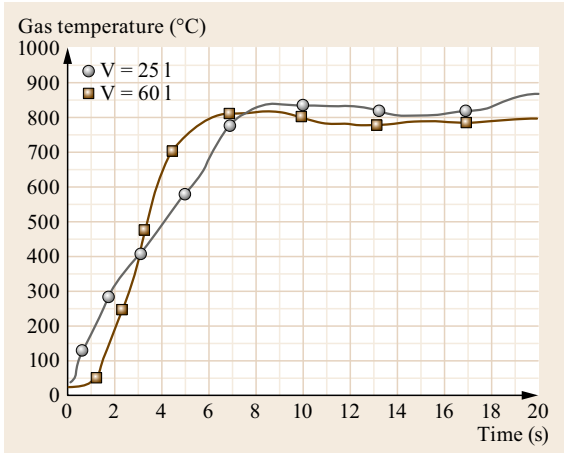

Fig. 8.11 Evolution with time of the gas temperature at the limit of the growth zone (1 cm away from the electrode axis and 1 cm above the arc center) for a graphite grain size of 1 µm and two chamber volumes. A smaller volume induces a lower temperature ramp thanks to an enhanced convection cooling, which seems to be favorable to SWNT formation

8.2.2 Gaseous Carbon Source–Based Synthesis Techniques

As mentioned in [8.1], the catalyst-enhanced thermal cracking of a gaseous carbon source (hydrocarbons, CO) – commonly referred to as catalytic chemical vapor deposition (CCVD) – has been known to produce carbon nanofilaments for over a century. However, in early works, carbon nanofilaments were mainly produced to act as a core substrate for the subsequent growth of larger (micrometric) carbon fibers – so-called vapor-grown carbon fibers – via thickening in catalyst-free CVD processes [8.47, 48].

Instead, later attempts in the 1990s focused on the synthesis of genuine CNTs (either single- or multi-walled) by CCVD. This method involves the catalytic decomposition of a carbon-containing source on small metallic particles or clusters, either through a heterogeneous (if a solid substrate is involved) or homogeneous

process (if everything takes place in the gas phase). The metals generally used for these reactions are transition metals, such as Fe, Co, and Ni. CNTs prepared by this method are generally much longer (a few tens to hundreds of micrometers) than those obtained by arc discharge (a few micrometers). It is also possible to grow dense arrays of nanotubes. CCVD processes appear very sensitive to the nature and the structure of the catalyst used, as well as to the operating conditions [8.49]. This is a rather low-temperature process typically between 600–1000 °C, which enables high selectivity for the production of MWNTs preferably to graphitic particles and amorphous-like carbon, compared to the solid carbon source-based methods such as arc discharge. In turn, this lower reaction temperature does not allow any structural rearrangements therefore leading to more structural defects (lower nanotexture) for MWNTs produced by CCVD compared to arc discharge. These defects can be removed by subsequent heat treatments in vacuum or inert atmosphere. Whether such a discrepancy is also true for SWNTs remains questionable as CCVD SWNTs are generally gathered into bundles of smaller diameter (a few tens of nm) than their arc discharge and laser ablation counterparts (around 100 nm in diameter). CCVD, specifically when performed in a fluidized bed reactor [8.50] (see next section), provides reasonably good prospects for use in large-scale and low-cost processes for the mass production of CNTs, a key point for their application at the industrial scale.

Heterogeneous Processes

Heterogeneous CCVD processes simply involve passing a gaseous flow containing a given proportion of a hydrocarbon (mainly CH_4, C_2H_2, C_2H_4, or C_6H_6, usually as a mixture with either H_2 or an inert gas such as Ar) over small transition metal particles (Fe, Co, Ni) in a furnace. The particles are deposited onto an inert substrate, by spraying a suspension of the metal particles on it or by another method. The reaction

$$C_xH_y \rightarrow xC + \frac{y}{2}H_2$$

is chemically defined as catalyst-enhanced thermal cracking and has been used since the late nineteenth century. Extensive publications on this topic include those by *Baker* et al. [8.3, 51], or *Endo* et al. [8.52, 53] as well as several review papers published after 1990, such as [8.54]. However, CO can be used instead of hydrocarbons; the reaction is then chemically defined as catalyst-enhanced disproportionation (the so-called Boudouard equilibrium)

$$2CO \rightleftharpoons C + CO_2 \,.$$

The ability of catalyst-enhanced CO disproportionation to make carbon nanofilaments was reported by *Davis* et al. [8.55] as early as 1953, probably for the first time. Extensive follow-up work was performed by *Boehm* [8.56], *Audier* et al. [8.14, 57, 58], and *Gadelle* et al. [8.59, 60].

Experimental Devices. Although formation mechanisms for SWNTs and MWNTs can be quite different (Sect. 8.3, or refer to a review article such as [8.61]), many of the catalytic process parameters play similar roles in the type of nanotubes formed: the temperature, the duration of the treatment, the gas composition and flow rate, and of course the catalyst nature and size. At a given temperature, depending mainly on the nature of the catalyst and the carbon-containing gas, catalytic decomposition will take place at the surface of the metal particles, followed by mass transport of the freshly produced carbon by surface or volume diffusion until carbon concentration exceeds the solubility limit causing precipitation to start.

CCVD CNTs form on very small metal particles, typically in the nanometer range [8.61]. These catalytic metal particles are prepared mainly by reducing transition metal compounds (salts, oxides) by H_2 prior to the nanotube formation step (where the carbon-containing gas is required). It is possible to produce these catalytic metal particles in situ in the presence of the carbon source, allowing for a one-step process [8.62]. As controlling the metal particle size is the key issue, coalescence is generally avoided by using low concentrations of catalytic metal precursors or by placing metal particles on an inert support such as an oxide (Al_2O_3, SiO_2, zeolites, $MgAl_2O_4$, MgO) or more rarely on graphite. The easiest hence most frequent route is to use the supported catalysts as a static phase placed within the gas flow. This is what most laboratories do, and also companies such as Nanocyl, the only CNT manufacturer in Belgium, which sells MWNTs (research grade NC3100, 95% C, $\approx$ 10 nm average diameter) at 5 €/g for 500 g order (2016 data). The CCVD process can also be coupled to a fluidization contactor by using catalytic porous powders to maximize the catalyst specific surface area.

In the fluidized bed (FB) reactor, gas-solid fluidization consists in flowing a gas upwards through a vertical bed of powders which form a suspension in the gas (Fig. 8.12). Gaseous bubbles appear and rise through the powders, generating intense gas–solid mixing and then high thermal and mass transfer rates between the gas, the powders, and the heated reactor walls [8.63]. As a consequence, a fluidized bed is fully isothermal. When coupled to CCVD, it maximizes the conversion rate of the gaseous carbon precursor, the catalyst

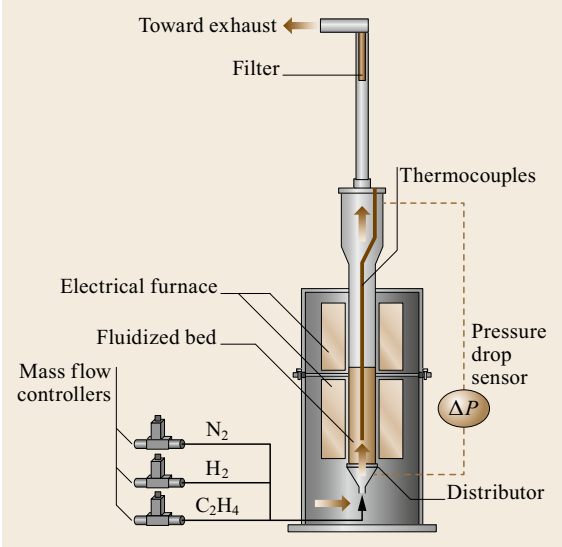

Fig. 8.12 Sketch of a typical lab-scale fluidized bed CCVD reactor as in use in the LGC-CNRS laboratory in collaboration with the LCC-CNRS laboratory, Toulouse (France). The *distributor* is a perforated plate supporting the powders when at rest

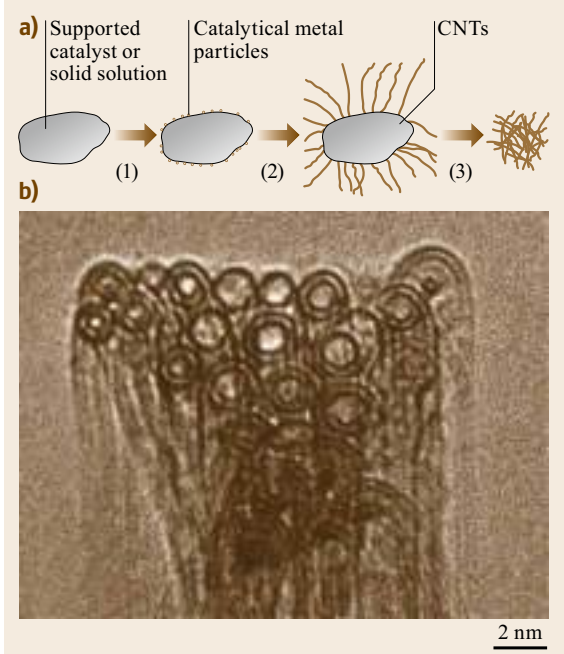

Fig. 8.13 **(a)** Formation of nanotubes via the CCVD-based impregnation technique. (1) Formation of catalytic metal particles by reduction of a precursor; (2) catalytic decomposition of a carbon-containing gas, leading to the growth of CNTs; (3) removal of the catalyst to recover the nanotubes (after [8.65]). **(b)** Example of a bundle of double-wall nanotubes (DWNTs) prepared this way (after [8.66])

selectivity, and the product uniformity. As the FB-CCVD process allows kilograms to tons of MWNTs to be produced from the lab scale to the industrial scale [8.64], it was selected by ARKEMA, the only CNT manufacturer in France, which is able to sell MWNTs (Graphistrength C100 grade) at $\approx 50\,€/\mathrm{kg}$ (2016 data).

There are two main ways to prepare the catalyst:

1. Impregnation of a substrate with a salt solution of the desired metal catalyst
2. Preparation of a solid solution of an oxide of the chosen catalytic metal in a chemically inert and thermally stable host oxide.

The catalyst is then reduced to form the metal particles on which the catalytic decomposition of the carbon source will lead to CNT growth. In most cases, the nanotubes can then be separated from the catalyst (Fig. 8.13).

Results with CCVD Involving Impregnated Catalysts. The impregnation-based process generally involves four successive steps:

1. Support impregnation by a salt solution (nitrate, chloride) of the metal catalyst
2. Drying and calcination of the supported catalyst to form the oxide of the catalytic metal
3. Reduction in a H_2-containing atmosphere to form the catalytic metal particles
4. Decomposition of a carbon-containing gas over the freshly prepared metal particles leading to nanotube growth.

For example, *Ivanov* et al. [8.67] prepared nanotubes through the decomposition of C_2H_2 (pure or mixed with H_2) on well-dispersed transition metal particles (Fe, Co, Ni, Cu) supported on graphite or SiO_2. Co-SiO_2 was found to be the best catalyst/support combination for the preparation of MWNTs, but most of the other combinations led to carbon filaments, sometimes covered with amorphous-like carbon. In order to improve the dispersion of metals, the same group developed a precipitation-ion-exchange method on silica then proposed the use of a zeolite-supported Co catalyst [8.68, 69], resulting in very finely dispersed metal particles (from 1 to 50 nm diameter). In the latter work, they reported the preparation of MWNTs with a diameter around 4 nm and only two or three walls. More recently, ethanol solutions containing a $NiCl_2$ salt were used to impregnate a carbon fiber paper. After drying

and reduction under H_2 at 1023 K, randomly orientated MWNTs with a diameter of ≈ 20 nm were grown on the paper from a C_2H_4/H_2 mixture, thus forming 3-D conductive layers for electrochemical capacitor applications [8.70].

Results with CCVD Involving Solid Solution–Based Catalysts. A solid solution of two metal oxides is formed when ions of one metal mix with ions of the other metal. For example, Fe_2O_3 can be prepared in solid solution in Al_2O_3 to give a $Al_{2-2x}Fe_{2x}O_3$ solid solution. The use of a solid solution allows homogeneous dispersion of one oxide in the other to be obtained. These solid solutions can be prepared in different ways; coprecipitation of mixed oxalates and combustion synthesis are the most common methods used to prepare nanotubes. Nanotube synthesis by catalytic decomposition of CH_4 over a $Al_{2-2x}Fe_{2x}O_3$ solid solution was first developed by *Peigney* et al. [8.62] and then studied extensively by the same group using different oxides such as spinel-based solid solutions ($Mg_{1-x}M_xAl_2O_4$ with M = Fe, Co, Ni, or a binary alloy [8.65, 71]) or magnesia-based solid solutions [8.65, 72] ($Mg_{1-x}M_xO$, with M = Fe, Co, or Ni). The homogeneous dispersion of the catalytic oxide makes it possible to produce very small catalytic metal particles at the high temperature required for CH_4 decomposition (chosen for its greater thermal stability compared to other hydrocarbons). This method involves heating the solid solution from room temperature to a temperature between 850–1050 °C in a mixture of H_2 and CH_4, typically containing 18 mol% of CH_4. The nanotubes obtained are typically gathered into small-diameter bundles (less than 15 nm) with lengths up to 100 µm. The nanotubes are mainly SWNTs and DWNTs, with diameters between 1–3 nm. Their properties depend upon the nature of the metal (or alloy) and the inert oxide (matrix); the latter because the Lewis acidity seems to play an important role [8.73]. For example, in the case of solid solutions containing around 10 wt% of Fe, the amount of CNTs obtained decreases in the following order depending on the matrix oxide: $MgO < Al_2O_3 < MgAl_2O_4$ [8.65].

Obtaining pure nanotubes by CCVD requires removing the catalyst (as for all other techniques). In the case of catalysts supported (impregnated) in a solid solution, the supporting – and catalytically inactive – oxide is the main impurity, both in weight and volume. Removing oxides such as Al_2O_3 or SiO_2 requires aggressive treatments (hot caustic solutions of KOH and NaOH for Al_2O_3, or an acidic solution of HF for SiO_2). However, such treatments have no effect on other impurities such as other carbon forms (amorphous-like carbon, graphitized carbon particles and shells, and so on). Oxidizing treatments (air oxidation, use of strong oxidants such as HNO_3, $KMnO_4$, H_2O_2) are thus required but inevitably result in low final yield of CNTs, which are often quite damaged. *Flahaut* et al. were the first to use MgO-based solid solutions (for example $Mg_xCo_yO_z$) to prepare SWNTs and DWNTs that could be easily separated without incurring any damage via fast and safe washing with an aqueous HCl solution [8.72].

In most cases, only very small quantities of catalyst (typically less than 500 mg) are used, and most claims for high-yield productions of nanotubes are based on laboratory experimental data, without taking into account all of the technical problems related to scaling up to a laboratory-scale CCVD reactor. At the present time, although the production of MWNTs is possible on an industrial scale, the production of affordable SWNTs is still a challenge, and controlling the arrangement of and the number of walls in the nanotubes is also problematic. For example, adding small amounts of molybdenum to the catalyst [8.74] can lead to drastic modifications of the nanotube type (from regular nanotubes to carbon nanofibers – Sect. 8.1). *Flahaut* et al. have recently shown that the method used to prepare a particular catalyst can play a very important role [8.75]. Double-walled CNTs (DWNTs) represent a special case: they are at the frontier between single- (SWNTs) and multiwalled nanotubes (MWNTs). Because they are the MWNTs with the lowest possible number of walls, their structures and properties are very similar to those of SWNTs. Any subsequent functionalization, which is often required to improve the compatibility of nanotubes with their external environment (composites) or to give them new properties (solubility, sensors), will partially damage the external wall, resulting in drastic modifications in terms of both electrical and mechanical properties. This is a serious drawback for SWNTs. In the case of DWNTs, the outer wall can be modified (functionalized) while retaining the structure of the inner tube. CCVD allows synthesis of DWNTs on a gram-scale [8.66] with high purity and high selectivity (around 80% DWNTs) (Fig. 8.13b).

Homogeneous Processes

The homogenous route, also called the *floating catalyst method*, differs from the other CCVD-based methods because it only uses gaseous species as catalyst and carbon precursors. The basic principle of this technique, whose mechanisms are similar to the other CCVD processes, is to produce in situ the catalyst particles from a gaseous precursor and then to decompose a gaseous carbon source in order to obtain CNTs.

Experimental Devices. The typical reactor used in this technique is a quartz tube placed in a furnace into

which the gaseous feedstock, containing the metal precursor, the carbon source, sometimes hydrogen, and a vector gas (N_2, Ar, or He), is passed. The first zone of the reactor is kept at a lower temperature to produce the catalyst particles, and the second zone is heated to 700–1200 °C to form the CNTs. The metal precursor is generally a metal-organic compound, such as a zero-valent carbonyl compound like [$Fe(CO)_5$] [8.76], or a metallocene [8.77–79] such as ferrocene, nickelocene, or cobaltocene. In recent works, ferrocene is diluted in ethanol [8.80] or in benzene [8.81] and the liquid solution is vaporized just before or at the entrance of the reactor to form a gaseous mixture containing both the metal and the carbon precursors. The use of metal salts, such as cobalt nitrate, has also been reported [8.82].

Results. This technique is quite flexible and SWNTs [8.80, 81], DWNTs [8.83], and MWNTs [8.84] have been obtained, in proportions depending on the carbon feedstock gas. The technique has also been exploited for some time in the production of vapor-grown carbon nanofibers [8.85].

The main drawback of this process concerns the difficulty to control the size of the metal nanoparticles, hence the CNT formation is often accompanied by the production of undesired carbon forms (amorphous carbon or polyaromatic carbon phases found as various phases or as coatings). In particular, encapsulated forms have been found as the result of the formation of metal particles that are too large to promote nanotube growth. The same operating parameters as for heterogeneous CCVD processes must be controlled in order to selectively obtain the desired CNTs morphology and structure, including the choice of the carbon source, the reaction temperature [8.86], the composition of the incoming gaseous feedstock [8.77], the presence and proportion of hydrogen, which can influence the orientation of the graphene with respect to the nanotube axis, thus switching from c-MWNT to h-MWNT [8.60].

The overall process can be improved by adding other compounds such as ammonia or sulfur-containing species to the reactive gas phase. The former allows aligned nanotubes and mixed C–N nanotubes [8.87] to be obtained, while the latter results in a significant increase in productivity [8.85, 88]. An interesting result is the increase in yield and purity brought about by a small input of oxygen, as achieved by using alcohol vapors instead of hydrocarbons as feedstock [8.89]. It is assumed that the oxygen (i) preferably burns the poorly organized carbon out into CO_2, thereby enhancing the purity; (ii) prevents the catalyst particles from being encapsulated in carbon shells too early (making them inactive), thereby enhancing the nanotube yield. Moreover, it was found to promote the formation of SWNTs over MWNTs, because suppressing the carbon shell formation limits the formation of MWNTs too.

It should be emphasized that only small amounts of CNTs have been produced so far, and scaling-up to industrial levels seems quite difficult. One reason is that the in situ produced catalyst particles stick to the reactor wall so that CNT growth from these particles may lead to clogging of the reactor [8.80]. Another bottleneck is to be able to increase the quantity of gaseous precursors fed in the reactor in order to increase production, without obtaining catalyst particles that are too big. This problem has not yet been solved.

A significant breakthrough concerning this technique could be the HiPco process developed at Rice University, which produces SWNTs of high purity [8.90, 91]. The current production yields approach 450 mg/h and nanotubes typically have no more than 7 mol% of iron impurities. In the HiPco process, nanotubes grow in high-pressure, high-temperature flowing CO on catalytic clusters of iron. Catalyst is formed in situ by thermal decomposition of $Fe(CO)_5$, which is delivered within a cold CO flow and then rapidly mixed with hot CO in the reaction zone [8.91]. Upon heating, the $Fe(CO)_5$ decomposes into atoms that condense into large clusters. SWNTs nucleate and grow on these particles via CO disproportionation (the Boudouard reaction, see Sect. 8.2.2, *Heterogeneous Processes*).

The company Continental Carbon Nanotechnologies Inc. (Houston, USA) currently sells raw SWNT materials prepared by this process, at a market price of 575 $/g, or 800 $/g if purified (2016 data). Other companies that specialize in MWNTs include Applied Sciences Inc. (Cedarville, USA), which currently has a production facility of ≈ 40 t/yr of ≈ 100 nm large MWNTs (Pyrograf-III), and Hyperion Catalysis (Cambridge, USA), which produces MWNT-based materials. Though prepared in a similar way by CCVD-related processes, MWNTs remain far less expensive than SWNTs, yet over a large price range depending on the manufacturer, the CNT type (herringbone, concentric etc.) and quality, and the amount to be ordered. Hence, prices can be as low as ≈ 0.5 $/g (2016 average ASI fare for Pyrograf-III grade), although this can be cut by a factor of 10 for very large quantities.

Templating

The templating technique is the only other method aside from the electric-arc technique that is able to synthesize CNTs without a catalyst. Another useful aspect of this approach is that it allows aligned nanotubes to be obtained naturally, provided the substrate is not removed.

The principle of this technique is to deposit the solid carbon coating obtained from the CVD method onto the walls of a porous substrate whose pores are arranged in

parallel channels. The substrate can be alumina or zeolite for instance, which present natural channel pores, while the whole system is heated to a temperature that cracks the hydrocarbon molecules selected as the carbon source [8.92].

Provided the chemical vapor deposition mechanism is well controlled, the synthesis results in the channel pore walls being coated with a variable number of graphenes. Either MWNTs (exclusively concentric type) or SWNTs can be obtained. The smallest SWNTs (diameters ≈ 0.4 nm) ever obtained were actually synthesized using this technique [8.9]. The nanotube lengths are directly determined by the channel lengths, in other words by the thickness of the substrate plate. One main advantage of the technique is the purity of the tubes (no catalyst remnants and few other carbon phases), and their well-calibrated, single-value diameters. Conversely, the nanotube structure is open at one end or both, which can be an advantage or a drawback depending on the application, and make them more sensitive to chemical attacks. The porous matrix can be kept or dissolved in order to recover the tubes, as needed. The method is not suitable for mass production.

8.2.3 Miscellaneous Techniques

In addition to the major techniques described in Sect. 8.2.1 and Sect. 8.2.2, other ways to produce nanotubes can be found in the literature. They can offer alternatives such as a low-cost or a catalyst-free production. However, none has been convincing enough or economically preferable so far with respect to the major processes described previously. Some examples are provided in the following, the three first sharing similarities (high temperature and solid carbon source) with the dc arc process.

For the laser ablation process a graphite pellet containing catalysts is vaporized using a focused laser beam [8.93]. The carbon species, swept along by a flow of neutral gas, are then deposited as soot in different regions: on a conical water-cooled copper collector, on the containment quartz tube walls, and on the backside of the pellet. Improvements of this method include the use of a second pulsed laser to get better pellet irradiation [8.94] or the use of two pellets (one made of graphite and one made of catalysts) simultaneously irradiated [8.95]. Laser-based methods can lead to high-quality SWNTs but are generally not considered to be competitive in the long term for the low-cost production of SWNTs.

Three-phase AC arc plasma has been used for the processing of carbon nanomaterials [8.96]. An electric arc is established between three graphite electrodes, the three-phase AC power supply being operated at 600 Hz and with arc currents of 250–400 A. Carbon precursors, gaseous, liquid or solid, are injected at the desired (variable) position into the plasma zone. It has been demonstrated that this plasma technology can be used to produce a wide range of carbon nanostructures ranging from carbon blacks to CNTs over fullerenes with a high product selectivity.

In solar furnace devices, solar rays are focused onto a graphite pellet containing catalysts in a neutral gas chamber. They have been used by several groups to first produce fullerenes but the original devices were then modified to achieve CNT production [8.97, 98]. It was demonstrated that solar energy-based synthesis is a versatile method for obtaining SWNTs that could be scaled up from 0.1–0.2 to 10 g/h and then to 100 g/h productivity using existing solar furnaces. A numerical reactor simulation was performed in order to improve the quality of the product, which was subsequently observed to reach 40% SWNT in the soot [8.99].

MWNTs (including coiled MWNTs, a peculiar morphology resembling a spring) have been successfully prepared by a catalyst-free (although Li was present) electrolytic method, by running a 3–5 A current between a graphite crucible (as anode) and a graphite rod (as cathode) [8.100]. The graphite crucible was filled with lithium chloride, while the whole system was heated in air or argon at $\approx 600\,^{\circ}$C. As with many other techniques, by-products such as encapsulated metal particles, carbon shells, amorphous carbon, and so on, are formed.

A pure chemistry route has also been proposed, using the polyesterification of citric acid onto ethylene glycol at 50 °C, followed by polymerization at 135 °C and then carbonization at 300 °C under argon, followed by oxidation at 400 °C in air [8.101]. Despite the latter oxidation step, the solid product contains short MWNTs, although they obviously have poor nanotextures. By-products such as carbon shells and amorphous carbon are also formed.

Short MWNTs have been obtained through a catalyst-free (although Si is present) pyrolytic method which involves heating silicon carbonitride nanograins in a BN crucible to 1200–1900 °C in nitrogen within a graphite furnace [8.102]. No details are given about the possible occurrence of by-products, but they are likely considering the complexity of the chemical system (Si-C-B-N) and the high temperatures involved.

The catalyzed reaction between a solid carbon source and atomic hydrogen has been investigated [8.103]. Graphite nanoparticles (≈ 20 nm) are sent with a stream of H_2 onto a Ta filament heated at 2200 °C. The species produced, whatever they are, then

hit a Si polished plate warmed to 900 °C that supports transition metal particles. The whole chamber is kept in a dynamic vacuum of 40 Torr. SWNTs are supposed to form according to the authors. One major drawback of the method, besides its complexity compared to the others, is that it is difficult to recover the nanotubes from the Si substrates to which they seem to be firmly bonded.

Diffusion flame synthesis was also attempted [8.104]. A regular gaseous hydrocarbon source (ethylene, and others) along with ferrocene vapor is passed into a laminar diffusion flame derived from air and CH_4 of temperature 500–1200 °C. SWNTs are formed, together with encapsulated metal particles, soot, and so on. In addition to a low yield, the SWNT structure is quite poor.

Finally, a recent and original technology should be mentioned, called the Graphetron 1.0 process, which is based on the decomposition of CO_2 into SWNTs by a high-temperature electrochemical reaction, likely assisted by an iron catalyst. The Russian company OCSiAl is claiming to be the world's largest facility with a 10 t/yr SWNT production complex, with prices as low as a few $/g for an SWNT-grade product (TUBALL) containing 75% SWNT, 15% catalyst, and 10% of other carbon forms, including carbon shells encapsulating the catalyst (2016 data).

8.2.4 Synthesis with Controlled Orientation

Several applications (such as field emission-based displays, see Sect. 8.7) require that CNTs grow as highly aligned individuals or bunches, in highly ordered arrays, or that they are located at specific positions. In this case, the purpose of the process is not mass production but controlled growth and purity, with subsequent control of nanotube morphology, texture, and structure. Generally speaking, the more promising methods for the synthesis of aligned nanotubes are based on CCVD processes (see Sect. 8.2.2). Although this approach initially produced mainly MWNTs, DWNT [8.105] and SWNT [8.106] arrays can be selectively obtained. Generally speaking, SWNTs and DWNTs nucleate at higher temperatures than MWNTs [8.107].

During CCVD growth, CNTs can self-assemble into nanotube bunches aligned perpendicularly to the substrate if the catalyst film on the substrate has a critical thickness [8.108, 109]. The driving forces for this alignment are the van der Waals interactions between the nanotubes, which allow them to grow perpendicularly to the substrates. When the catalyst nanoparticles are deposited onto a mesoporous substrate (such as mesoporous silica [8.110, 111] or anodic alumina [8.112]), the mesoscopic pores control the growth direction of the nanotubes (of course, removing the substrate may result in loosing the alignment).

Here is a list of the most common deposition methods:

1. Metal salt impregnation followed by oxidation/reduction steps for thin film deposition on alumina substrates [8.113].
2. Embedding catalyst particles in mesoporous silica by sol–gel processes [8.110].
3. Thermal evaporation of Fe, Co, Ni, or Co-Ni metal alloys on SiO_2 or quartz substrates under high vacuum [8.114, 115].
4. Photolithographic patterning of metal-containing photoresist polymer using conventional black and white films as a mask [8.116] or photolithography and inductive plasma deep etching [8.117].
5. Electrochemical deposition into pores in anodic aluminum oxide templates [8.112].
6. Spin-coating colloidal suspensions of catalyst particles with tailored diameters on a support [8.118–121].
7. Stamping a catalyst precursor over a patterned Si wafer has been used to grow networks of nanotubes parallel to the substrate (Fig. 8.14b), or more generally to localize the growth of individual CNTs [8.122]. Combining e-beam lithography and template methods has also been reported for large-scale production of ordered MWNTs [8.123] or atomic force microscope/microscopy (AFM) tips [8.124].

Depositing the catalyst nanoparticles onto a prepatterned substrate allows control of the frequency of local occurrence and the arrangement of the nanotube bunches formed. The materials produced mainly consist of arrayed, densely packed, freestanding, aligned MWNTs (Fig. 8.14a), which are suitable for field emission-based applications for instance [8.125]. SWNTs have also been produced, and it was reported that the introduction of water vapor during the CVD process allows impurity-free SWNTs to be synthesized [8.126], due to a mechanism related to that previously proposed for the effect of using alcohol instead of hydrocarbon feedstock [8.89].

The pyrolysis of hydrocarbons in the presence of organometallic precursor molecules such as metallocene or iron pentacarbonyl, operating in a dual furnace system (Fig. 8.15a,b) leads to densely packed vertically aligned MWNTs (Fig. 8.15c). The precursor is first sublimed at low temperature in the first furnace or injected as a solution along with the hydrocarbon feedstock, and then the whole system is pyrolyzed at higher temperature in the second furnace [8.83, 129, 130]. Important synthesis parameters include the heat-

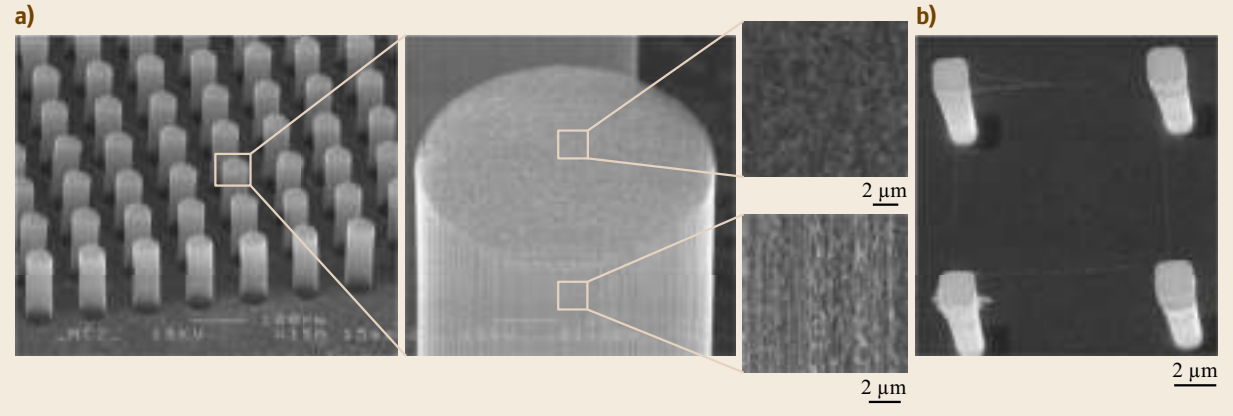

Fig. 8.14a,b Examples of directional growth of CNTs obtained from the pyrolysis of a gaseous carbon source over catalyst nanoparticles previously deposited onto a patterned substrate: **(a)** a controlled pattern of nanotube pillars grown perpendicular to the substrate: each pillar is made of thousands of DWNTs aligned vertically (after [8.127]); **(b)** suspended SWNTs grown parallel to the substrate interconnecting silicon pillars (after [8.128])

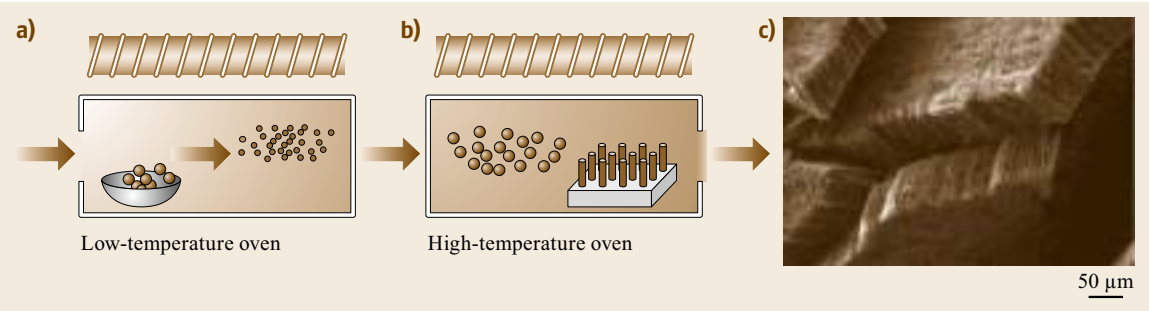

Fig. 8.15a–c Sketch of a double-furnace CCVD device used in the organometallic/hydrocarbon copyrolysis process. **(a)** Sublimation of the precursor. **(b)** Decomposition of the precursor and MWNT growth onto the substrate. **(c)** Example of the densely packed and aligned MWNT material obtained (after [8.129])

ing and feeding rate of the precursors, vector gas (Ar or N_2) and gaseous hydrocarbon flow rates, and the pyrolysis temperature (650–1050 °C). Using [$Fe(CO)_5$] as the catalyst source results in thermal decomposition at elevated temperatures, producing atomic iron that deposits on the substrates in the hot zone of the reactor. CNT growth occurs immediately after the introduction of [$Fe(CO)_5$] so the growth temperature depends mainly on the carbon feedstock used (from 750 °C for acetylene to 1100 °C for methane).

The nanotube yield and quality are directly linked to the amount and size of the catalyst particles, and since the planar substrates used do not exhibit high surface areas,the catalyst dispersion is a critical step in the process. NH_3-etching of the catalyst thin film provides the appropriate metal particle size distribution and may also favor the MWNT alignment and prevent the formation of amorphous carbon [8.131]. The use of phthalocyanines of Co, Fe, and Ni has also been reported, and in this case the organometallic precursors pyrolysis is also the carbon source for the vertically aligned MWNT growth [8.132].

Densely packed coatings of vertically aligned MWNTs may also be produced over metal-containing deposits, such as iron oxides on aluminum [8.133]. Well-aligned MWNT arrays can be produced on a large scale on ceramic spheres using the floating catalyst technique [8.134]. Finally, the Langmuir–Blodgett method can be used to produce densely packed monolayers of aligned noncovalently functionalized SWNTs from an organic solvent [8.135]. This method seems valid for bulk materials with various diameters and offers the advantage that the SWNT monolayers are readily patterned for device integration by microfabrication.

8.3 Growth Mechanisms of Carbon Nanotubes

The growth mechanisms of CNTs have been highly debated for the main reason that the conditions that allow carbon nanofilaments to grow are very diverse, which means that there are many related growth mechanisms. Another reason is that the phenomena that occur during growth are pretty rapid and difficult to observe in situ. It is generally agreed, however, that growth occurs such that the number of dangling bonds is minimized, for energetic reasons. Much related information can be found in review papers such as [8.136–138].

8.3.1 Catalyst-Free Growth

In addition to the templating technique, which is merely a chemical vapor infiltration mechanism for pyrolytic carbon, the growth of c-MWNT as a deposit on the cathode in the electric-arc method is a rare example of catalyst-free carbon nanofilament growth. The driving force is related to charge transfer from one electrode to the other via the particles contained in the plasma. It is not clear how the MWNT nucleus is formed, but once it has, it may include the direct incorporation of C_2 species into the primary graphene structure, as was previously proposed for fullerenes [8.139].

8.3.2 Catalytically Activated Growth

Although growth mechanisms involving catalysts include a more or less extensive contribution from a VLS [8.140] mechanism, it is quite difficult to find comprehensive and plausible explanations that are able to account for both the various conditions used and the various morphologies observed. What follows is an attempt to provide overall plausible explanations of most of the phenomena, while remaining consistent with the experimental data. From various results, it appears that the most important parameters are probably the thermodynamic ones (only temperature will be considered here), the catalyst particle size, and the presence of a substrate.

Low-Temperature Conditions

In CCVD, nanotubes are frequently found to grow far below 1000 °C, yet 800–1200 °C is the most common temperature range for growing well-structured nanotubes with the usual catalysts.

If the conditions are such that the catalyst is a crystallized solid, the nanofilament is probably formed via a mechanism similar to a VLS mechanism, in which three steps are defined:

1. Adsorption then decomposition of C-containing gaseous moieties at the catalyst surface
2. Dissolution then diffusion of the C species through the catalyst, thus forming a solid solution
3. Back-precipitation of solid carbon as nanotube walls. The texture is then determined by the orientation of the crystal faces relative to the filament axis [8.15, 16].

This mechanism can therefore provide either c-MWNT, h-MWNT, or platelet nanofibers. The latter, however, are mainly formed when catalyst particles are crystallized and large enough to exhibit fully developed crystal faces with extensions in the range of at least 40–50 nm onto which graphenes form and then pile up. Indeed, platelet nanofibers with low diameters (< 40 nm) have never been observed. The reasons for this are related to graphene energetics, such as the need to reach the optimal ratio between the amount of edge carbon atoms (with dangling bonds) and inner carbon atoms (where all of the σ and π orbitals are shared).

If conditions are such that the catalyst is a liquid droplet, due to the use of temperatures beyond the catalyst melting temperature, a mechanism similar to that described above can still occur, which is really VLS (vapor = gaseous C species, liquid = molten catalyst, S = graphenes), but there are no crystal faces to preferentially orient the rejected graphenes. Energy minimization requirements will therefore make them concentric and parallel to the filament axis. With large catalyst particles (or in the absence of any substrate), the mechanisms above will generally follow a *tip-growth* scheme: the catalyst moves forward while the rejected carbon forms the nanotube behind, whether there is a substrate or not. One end might be left open. Conversely, when the catalyst particles deposited onto the substrate are small enough to be held in place by interaction forces with the substrate, the growth mechanism will follow a *base-growth* scheme, where the carbon nanofilament grows away from the substrate, leaving the catalyst nanoparticle attached to it (Fig. 8.16).

The bamboo texture that affects both the herringbone and the concentric textures may reveal a distinguishing aspect of the dissolution-rejection mechanism: the periodic, discontinuous dynamics of the phenomenon. Once the catalyst has reached the saturation threshold in terms of its carbon content, it expels it quite suddenly. Then it becomes able to incorporate a given amount of carbon again without having any catalytic activity for a little while. Then over-saturation is reached again, and so on [8.141].

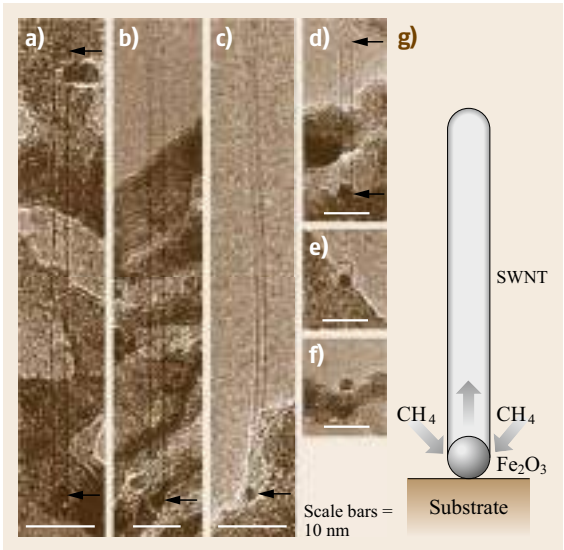

Fig. 8.16a–g High-resolution TEM images of several SWNTs grown from iron-based nanoparticles using the CCVD method, showing that particle sizes determine SWNT diameters in this case (after [8.142]). Yet the catalyst crystal imaged (the *dark spot* at the bottom of each tube) is different for each figure, considering images backward from (f) to (c) illustrates what could be a sequence of growth of an SWNT from a single nanocrystal, as sketched in (g). (a) and (b) show additional examples of fully grown SWNTs, similar to (c) ◄

Therefore, it is clear that 1 catalyst particle = 1 nanofilament in any of the mechanisms above. This explains why achieving a narrow distribution of nanotube diameters in CCVD is quite challenging, particularly when nanosizes are required for the growth of SWNTs. Only particles < 2 nm are useful for this (Fig. 8.16), since larger SWNTs are not favored energetically [8.8]. Another distinguishing aspect of the CCVD method is that growth can occur all along the isothermal zone of the reactor furnace as it is continuously fed with a carbon-rich feedstock, which is generally in excess, with a constant composition at a given species time of flight. Roughly speaking, the longer the isothermal zone, the longer the nanotubes. This is why the lengths of the nanotubes can be much longer than those obtained using solid carbon source-based methods.

The comments above are summarized in Table 8.1, compared with basic information relating to the high-temperature growth conditions (Sect. 8.3.2, *High-Temperature Conditions* below).

High-Temperature Conditions

High-temperature conditions (several thousands of °C) are typically used in solid carbon source-based methods such as the electric-arc method. Both the carbon source and the catalysts are atomized. Of course, catalyst-grown SWNTs do not form in the plasma, where temperatures are the highest whereas c-MWNTs do. The plasma medium is a mixture of atoms and radicals,

Table 8.1 Guideline indicating the relationships between possible carbon nanofilament morphologies and some basic synthesis conditions. Columns (1) and (2) mainly relate to CCVD-based methods; column (3) mainly relates to plasma-based methods

	Increasing temperature … → … and physical state of catalyst			Substrate		Thermal gradient

some of which are likely to combine and condense into liquid droplets. At some distance from the atomization zone, the medium is therefore made of carbon-metal alloy droplets and of secondary carbon species that range from C_2 to higher order molecules such as corannulene, which is made of a central pentagon surrounded by five hexagons (as the fastest way to limit dangling bonds at low energetic cost), thereby providing a fixation site for other carbon atoms (or C_2) which also will tend to close into a ring. Since adjacent pentagons are not energetically favored, these cycles will be hexagons. Such a molecule is thought to be a probable precursor for fullerenes. Fullerenes are actually always produced, even in conditions that produce SWNTs. The same saturation in C described in Sect. 8.3.2 occurs for the carbon-metal alloy droplets as well, resulting in the precipitation of excess C outside the particle due to the effect of the decreasing thermal gradient in the reactor, which decreases the solubility threshold of C in the metal [8.143]. Once the *inner* carbon atoms reach the surface of the catalyst particle, they meet the *outer* carbon species, including corannulene, that will contribute to capping the merging nanotubes. Once formed and capped, nanotubes can grow both from the inner carbon atoms (Fig. 8.17a), according to the VLS mechanism proposed by *Saito* et al. [8.143], and from the outer carbon atoms, according to the adatom mechanism proposed by *Bernholc* et al. [8.144]. In the latter, carbon atoms from the surrounding medium in the reactor are attracted then stabilized by the carbon/catalyst interface at the nanotube/catalyst surface contact, promoting their subsequent incorporation at the tube base. The growth mechanism therefore mainly follows the base growth scheme. The occurrence of a nanometer-thick surface layer of yttrium carbide (onto the main Ni-containing catalyst core), the lattice distance of which is commensurable with that of the C−C distance in graphene, could possibly play a beneficial role in stabilizing the nanotube/catalyst interface, which could explain why the SWNT yield is enhanced by bimetallic alloys (as opposed to single metal catalysts) [8.41]. But this needs the catalyst to be crystallized during CNT growth, which is not ascertained. For instance, as SWNTs only grow as bundles, it was proposed that those could result from the occurrence of a cell structuration phenomenon of the liquid catalyst according to the so-called solutal Bénard–Marangoni instability mechanism [8.145]. Hence, alternatively, Y could mostly play a major role in providing the plasma with the favorable thermal properties.

A major difference from the low-temperature mechanisms described for CCVD methods is that many nanotubes are formed from a single, relatively large ($\approx$ 10−50 nm) catalyst particle (Fig. 8.17b). This is why the diameters of SWNTs grown at high temperature are much more homogeneous than those associated with CCVD methods. The reason that the most frequent diameter is $\approx$ 1.35 nm is again a matter of energetic compromise. Larger SWNTs are less stable [8.8]. Conversely, the strain on the C−C bond increases as the radius of curvature decreases. Another difference from the low-temperature mechanism for CCVD is that temperature gradients in high-temperature methods are huge (Fig. 8.10), and the gas-phase composition surrounding the catalyst droplets is also subjected to rapid changes. This explains why nanotubes from arc are generally shorter than nanotubes from CCVD, and why mass production by CCVD is favored.

8.4 Properties of Carbon Nanotubes

In MWNTs that consist of stacked graphenes, the bond strength varies significantly depending on whether the in-plane direction (characterized by very strong covalent and therefore very short – 0.142 nm – bonds) or the direction perpendicular to it (characterized by very weak van der Waals and therefore very loose – ≈ 0.34 nm – bonds) is considered. Such heterogeneity is not found in single SWNTs. However, the heterogeneity returns, along with the related consequences, when SWNTs associate into bundles. Therefore, the properties – and applicability – of SWNTs may also change dramatically depending on whether single SWNTs or SWNT ropes are involved.

In the following, we will emphasize the properties of SWNTs, since their unique structures often lead to different properties to regular polyaromatic solids. However, we will also sometimes discuss the properties of MWNTs for comparison.

8.4.1 Overall Properties of SWNTs

With diameters in the nanometer range, and lengths in the range of micrometer to hundreds of micrometers, SWNTs exhibit huge aspect ratios. They are stable up to 600–700 °C in air and up to ≈ 1500–1800 °C in an inert atmosphere, beyond which they transform into regular graphene-based solids [8.146]. They have half the mass density of aluminum. The properties of SWNTs, like any molecule, are heavily influenced by the way their atoms are arranged, hence by their helicity [8.147].

8.4.2 Adsorption Properties

Accessible Specific Surface Area of CNTs

Various studies dealing with the adsorption of nitrogen onto MWNTs [8.148–150] and SWNTs [8.150, 151] have highlighted the porous nature of both materials. CNTs present large surface areas because of their structure and physical form. Their actual surface areas may be influenced by a variety of properties such as tube/fiber diameter, bundling and agglomeration, purity, and surface functionalization [8.150]. The theoretical surface area of CNTs has a broad range, from 50–1315 $m^2\,g^{-1}$ depending on the number of walls, the diameter, and the number of nanotubes in a bundle of CNTs [8.152]. Experimentally, the surface area of an SWNT is often larger than that of an MWNT. The total surface area of as-grown SWNTs is typically between 400–900 $m^2\,g^{-1}$ (micropore volume 0.15–0.3 $cm^3\,g^{-1}$), whereas values of 200–400 $m^2\,g^{-1}$ for as-produced MWNTs are often reported (Table 8.2).

However, the mesopores of the SWNT, obtained by subtracting the micropore volume from the total, constitute the major fraction of the pores [8.154]. The pores in MWNTs can be divided mainly into hollow inner cavities with small diameters (with narrow size distributions, mainly 3–10 nm) and aggregated pores (with wide size distributions, 20–40 nm), formed by interactions between isolated MWNTs. It is worth noting that opening or closing the central canal significantly influences the adsorption properties of CNTs. Opening, closing, or cutting CNTs, as well as heating them can considerably affect their surface area and pore structure. For instance, activating MWNTs with KOH or NaOH was shown to promote microporosity and reaching surface areas as high as 1050 $m^2\,g^{-1}$ [8.155, 156].

Adsorption Sites and Binding Energy of the Adsorbates

It is expected that adsorption properties of small-diameter CNTs such as SWCNTs are strongly affected by tube diameter and helicity, as the electronic structure is. Generally speaking, three types of sites exist on a graphene lattice: top (T), bridge (B), and center (C) (Fig. 8.18a). Additionally, the possibility to adsorb species on the convex (exohedral adsorption) or concave (endohedral adsorption) surface should be taken into account [8.157]. For SWNT bundles, adsorption may occur onto the various types of surface available (Fig. 8.18b). For MWCNTs, adsorption can occur in the aggregated pores, inside the tube or on the external walls; in this latter case, the presence of structural defects (vacancies, Dienes/Stone–Wales defects, dopants) plays a significant role in the adsorption as they can be seen as islands with elevated reactivity. Additionally, modeling studies have shown that the CNT convex (outer) surface is chemically reactive because the convex arrangement of pyramidalized sp^2 carbon atoms makes the formation of chemical bonds with reagent species possible. For a related reason, the concave (inner) surface should be more inert and can withstand the presence of highly reactive species encapsulated within the nanotubes. This difference in reactivity between convex and concave surfaces increases as the tube diameter decreases [8.158, 159].

Generally speaking, the adsorbates can be either charge donors or acceptors to the nanotubes. Trends in the binding energies of gases with different van der Waals radii suggest that the groove sites of SWNTs are the preferred low-coverage adsorption sites due to their higher binding energies (Table 8.2). In the first stages of adsorption (occurring at the most attractive sites), it

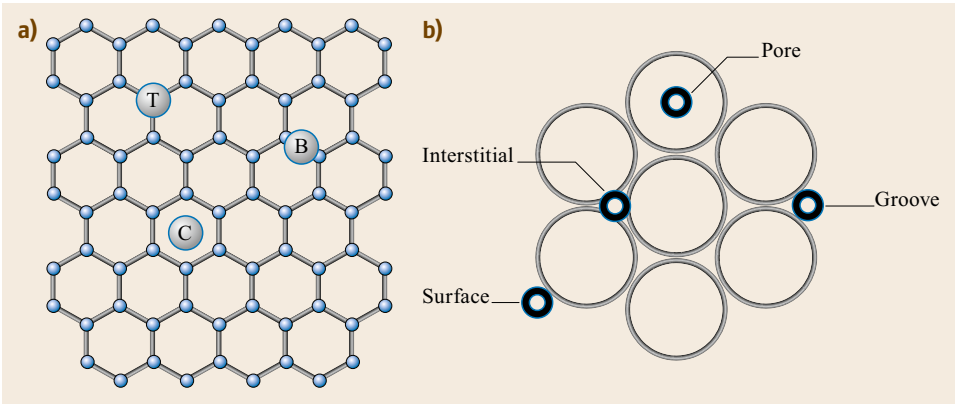

Fig. 8.18 **(a)** Adsorption sites on graphene; **(b)** sketch of an SWNT bundle cross-section, illustrating the four different adsorption sites

Table 8.2 Adsorption properties and sites of SWNTs and MWNTs. The data in the last two columns are from [8.153]

Type of nanotube	Porosity (cm^3/g)	Surface area (m^2/g)	Binding energy of the adsorbate	Adsorption sites	Attractive potential per site (eV)	Surface area per site (m^2/g)
SWNTs (bundle)	Microporous (0.15–0.3)	400–900	Low, mainly physisorption (25–75% higher than graphene)	Surface Groove Pore Interstitial	0.049 0.089 0.062 0.119	483 22 783 45
MWNT	Mesoporous	200–400	Physisorption	Surface pore Aggregated pores	–	–

seems that adsorption or condensation in the interstitial channels of the SWNT bundles depends on the size of the molecules (and/or on the SWNT diameters) and on their interaction energies [8.160–162]. For hydrogen and other small molecules like CO, computational methods have shown that, for open SWNTs, the pore, interstitial and groove sites are energetically more favorable than surface sites [8.163, 164]. Quantum chemical calculations suggest that adsorption in interstitial channels of bundles formed of large-diameter SWCNTs is possible and can account for high desorption barriers, a result of strong dispersion interactions between neighboring SWCNTs [8.165]. Opening CNTs favors gas (including O_2, N_2) adsorption within the inner walls [8.166, 167]. Finally, several studies have shown that, at low coverage, the binding energy of the adsorbate on an SWNT is between 25–75% higher than the binding energy on a single graphene (Table 8.2). This discrepancy can be attributed to an increase of effective coordination at the binding sites in SWNT bundles [8.168, 169]. Only a few studies deal with adsorption sites in MWNTs, but it has been shown that butane adsorbs more onto MWNTs with smaller outside diameters, which is consistent with another statement that the strain on curved graphene surfaces affects sorption. Most of the butane adsorbs to the external surface of the MWNTs while only a small fraction of the gas condenses in the pores [8.170].

A limited number of theoretical as well as experimental studies on the binding energies of gases onto CNTs exist. While most of these studies report low binding energies on SWNTs, consistent with physisorption, some experimental results, in particular for hydrogen, are still controversial. The energetics of hydrogen chemisorption on a (6,6) nanotube has been modeled using gradient-corrected density functional theory [8.171]. The chemical reaction of hydrogen with carbon nanotubes is expected to become increasingly exothermic and also to proceed more rapidly at high coverages. Oxygen gas could be physisorbed via dispersive van der Waals forces or chemisorbed via formation of a chemical bond, and adsorption could take place either on perfect nanotube walls or at defect sites [8.172]. The adsorption of single atoms on a semiconducting and metallic SWNT was studied from first principles for a large number of foreign atoms [8.173]. The stable adsorption sites, binding energy, and the resulting electronic properties were analyzed. The character of the bonding and associated physical properties exhibit dramatic variations depending on the type of adsorbed atom. While the atoms of good conducting metals, such as Cu and Au, form very weak bonding, atoms such as Ti, Sc, Nb, and Ta are adsorbed with relatively high binding energy. Adsorption geometries and binding affinities of metal nanoparticles onto CNTs were also investigated through DFT (density functional the-

ory) calculations [8.174]. Pd, Pt, and Ti nanoparticles strongly chemisorb to the CNT surface. Unlike the cases of atomic adsorptions, the aluminum particle has the weakest binding affinity with the CNT. Aluminum or gold nanoparticles accumulated on the CNT develop the triangular bonding network of the metal surfaces in which the metal–carbon bond is not favored.

8.4.3 Electronic and Optical Properties

The electronic states in SWNTs are strongly influenced by their 1-D cylindrical structures. One-dimensional sub-bands are formed that have strong singularities in the density of states (Van Hove singularities) [8.175]. By rolling the graphene sheet to form a tube (n, m), new periodic boundary conditions are imposed on the electronic wavefunctions, which give rise to one-dimensional sub-bands: $C_\mathrm{h}\,\mathrm{K} = 2q$ where q is an integer and C_h is the helicity vector defined in Sect. 8.1. Much of the electronic band structure of an SWNT can be derived from the electronic band structure of graphene by applying the periodic boundary conditions of the tube considered. The graphene conduction and valence bands touch each other at six corners (K points) of the Brillouin zone [8.176]. If one of these sub-bands passes through the K point, the nanotube is metallic; otherwise it is semiconducting. This is a unique property that is not found in any other 1-D system, which means that for certain orientations of the honeycomb lattice with respect to the tube axis (chirality), some nanotubes are semiconducting and others are metallic. The band gap for semiconducting tubes is found to be inversely proportional to the tube diameter. As pointed out in Sect. 8.1, knowing (n, m) allows – in principle – prediction of whether the tube is metallic or not. However, the gap energy of semiconducting SWNTs decreases as their diameter increases, whatever their (n, m) values, up to a value of ≈ 14 nm at which point the gap energy approaches the energy range brought by the room temperature [8.10]. Hence MWNTs with diameters beyond this value are no longer semiconducting and exhibit properties similar to other forms of regular, polyaromatic solids. It has been shown that electronic conduction mostly occurs through the external tube for MWNTs; even so, interactions with internal tubes often cannot be neglected and they depend upon the helicity of the neighboring tubes [8.177].

The electronic and optical properties of SWNTs are considerably influenced by the environment [8.178], starting with the bundle configuration as compared to isolated. In such a case, due to the interactions between neighboring tubes, a bundle of identical, metallic SWNTs can behave as a semiconducting object [8.179]. When multiple-wall tubes such as DWNTs are subjected to external pressure, the small interaction between the tube walls results in the internal tubes experiencing reduced pressure [8.180]. The electronic transition energies are in the infrared and visible spectral range. The 1-D Van Hove singularities have a large influence on the optical properties of CNTs. Visible light is selectively and strongly absorbed, which can lead to the spontaneous burning of agglomerated SWNTs in air at room temperature [8.181]. Strong Coulomb interaction in quasi-one dimension leads to the formation of excitons with very large binding energies in CNTs (200–400 meV), and degenerated states at the K, K′ points lead to multiple exciton states with dipole-allowed (bright) and dipole-forbidden transitions (dark) [8.182, 183]. Photoluminescence can be observed in individual SWNT aqueous suspensions stabilized by the addition of surfactants. Detailed photoexcitation maps provide information about the helicity-dependent transition energies and the electronic band structures of CNTs [8.184]. The agglomeration of SWNTs into bundles influences their electronic states. Photoluminescence signals are quenched for bundles.

CNTs are model systems for the study of 1-D transport in materials. Apart from the singularities in the density of states, electron–electron interactions are expected to show drastic changes at the Fermi edge; the electrons in CNTs are not described by a Fermi liquid, but instead by a Luttinger liquid model [8.185] which describes electronic transport in 1-D systems. It is expected that the variation of electronic conductance versus temperature follows a power law, with zero conductance at low temperatures. Depending on how L_ϕ (the coherence length) on the one hand and L_m (the electronic mean free path) on the other hand compare to L (the length of the nanotube), different conduction modes are observed: ballistic if $L \ll L_\phi$, $L \ll L_\mathrm{m}$, diffusive if $L_\phi \ll L_\mathrm{m} < L$, and localization if $L_\mathrm{m} \ll L_\phi \ll L$. Fluctuations in the conductance can be seen when $L \approx L_\phi$. For ballistic conduction (a small number of defects) [8.186–188], the predicted electronic conductance is independent of the tube length. The conductance value is twice the quantum of conductance (the fundamental conductance unit) $G_0 = 4e/h$ due to the existence of two propagating modes. Because of the reduced electron scattering observed for metallic SWNTs and their stability at high temperatures, CNTs can support high current densities (max. $10^9\,\mathrm{A/cm^2}$): about three orders of magnitude higher than Cu. Structural defects can, however, lead to quantum interference of the electronic wave function, which localizes the charge carriers in 1-D systems and increases resistivity [8.185, 189, 190]. Localization and quantum interference can be strongly influenced by applying a magnetic field [8.191]. At low temperatures,

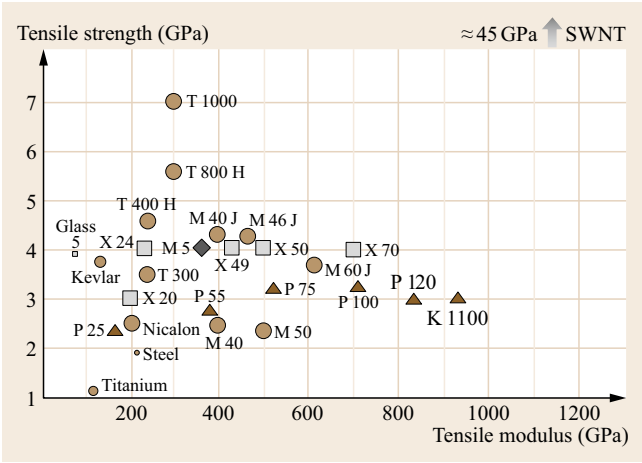

Fig. 8.19 Plot of the tensile strength versus the tensile modulus for various fibrous materials compared to SWNTs. *Large circles* are PAN-based carbon fibers, *triangles* are pitch-based carbon fibers

the discrete energy spectrum leads to a Coulomb blockade resulting in oscillations in the conductance as the gate voltage is increased [8.190]. In order to observe the different conductance regimes, it is important to consider the influence of the electrodes where Schottky barriers are formed. Palladium electrodes have been shown to form excellent junctions with nanotubes [8.192]. The influence of superconducting electrodes or ferromagnetic electrodes on electronic transport in CNTs due to spin polarization has also been explored [8.193, 194].

As a probable consequence of both the small number of defects (at least the kind of defects that oppose phonon transport) and the cylindrical topography, SWNTs exhibit a large phonon mean free path, which results in a high thermal conductivity. The thermal conductivity of SWNTs is comparable to that of a single, isolated graphene layer or high purity diamond [8.195], or possibly higher ($\approx 6000\,\mathrm{W\,m^{-1}\,K^{-1}}$).

8.4.4 Mechanical Properties

CNTs are unique due to the particularly strong bonding between the carbons (sp^2 hybridization) of the curved graphene sheet, which is stronger than in diamond (sp^3 hybridization; 0.142 versus 0.154 nm for the C−C bond length in graphene and diamond respectively). This makes CNTs – SWNTs or c-MWNTs – particularly stable against deformations. The tensile strength of SWNTs can be 20−100 times that of steel [8.196] (while being 6 times lighter) and has actually been measured as ≈ 45 GPa [8.197]. Very high tensile strength values are also expected for ideal (defect-free) c-MWNTs, since combining perfect tubes concentrically is not supposed to be detrimental to the overall tube strength, provided the tube ends are well capped (otherwise, concentric tubes could glide relative to each other, inducing high strain). Tensile strength values as high as ≈ 150 GPa have actually been measured for perfect MWNTs from an electric arc [8.198]. The flexural modulus of perfect MWNTs should logically be higher than that for SWNTs [8.196], with a flexibility that decreases as the number of walls increases. Conversely, measurements performed on defective MWNTs obtained from CCVD exhibit a range of 3−30 GPa [8.199]. Values of tensile modulus are also the highest values known, in the range of 1−1.3 TPa for both SWNTs and MWNTs [8.200–202]. Figure 8.19 illustrates how defect-free CNTs could spectacularly revolutionize the field of high mechanical performance fibrous materials. However, making micrometer-sized fibers out of carbon nanotubes while maintaining the ultimate CNT properties remains an unaddressed challenge due to the problem of creating covalent bonds between the CNTs that have to be as strong as that of the CNT C–C bonds without creating defects in CNT structure [8.203].

8.4.5 Reactivity

CNTs have a large surface to interact with their environment (Sect. 8.4.2, *Accessible Specific Surface Area of CNTs*). Although SWNTs belong to the graphene-based material family, unlike graphite, they have no (chemically active) dangling bonds, and unlike fullerenes, the ratio of *weak* sites (C−C bonds involved in heterocycles) over strong sites (C−C bonds between regular hexagons) only deviates slightly from 0 whereas it is 1 for C_{60} fullerenes. Although graphene faces are chemically relatively inert, the radius of curvature imposed on the graphene in nanotubes causes the three normally planar sp^2 C−C bonds to undergo distortions, resulting in bond angles that are closer to the sp^3 C−C bond angle in diamond as the radius of curvature shortens. Even though it is not enough to make the carbon atoms chemically reactive, one consequence is that nesting sites are created at the concave surface and physisorption sites are created on the convex surface, both with an adsorption efficiency that increases as the nanotube diameter decreases.

The chemical reactivities of SWNTs (and c-MWNTs) are believed to derive mainly from the caps, since they contain six pentagons each, as opposed to the tube body, which supposedly only contains hexagons. Indeed, applying oxidizing treatments to CNTs (air oxidation, wet-chemistry oxidation) selectively opens the nanotube tips [8.204]. However, that SWNTs can be filled with foreign molecules such as fullerenes (Sect. 8.5.2) with ≈ 90% filling rate suggests the occurrence of side defects (typically Dienes defects, oth-

erwise wrongly named Stone–Wales defects [8.205]) able to be chemically attacked [8.206, 207], thereby creating additional entry ports along the tube. An average of one Dienes defect every 5 nm along the tube length, involving about 2% of the carbon atoms in a regular (10,10) SWNT has been estimated [8.207]. This means that the overall chemical reactivity of CNTs should depend strongly on how they are synthesized. For example, SWNTs prepared by the arc-discharge method, because they grow very fast in nonsteady conditions, are likely to contain more structural defects than CCVD-synthesized SWNTs. It is however the contrary for arc-prepared c-MWNTs, which exhibit a perfect, defect-free nanotexture [8.20] as compared to CCVD-prepared c-MWNTs. Finally, the reactivity of h-MWNT-type nanotubes is intrinsically higher, due to the occurrence of accessible graphene edges at the nanotube surface.

8.5 Carbon Nanotube-Based Nano-Objects (Carbon Meta-Nanotubes)

Carbon nanotubes are beautiful objects exhibiting a variety of amazing properties from a theoretical point of view or when investigated at lab-scale. However, as soon as actual devices and materials have to be prepared, and moreover made compatible with upscaled processes, they more often than not need to be modified. Several modification routes have been distinguished [8.208], which are listed in the following sub-sections. As it is a very active, multiple-field research area, only the basis is provided here. Further information can be found in related chapters and review papers from the current literature, beginning with the book which was dedicated to it [8.209].

8.5.1 Heteronanotubes

It is possible to replace some or all of the carbon atoms in a nanotube with atoms of other elements – mostly boron and nitrogen [8.210], but also phosphorus [8.211] and possibly sulfur – without affecting the overall honeycomb lattice-based graphene structure. Nanotubes modified in this way are termed *heteronanotubes* [8.210]. They can exhibit new behaviors (for example, BN nanotubes are electrical insulators) or modified properties (e.g., enhanced resistance to oxidation, modulation of electronegativity). This is indeed a way to enable better control over such properties. For instance, one current challenge in carbon-SWNT synthesis is to obtain selective formation of the desired SWNT structure, as it drives the metallic or semiconductor character. In this regard, it was demonstrated that replacing some C atoms with N or B atoms leads to SWNTs with systematic metallic electrical behavior [8.212, 213]. Most examples of heteronanotubes found in the literature are MWNTs. The heteroatom usually involved is nitrogen, due to the ease with which gaseous or solid nitrogen- and/or boron-containing species (such as N_2, NH_3, BN, HfB_2) can be passed into existing equipment for synthesizing MWNTs [8.212, 214] until complete substitution of carbon occurs [8.215, 216]. An amazing result of such attempts to synthesize hetero-MWNTs is the subsequent formation of c-MWNTs made up of coaxial alternate carbon graphene tubes and boron nitride graphene tubes [8.217]. Conversely, examples of hetero-SWNTs are few, although the synthesis of B- or N-containing SWNTs has recently been reported [8.213, 218, 219]. Only one successful synthesis of genuine BN-SWNTs has been reported so far [8.220].

8.5.2 Filled Carbon Nanotubes

SWNTs or MWNTs can have their inner cavities filled (partially or entirely) with foreign atoms, molecules, compounds, or crystals [8.207, 221]. The terminology X@SWNT (or X@MWNT, if appropriate, where X is the atom, molecule and so on involved) has been used for such structures since 1999 [8.222]. The very small inner cavity of nanotubes is indeed an amazing tool for preparing and studying the properties of confined nanostructures of any type, such as salts, metals, oxides, gases, or even discrete molecules like C_{60}, for example. Because of the almost one-dimensional structure of CNTs (particularly for SWNTs), encapsulated materials might have different physical and/or chemical properties and stability with respect to the unencapsulated or bulk material. Indeed, if the volume available inside a CNT is small enough, the foreign material is mostly made of *surface atoms* with reduced coordination. Filling material/nanotube interactions can also result in the filled nanotube itself behaving differently from a *pure* nanotube. This the basis of the current efforts being made to develop SWNT-based cables exhibiting electrical conductivity reaching that of metals such as copper, thanks to interactions of the SWNT bundle with iodine and sulfuric acid molecules as *dopents* [8.223].

Because of the limitations of some desirable CNT filling materials, such as very high melting temperature or poor solubility, it is also possible to fill CNTs

with appropriate precursors (i. e., able to sublime, melt, or solubilize) which will later be transformed into the required material by a physical interaction mechanism such as electron beam irradiation for example [8.224], or by in situ chemical transformations such as reduction by H_2 or H_2S [8.225].

Generally speaking, it is difficult to estimate the filling rate, and this is usually achieved in published papers through TEM observations, although they are barely based on reliable statistics regarding the number of tubes observed. Moreover, as far as SWNTs are concerned, the fact that the nanotubes are gathered into bundles makes it difficult to observe the exact number of filled tubes, as well as to estimate the filled length for each tube. However, an estimation of filling rates can also be obtained from x-ray studies and Raman spectroscopy.

It has to be pointed out that the driving forces involved in filling events are not fully yet understood [8.207, 221].

In Situ Filling Method

Initially, most hybrid CNTs synthesized were based on MWNTs prepared using the electric-arc method, and were obtained directly during processing. The filling materials were easily introduced into the system by drilling a central hole in the anode and filling it with the heteroelement. The first hybrid products obtained using this approach were all reported in the same year [8.226–230] for heteroelements such as Pb, Bi, YC_2, and TiC. Later on, *Loiseau* and *Pascard* [8.231] showed that MWNTs could also be filled to several μm in length by elements such as Se, Sb, S, and Ge, but only for nanoparticles of elements such as Bi, B, Al, and Te. Sulfur was suggested to play an important role during the in situ formation of filled MWNTs using arc discharge [8.232]. This technique is no longer preferred because it is difficult to control the filling ratio and yield and to achieve mass production, and it is not suitable for filling SWNTs, nor for filling MWNTs with transition metals as this induces the formation of (empty) SWNTs instead. Conversely, significant in situ filling can occur during CVD-based processes, but only with the catalyst that helped with MWNT growth (most often Fe, but possibly Co and Ni as well).

Wet Chemistry Filling Method

For the wet chemistry method the nanotube tips must be opened by chemical oxidation prior to the filling step. This is generally achieved by refluxing the nanotubes in dilute nitric acid [8.233–235], although other oxidizing liquid media may work as well, such as [HCl $+CrO_3$] [8.236] or chlorocarbenes formed from the photolytic dissociation of $CHCl_3$ [8.207], a rare example of a nonacidic liquid route to opening SWNT tips. If a dissolved form (such as a salt or oxide) of the desired metal is introduced during the opening step, some of it will get inside the nanotubes. An annealing treatment (after washing and drying the treated nanotubes) may then lead to the oxide or to the metal, depending on the annealing atmosphere [8.204]. The wet chemistry method initially looked promising because a wide variety of materials can be introduced into nanotubes in this way and because it operates at temperatures that are not much different from room temperature, allowing the filling of CNTs with materials with low temperature stability. However, close attention must be paid to the oxidation method that is used. The damage caused to nanotubes by severe treatments (such as using nitric acid) makes them unsuitable for use with SWNTs. Moreover, the filling yield is not very good, obviously because the solvent molecules also enter the tube cavity, hence filled lengths rarely exceed 100 nm.

Molten-State Filling Method

The physical filling method involving a liquid (molten) phase is more restrictive, firstly because some materials can decompose when they melt, and secondly because the melting point must be compatible with the nanotubes, so the thermal treatment temperature should remain below the temperature of transformation or the nanotubes will be damaged. Because the filling occurs due to capillarity hence obeying Jurin's law, the surface tension of the filling material in the molten state is probably important, and a threshold of 100−200 N/cm^2 was proposed [8.237]. However, a related study investigated MWNTs, whose inner diameters (5−10 nm) are generally larger than for SWNTs (1−2 nm). In addition, a major problem is that related data are barely available in the literature, therefore a lot of uncertainties remain regarding the various factors affecting filling rates. In a typical filling experiment, the MWNTs are well mixed with the desired amount of filler by gentle grinding, and the mixture is then vacuum-sealed in a silica ampoule. The ampoule is then slowly heated to a temperature above the melting point of the filler and then slowly cooled. This method does not always require that the nanotubes are opened prior to heat treatment, as some molten filling materials (e.g., halides) are able to react with CNT tips and open them (definitely thanks to the presence of heterocycles – pentagons for example – which are more reactive).

Most of the works involving the application of this method to SWNTs come from Oxford University [8.238–242], although other groups have followed the same procedure [8.233, 235, 243]. As the precursors used were mainly metal salts, the crystallization of molten halides within small-diameter SWNTs has been

studied in detail, and the resulting one-dimensional crystals have been shown to interact strongly with the surrounding graphene wall. For example, *Sloan* et al. [8.240] described two-layer 4 : 4 coordinated KI crystals that formed within SWNTs that were ≈ 1.4 nm in diameter. These two-layer crystals were *all surface* and had no *internal* atoms. Significant lattice distortions occurred compared to the bulk structure of KI, where the normal coordination is 6 : 6 (meaning that each ion is surrounded by six identical close neighbors). Indeed, the distance between two ions across the SWNT capillary is 1.4 times as much as the same distance along the tube axis. This suggests an accommodation of the KI crystal into the confined space provided by the inner nanotube cavity in the constrained crystal direction (across the tube axis). This implies that the interactions between the ions and the surrounding carbon atoms are strong. The volume available within the nanotubes thus somehow controls the crystal structures of inserted materials. Taking the example of PbI_2, the structures and orientations of encapsulated PbI_2 crystals were found to depend on the diameter of the confining nanotubes [8.238]. For SWNTs, most of the encapsulated one-dimensional PbI_2 crystals obtained exhibited a strong preferred orientation, with their (110) planes aligning at an angle of around 60 °C to the SWNT axes, as shown in Fig. 8.20a,b. Because of the extremely small diameters of the nanotube capillaries, individual crystallites are often only a few polyhedral layers thick, as outlined in Fig. 8.20d–h. The unusual lattice terminations enforced by capillary confinement, cause the edging polyhedra to be of reduced coordination, as indicated in Fig. 8.20g,h. However, as the diameter of the encapsulating capillary increases, different preferred orientations were frequently observed [8.238].

High-yield filling of CNTs by the capillary method is generally difficult but fillings of more than 60% have been reported for different halides, with filling lengths of up to several hundred nm [8.244]. Results from the imaging and characterization of individual molecules and atomically thin, effectively one-dimensional crystals of rock salt and other halides encapsulated within SWNTs were reviewed by *Sloan* et al. [8.245].

Sublimation Filling Method

This method is more restrictive than the previous one, since it is only applicable to compounds able to sublimate within the temperature range of thermal stability of the nanotubes. Examples are therefore scarce. The first and still most successful example published so far is the formation of C_{60}@SWNT (nicknamed *peapods*), reported for the first time in 1998 [8.246], where regular ≈ 1.4 nm-large SWNTs were filled with C_{60} fullerene molecule chains. On the basis of this work, many fullerene-related molecules have been successfully encapsulated as well, e.g., C_{70} (Fig. 8.21a), or endofullerenes (La_2@C_{80} [8.247], Gd @C_{82} [8.248], and $Er_xSc_{3-x}N$@C_{80} [8.249] among other examples). Other attempts have followed, for instance involving $ZrCl_4$ [8.241], selenium [8.250], or iodine [8.243, 251] (Fig. 8.21b). Of course, the process requires that the SWNTs are opened by some method, as discussed previously, typically by either acid attack [8.252] or heat treatment in air [8.253]. The opened SWNTs are then in-

serted into a glass or quartz tube together with fullerene powder, which is sealed and placed into a furnace heated above the sublimation temperature for fullerite ($> 350\,^{\circ}C$). As gaseous molecules are involved, the filling mechanism somewhat relates to capillary condensation instead of capillary wetting, meaning that there are no filling limitations related to Jurin's law or the presence of solvent. Consequently, filling efficiency may actually reach $\approx 100\%$ with this filling route [8.253].

8.5.3 Functionalized Nanotubes

Nanotube functionalization reactions can be divided into two main groups: (i) the chemical oxidation of the tips and structural defects leading to carboxylic, carbonyl, and/or hydroxyl functions. These functions are then used for additional reactions, to attach oligomeric or polymeric functional entities; (ii) the direct addition to the graphenic surface (without any intermediate step). Examples of the latter reactions include oxidation or fluorination (an important first step for further functionalization with other organic groups). The properties and applications of functionalized nanotubes have been reviewed in [8.254, 255]. It must be noted that these chemical reactions also affect any graphene-based impurities, making quantification difficult, either because raw yet pure CNT materials barely exist, or because purification procedures induce their own functionalization.

Oxidation of Carbon Nanotubes

CNTs are often oxidized and therefore opened before chemical functionalization in order to increase their chemical reactivity (by creating dangling bonds). The chemical oxidation of nanotubes is mainly performed using either wet chemistry or gaseous oxidants such as oxygen (typically air), ozone, or CO_2. Depending on the process they were synthesized with, the oxidation resistance of nanotubes can vary. When oxidation is achieved using a gas phase, thermogravimetric analysis (TGA) is of great help for determining the temperature at which the treatment should apply (attention should be paid to the use of low heating rates so that overestimated oxidation temperatures are not provided). Differences in the presence of catalyst remnants (metals or, more rarely, oxides) and other by-products, variations in the type of nanotube-oxidizing agent and TGA conditions (heating rate, flow rate) used make published results difficult to compare. It is generally agreed, however, that amorphous carbon burns first, followed by SWNTs and then multiwall materials (shells, MWNTs), even if TGA is often unable to separate the different oxidation steps clearly. Aqueous solutions of oxidizing reagents are often used for nanotube oxidation. The main reagent is nitric acid, either concentrated or diluted (around 3 mol/l in most cases), but oxidants such as potassium dichromate ($K_2Cr_2O_7$), hydrogen peroxide (H_2O_2), or potassium permanganate ($KMnO_4$) are often used as well. HCl, like HF, does not damage nanotubes because it is not oxidizing. However, the liquid wastes generated by the wet oxidation methods and the necessity of filtration/drying steps are not well suited for industrial use. Gas-phase oxidation of CNTs using either oxygen [8.227, 256] or nitric acid vapors [8.257] at moderate or high temperature removes disordered carbon but can lead to weight loss due to the etching of nanotube outer walls. As a consequence, high purity materials are obtained, but the yield is generally low. Conversely, gas-phase oxidation from ozone (O_3) per-

formed at ambient temperature is an environmentally friendly and low cost route to form oxygen-containing groups on the whole CNT surface without too much structural damage. It is suited for mass treatment since it can be performed in a fluidized bed [8.258, 259].

Functionalization of Oxidized Carbon Nanotubes

The defects on CNTs created by oxidants are stabilized by bonding with carboxylic acid (–COOH) or hydroxyl (–OH) groups. These functional groups have rich chemistry and the CNTs can be used as precursors for further chemical reactions, such as silanation, polymer grafting, esterification, thiolation, alkylation, arylation, and even some biomolecules. Oxidized nanotubes are usually reacted with thionyl chloride ($SOCl_2$) to generate the acyl chloride. The reaction of SWNTs with octadecylamine was reported by *Chen* et al. [8.260] after reacting oxidized SWNTs with $SOCl_2$. Many other reactions between functionalized nanotubes (after reaction with $SOCl_2$) and amines have been reported in the literature [8.261]. The common outcome of these functionalizations is the increased solubility of CNTs either in the organic solvent or water. Noncovalent reactions between the carboxylic groups of oxidized nanotubes and octadecylammonium ions are also possible [8.262], providing solubility in tetrahydrofuran (THF) and CH_2Cl_2. The attachment of proteins onto CNTs using diimide-activated amidation (through direct coupling of the carboxylic acid to proteins using a coupling agent) is possible [8.263]. DNA functionalization of CNTs was also reported [8.264].

Functionalization with lipophilic (long alkyl chains) and hydrophilic (oligomeric poly(ethyleneglycol) groups) dendra has been achieved via amination and esterification reactions [8.265]. In that case, the functional groups could be removed simply by modifying the pH of the solution [8.266]. The possible interconnection of nanotubes was reported by *Chiu* et al. [8.267] using the acyl chloride method and a bifunctionalized amine to link the nanotubes through the formation of amide bonds.

Finally, it has been discovered that imidazolium ion-functionalized CNTs are highly dispersible in ionic liquids of analogous chemical structure and that mixtures of functionalized CNT and ionic liquids can form gels upon sonication or waxes that could find applications as soft composite materials for electrochemistry [8.268].

Sidewall Functionalization of Carbon Nanotubes

There are two main approaches for the side-wall functionalization of CNTs: i) the covalent attachment of chemical groups through reactions onto the π-conjugated skeleton; and ii) the noncovalent adsorption or wrapping of various functional molecules [8.261, 269]. Covalent functionalization is based on the formation of a covalent linkage between functional entities and the carbon skeleton of nanotubes. It could also be divided into direct covalent sidewall functionalization and indirect covalent functionalization with carboxylic groups on the surface of CNTs (Fig. 8.22). Direct covalent sidewall functionalization is associated with a change in hybridization from sp^2 to sp^3 and a simultaneous loss of conjugation (e.g., fluorination of nanotubes [8.270, 271]). Indirect covalent functionalization takes advantage of chemical transformations of carboxylic groups at the open ends and holes in the sidewalls (see above). The drawback of covalent functionalization is that the perfect structure of CNTs has to be destroyed, resulting in significant changes in their physical properties. Noncovalent functionalization is mainly based on supramolecular complexation using various adsorption forces, such as Van der Waals force, hydrogen bonds, electrostatic force, and π-stacking interactions [8.269]. Compared to chemical functionalization, the advantages of noncovalent functionalization are that it can operate under relatively mild reaction conditions and that the perfect graphene structure of CNTs can be maintained.

Numerous chemical reactions including hydrogenation, halogenation, esterification, amidation, cycloaddition, radical addition, azide chemistry, nucleophilic addition, electrophilic addition, inorganic complex addition, ozonolysis, surface-initiated polymerization, and physical methods such as plasma treatment, π–π stacking and solid-phase mechanical milling have been tried to functionalize CNTs, offering alternative approaches to the solubilization of CNTs with desired functionality and surface characteristics [8.261, 269, 272–274].

8.5.4 Coated/Decorated Nanotubes

In contrast to functionalization, the decoration of CNTs consists in depositing solids, mainly nanoparticles (NPs), physi- or chemisorbed onto the nanotube's outer surface. Because of their interaction with the nanotube structure, the deposited metals, semiconductors, oxides, or organic materials often present unique properties [8.275]. Consequently, the coated CNTs find numerous applications in catalysis, electronics, energy conversion and storage, environment, and medicine [8.275, 276].

Even if the outer surface of tubes and tube ends present potential adsorption sites, numerous studies have shown that surface activation is essential to reach a high coating density. Oxidation (Sect. 8.5.3, *Oxida-*

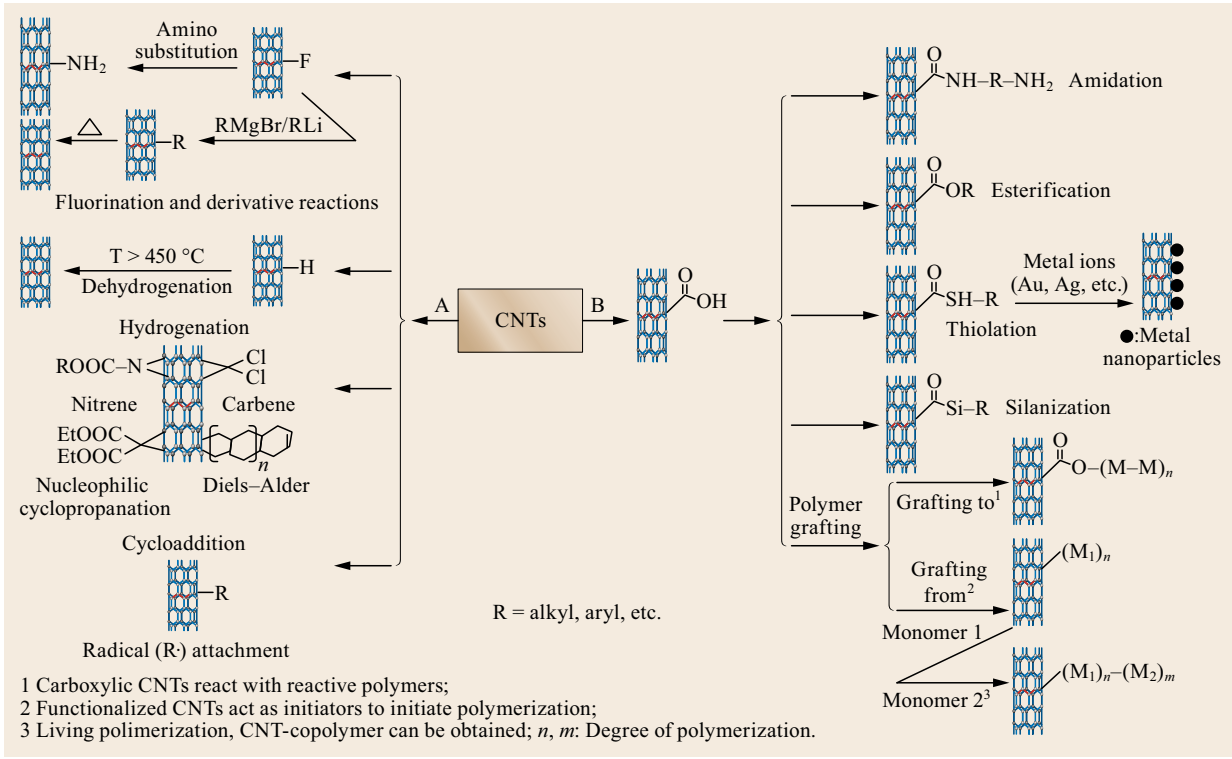

Fig. 8.22 Strategies for covalent functionalization of CNTs (*A*: direct sidewall functionalization; *B*: defect functionalization)

tion of Carbon Nanotubes) is the most popular route to activate the nanotube surface by creating surface carbonyl and carboxyl groups. There are many methods for the deposition of nanoparticles onto nanotubes, each offering different degrees of control of NP size and distribution along the tubes [8.275, 277]. Their choice often depends on the application field and on the scale of treatment. They are generally classified into two groups: the wet methods including the electrochemical, sol-gel and impregnation methods, and the gas processes such as physical vapor deposition (PVD), atomic layer deposition (ALD), and chemical vapor deposition (CVD) [8.275, 278–280].

The wet impregnation method is the most widely used technique even though it is multistep, because of its simplicity and cheapness [8.275]. It involves the impregnation of nanotubes by a solution of precursor salt or organometallic complex, followed by drying, calcination, and reduction. However, the size of the coated particles may be difficult to control precisely [8.278]. As an example, Pd nanoparticles were deposited on MWNTs by wet impregnation and by a functionalization using poly-alcohol based ligands, in order to increase the hydrogen absorption properties of nanotubes [8.280]. The polyol route gave much better dispersion of Pd on the MWNTs with smaller Pd nanoparticle size distribution.

The gas processes yield products often purer than the wet methods. They are single step and generally involve high coating rates [8.275]. CVD on MWNTs has often been used to deposit metallic (Pt, Pd, Ru, Rh) or semiconducting (InP, CdSe) nanoparticles on nanotubes [8.275]. The deposition of silicon layers on MWNT networks has been explored to prepare anodes of Li-ion batteries by combining the high specific energy capacity of silicon and the good mechanical strength and structural flexibility of nanotubes [8.281]. Composites made of SnO_2 NPs deposited on MWNTs have demonstrated excellent sensing responses for gas detection at room temperature [8.282]. As an alternative to oxidizing pretreatments, the predeposition of a titanium carbide (TiC) layer by CVD acting as a surface functionalization has successfully increased the surface coverage of MWNTs by Ni, Pd and Pt thin layers deposited by CVD [8.283]. Such depositions can be performed at large scale using the fluidized bed CVD process (Sect. 8.2.2, *Heterogeneous Processes*) [8.259, 284].

8.6 Carbon-Nanotube-Containing Materials (Composites)

Because of their unique and exceptional morphological characteristics and properties, CNTs make particularly promising component materials of composites with metals, ceramics, or polymer matrices. Key issues to address include the homogeneous dispersion of the CNTs (without damaging the CNTs), the control of the CNT/matrix bonding, the densification of bulk composites, and the possibility of aligning CNTs. In addition, the CNT type (SWNT, DWNT, MWNT, etc.) and production origin (arc, laser, CCVD, etc.) are also important variables that control structural perfection, surface reactivity, and aspect ratio of the reinforcement. The application of CNTs in this field is expected to lead to major advances in composites.

8.6.1 Metal Matrix Composites

CNT-metal matrix composites are less studied despite promising applications as structural materials in aeronautics, aerospace, and automotive fields. The main matrices are Al, Cu, Mg, Ti, and Ni. The materials are generally prepared by standard powder metallurgy techniques [8.285]. The spark plasma sintering (SPS) technique is sometimes used to densify the composites whilst avoiding matrix-grain growth [8.286]. Other techniques such as liquid metallurgy, thermal spray, and electrochemical deposition are also currently employed [8.287]. To achieve better dispersion of CNTs, new processing methods such as molecular level mixing and stir friction processing have been developed in recent years [8.287]. The room temperature electrical resistivity of hot-pressed MWNT-Al composites increases slightly upon increasing the MWNT volume fraction [8.288]. The tensile strengths and elongations of unpurified arc-discharge MWNT-Al composites are only slightly affected by annealing at 873 K in contrast to those of pure Al [8.289]. The addition of 1 vol.% MWNT to Al greatly enhances its tensile strength without sacrifices to its tensile elongation [8.290]. The elastic modulus, yield strength, and fracture toughness of 1.5, 3, and 4.5 vol.% MWNT-Al composites increase with carbon content [8.291]. The coefficient of thermal expansion (CTE) of 1 wt% MWNT-Al composite fabricated by cold isostatic pressing and the hot squeeze technique is 11% lower than that of pure Al or 2024 Al matrix, showing some promise as low-CTE materials. Associated with a high thermal conductivity, such materials would be interesting for applications such as packaging and space structures [8.292]. The stiffness, yield, and tensile strengths of spark-plasma-sintered MWNT-Cu composites increase with increasing carbon content up to 15 vol.% [8.293, 294]. 0.5 vol.% DWNT-Cu composite macroscopic wires prepared using a combination of SPS and room-temperature wire drawing present an increase of ultimate tensile strength by about 10% compared to the corresponding pure copper wires [8.295]. DWNT- and MWCNT-Cu composites also show a higher hardness and a lower friction coefficient and wear loss [8.296]. Hot-extruded CNT-Mg nanocomposites showed a simultaneous increase in yield strength, ultimate tensile strength and ductility, until a threshold of 1.3 wt% was reached [8.297]. Compared to pure Mg, a 45% increase of tensile strength was obtained for 2.4 wt% MWNT-Mg composites prepared by in situ synthesis of the CNTs within the Mg powder followed by hot extrusion [8.298]. The Young's modulus of nonpurified arc-discharge MWNT-Ti composite is about 1.7 times that of pure Ti [8.299]. The formation of TiC, probably resulting from a reaction between amorphous carbon and the matrix, was observed, but the MWNTs themselves were not damaged. An increase in the Vickers hardness by a factor of 5.5 over that of pure Ti was associated with the suppression of coarsening of the Ti grains, TiC formation, and the addition of MWNTs. The addition of small MWNT loadings of 0.18–0.35 wt% also improves the yield stress and tensile strength of Ti markedly [8.300]. Ni-plated MWNTs give better results than unplated MWNTs in strength tests. Indeed, CNT coating is a promising way to improve the strength of bonding with the matrix [8.301]. Composite films and coatings deposited by electroless or electrodeposition techniques on various substrates have also been studied. The addition of up to 15 vol.% purified SWNTs to nanocrystalline Al films reduces the coefficient of thermal expansion by as much as 65% and the resulting material could be a promising electronic packaging material [8.302]. CNT-Ni coatings deposited on a carbon steel plate by electroless deposition show significantly increased resistance to corrosion [8.303] and higher Vickers microhardness, higher wear resistance, and lower friction coefficient than SiC-reinforced composite deposits [8.304].

8.6.2 Ceramic Matrix Composites

Many different ceramic matrices have been studied over the years, although oxides (in particular Al_2O_3) are still the most studied [8.305–307]. There are three main methods for the preparation of CNT-ceramic nanocomposite powders. One is mechanical milling which usually involves long times that could damage the CNTs. Wet-milling is preferred but often requires the addition of organic additives to stabilize both the CNTs and the ceramic powder. This is also true for a second

method, i. e., the in situ synthesis of the matrix on preformed CNTs. It can lead to a good adhesion between the CNTs and the ceramic, but can be rather complex to implement. A third method is the in situ synthesis of the CNTs within the ceramic powder using procedures closely related to those described in Sect. 8.2.2, *Heterogeneous Processes*. The densification of the nanocomposite powders is made difficult by the detrimental influence of the CNTs. The most common methods are hot pressing (HP) and spark plasma sintering (SPS). Most of the works report that increasing the carbon content inhibits the densification of the composite, all the more when CNTs are homogeneously dispersed in the matrix. The SPS technique has been reported as an efficient method to achieve the total densification of CNT-oxide composites without damaging the CNTs [8.308, 309]. Full densification can be reached with SPS at comparatively lower temperatures with substantial shorter holding times. However, the successful densification by SPS at a lower temperature than for HP suggests that matrix grains are nonagglomerated and with sizes in the range of a few tens of nanometers. The influence of CNT dispersion on mechanical properties, in particular on toughness, has been controversial. Indeed, strong increases in toughness derived from the measurement of Vickers indentation cracks have been reported [8.307], but they were shown to be probably widely overestimated because such materials are very resistant to contact damage [8.310, 311]. *Xia* et al. [8.312] reported microstructural investigations on MWNTs well aligned in the pores of an Al_2O_3 membrane. Different possible reinforcement mechanisms induced by the MWNTs have been evidenced, such as crack deflection, crack bridging, MWNT pulling-out, and MWNT collapsing in shear bands. Indeed, although so far neither single-edge notched beam nor single-edge V-notched beam results have evidenced that CNTs can significantly reinforce Al_2O_3 ceramics [8.313], a strong and unambiguous increase in toughness has been obtained for DWNT-MgO composites in which the CNTs are very homogeneously dispersed [8.314]. Enhanced tribological properties (low friction and/or wear) of composites have been reported [8.315–318]. The microhardness is found to either increase or decrease, and this depends greatly on the powder preparation route. As noted in [8.311], processing-induced changes in the matrix may have greater effects on the mechanical properties than the actual presence of CNTs. Regarding the thermal properties, CNT-ceramic composites often show a lower thermal conductivity than the corresponding ceramics, probably caused by too high thermal contact resistances at CNT-CNT and CNT-ceramic grain junctions [8.319, 320]. By contrast, CNTs increase the electrical conductivity of insulating ceramic nanocomposites [8.321–324], with a low percolation threshold (less than 1 vol.%) due to their very high aspect ratio [8.322]. The electrical conductivity can be tailored within several orders of magnitude directly by the CNT quantity and is well fitted by the scaling law of the percolation theory with the exponent close to the theoretical value characteristic of a three-dimensional network [8.322]. An anisotropic conductivity is obtained when the CNTs are aligned within the composite by high-temperature extrusion [8.325].

8.6.3 Polymer-Matrix Composites

CNT-polymer composites, first reported by *Ajayan* et al. [8.326], are still being intensively studied, especially epoxy- and polymethylmethacrylate (PMMA)-matrix composites. A review on the chemistry, processing, mechanical, and electrical properties can be found in [8.327]. In terms of mechanical characteristics, the three key issues that affect the performance of a fiber-polymer composite are the strength and toughness of the fibrous reinforcement, its orientation, and good interfacial bonding, which is crucial to load transfer [8.328]. The ability of the polymer to form large-diameter helices around individual CNTs favors the formation of a strong bond with the matrix [8.328]. Isolated SWNTs may be more desirable than MWNTs or bundles for dispersion in a matrix because of the weak frictional interactions between layers of MWNTs and between SWNTs in bundles [8.328]. The main mechanisms of load transfer are micromechanical interlocking, chemical bonding, and van der Waals bonding between the CNTs and the matrix. A high interfacial shear stress between the fiber and the matrix will transfer the applied load to the fiber over a short distance [8.329]. SWNTs longer than 10−100 μm would be needed for significant load-bearing ability in the case of nonbonded SWNT-matrix interactions, whereas the critical length for SWNTs cross-linked to the matrix is only 1 μm [8.330]. Defects are likely to limit the working length of SWNTs, however [8.331]. The load transfer to MWNTs dispersed in an epoxy resin was much higher in compression than in tension [8.329]. It was proposed that all of the walls of the MWNTs are stressed in compression, whereas only the outer walls are stressed in tension because all of the inner tubes are sliding within the outer tube. Mechanical tests performed on 5 wt% SWNT-epoxy composites [8.332] showed that SWNT bundles were pulled out of the matrix during the deformation of the material. The influence of the interfacial CNT/matrix interaction was demonstrated by *Gong* et al. [8.333]. It was also reported that coating regular carbon fiber with MWNTs prior to their dispersion into an epoxy matrix

improves the interfacial load transfer, possibly via local stiffening of the matrix near the interface [8.334]. DWNT-epoxy composites prepared by a standard calendaring technique were shown to possess higher strength, Young's modulus, and strain to failure at a carbon content of only 0.1 wt% [8.335]. Significantly improved fracture toughness was also observed. The influence of the different types of CNTs (SWNTs, DWNTs, and MWNTs) on the mechanical properties of epoxy-matrix composites is discussed in [8.336]. The stiffness and damping properties of SWNT- and MWNT-epoxy composites were investigated for use in structural vibration applications [8.337]. It was shown that enhancement in damping ratio is more dominant than enhancement in stiffness, MWNTs making a better reinforcement than SWNTs. Indeed, up to 700% increase in damping ratio is observed for MWNT-epoxy beam as compared to the plain epoxy beam. The outstanding potential of CNTs as reinforcements in polymer composites is evident from the supertough composite fibers fabricated by the groups of *Baughman* et al. [8.338] and *Poulin* et al. [8.339]. By optimizing the *coagulation spinning* method [8.340, 341], they spun several hundred meters of CNT-polyvinyl alcohol composite fibers, which have tensile properties comparable to that of a spider silk. As for ceramic matrix composites, the electrical characteristics of CNT-polymer composites are well described by the percolation theory [8.327, 342]. Polymer hosting CNTs such as PMMA, epoxy, polyimide, and polystyrene exhibit extremely low percolation threshold values (much below 1 wt%) [8.327]. An ultralow electrical percolation threshold of 0.0025 wt% was reported for aligned MWNT-epoxy composites [8.343]. The thermal conductivity of composites can also be greatly enhanced by the alignment of CNTs [8.344]. Polymer composites with other matrices include CCVD-prepared MWNT-polyvinyl alcohol [8.345], arc-prepared MWNT-polyhydroxyaminoether [8.346], arc-prepared MWNT-polyurethane acrylate [8.347, 348], SWNT-polyurethane acrylate [8.349], SWNT polycarbonate [8.350], MWNT-polyaniline [8.351], MWNT-polystyrene [8.352], CCVD double-walled nanotubes-polystyrene-polymethylacrylate [8.353], MWNT-polypropylene [8.354, 355], SWNT-polyethylene [8.356–358], SWNT-poly(vinyl acetate) [8.357, 358], CCVD-prepared MWNT-polyacrylonitrile [8.359], SWNT-polyacrylonitrile [8.360], MWNT-oxotitanium phthalocyanine [8.361], arc-prepared MWNTpoly(3-octylthiophene) [8.362], SWNT-poly-(3-octylthiophene) [8.363], and CCVD MWNT-poly(3-hexylthiophene) [8.364]. These works deal mainly with films 100–200 μm thick, and aim to study the glass transition of the polymer, its mechanical and electrical characteristics, as well as the photoconductivity. A great deal of work has also been devoted to the applications of CNT-polymer composites as materials for molecular optoelectronics, using primarily poly[(*m*-phenylenevinylene)-*co*-(2,5-dioctoxy-*p*-phenylenevinylene)] (PmPV) as the matrix. This conjugated polymer tends to coil, forming a helical structure. The electrical conductivity of the composite films (4–36 wt% MWNTs) is increased by eight orders of magnitude compared to that of PmPV [8.365]. Using MWNT-PmPV composites as electron transport layers in light-emitting diodes results in a significant increase in brightness [8.366]. The SWNTs act as a hole-trapping material that blocks the holes in the composites; this is probably induced through long-range interactions within the matrix [8.367]. Similar investigations were carried out on arc-discharge SWNT-polyethylene dioxythiophene (PEDOT) composite layers [8.368] and MWNT-polyphenylenevinylene composites [8.369].

To conclude, two critical issues must be considered when using nanotubes as components for advanced composites. One is to choose between SWNTs, DWNTs, and MWNTs. The former seem more beneficial to mechanical strengthening, provided that they are isolated or arranged into cohesive yarns so that the load can be conveniently transferred from one SWNT to another. Unfortunately, despite many advances [8.340, 341, 370–373], this remains a technical challenge. The other issue is to tailor the CNT/matrix interface with respect to the matrix. In this case, DWNTs and MWNTs may be more efficient than SWNTs.

8.6.4 Composites as Multifunctional Materials

One of the major benefits expected from incorporating CNTs into other solid or liquid materials is that they endow the material with some electrical conductivity while leaving other properties or behaviors unaffected. As already mentioned in the previous section, the percolation threshold is reached at very low CNT loadings. Tailoring the electrical conductivity of a bulk material is then achieved by adjusting the CNT volume fraction in the formerly insulating material while making sure that this fraction is not too large. According to *Maruyama* [8.374], there are three areas of interest regarding the electrical conductivity:

1. Electrostatic discharge (for example, preventing fire or explosion hazards in combustible environments or perturbations in electronics, which requires an electrical resistivity of less than $10^{12}\ \Omega$cm)
2. Electrostatic painting (which requires the material to be painted to have enough electrical conductiv-

ity – an electrical resistivity below $10^6\,\Omega$cm – to prevent the charged paint droplets from being repelled)
3. Electromagnetic interference shielding (which is achieved for an electrical resistivity of less than $10\,\Omega$cm).

Materials are often required to be multifunctional; for example, to have both high electrical conductivity and high toughness, or high thermal conductivity and high thermal stability. An association of several materials, each of them bringing one of the desired features, generally meets this need. The exceptional features and properties of CNTs make them likely to be a perfect multifunctional material in many cases. For instance, materials used in satellites are often required to be electrically conductive, mechanically self-supporting, able to transport away excess heat, and often to be robust against electromagnetic interference, while being of minimal weight and volume. All of these properties should be possible with a single nanotube-containing composite material instead of complex multimaterials combining layers of polymers, aluminum, copper, and so on. Table 8.3 provides an overview of various fields in which nanotube-based multifunctional materials should find application.

8.7 Current Applications of Carbon Nanotubes (on the Market)

Perfect CNTs exhibit high aspect ratio, high tensile strength, low mass density, high heat conductivity, large surface area, poor chemical reactivity, and versatile electronic behavior, including high electron conductivity. However, while these are the main characteristics of individual nanotubes, many of them can form secondary structures such as ropes, fibers, papers, and thin films with aligned tubes, all with their own specific properties. These properties make them potential candidates for a nearly infinite variety of applications, regardless of their cost [8.375]. Cost is an issue, though, which strongly depends in first place on both the CNT type and quality and on the production process type (e.g., all semiconducting, high-quality SWNTs can cost ≈ 50 times more than gold to date (2016)!). Cost is also strongly affected by the modifications to be brought to production lines for being nanocompatible, as well as that of the specific studies for assessing potential public health issues all along the material/device life (i. e., from production to waste and recycling). All this can prevent a CNT-based material or device, although capable of superior performance, from reaching the market. Because of this, we only list below CNT-based applications which actually are on the market, and readers who are interested in the vast potentiality of CNTs may refer to other literature sources [8.375, 376].

8.7.1 Carbon Nanotubes and Master Batches

Carbon nanotubes have become commercial products by themselves, for supplying research laboratories and start-ups. Table 8.4 provides a list of CNT-selling companies around the world. This list was probably nonexhaustive, and is certainly already partly obsolete, and partly incomplete. Examples of current price ranges are provided in the various sub-sections of Sect. 8.2.

Companies also (or instead) sell *CNT master batches*, i. e., premixed CNT-polymers for instance, or transformed products containing nanotubes (e.g., sheets, tapes, yarns, etc.) to be subsequently used by the buyer as starting materials for fabricating parts and devices for their own uses or for final products to sell.

8.7.2 Near-Field Microscopy Probes

The high mechanical strength and aspect ratio of carbon nanotubes makes them almost ideal candidates for use as force sensors in scanning probe microscopy (SPM). They provide higher durability, low sensitivity to electrostatic charges, and the ability to image surfaces with a high lateral resolution, with respect to conventional (ceramic-based) force sensors. The idea was first proposed and tested by *Dai* et al. [8.377] using c-MWNTs. Although it was extended to SWNTs by *Hafner* et al. [8.378], commercial nanotube-based probes use MWNTs for processing convenience. CNT-based SPM tips also offer the potential to be functionalized, leading to the prospect of selective imaging based on chemical discrimination in *chemical force microscopy* (CFM), allowing the chemical mapping of molecules [8.379, 380]. CNT-based SPM tips are not drawback-free, however. They may generate specific image artifacts (e.g., *ringing* effect), and exhibit highly variable geometry and alignment from a tip to another even within the same probe batch and brand. Current nanotube-based SPM tips or high-resolution AFM tips can be quite expensive, in the range of ≈ 450 \$/tip on the average, depending on the geometrical characteristics and the supplier (CDI, NanoSensors). The market for nanotube AFM tips is growing, and was estimated to reach $\approx 150\,$M€/yr in 2016.

Table 8.4 Listing of companies selling nanotubes (all types included) around the world (2015 data)

8.7.3 Electron Emitter

In a pioneering work by *de Heer* et al. [8.381], CNTs were shown to be efficient field emitters. Briefly, a potential difference is set up between the emitting tip(s) and an extraction grid (or an anode) so that electrons are pulled from the tip(s) onto an electron-sensitive screen layer. With respect to regular (Mo, doped-Si, W) electron-emitting tips, the structural perfection of CNTs is supposed to provide higher electron emission stability, higher mechanical resistance, longer lifetimes, and $1/3-1/10$ lower energy consumption (for example, nanotubes are able to produce a current density of $1\,\mathrm{mA/cm^2}$ for a threshold voltage of $3\,\mathrm{V/\mu m}$, while regular Mo or Si tips require $100\,\mathrm{V/\mu m}$). Generally speaking, the maximum current density that can be obtained with CNTs ranges from 10^6 to $10^8\,\mathrm{A/cm^2}$ depending on the nanotubes involved (SWNT or MWNT, opened or capped, aligned or not, and so on) [8.382–384]. Those properties have made CNTs potential candidates for a variety of applications, yet comprising two categories: (i) those in which electron emitters are displayed by thousands according to a periodic pattern, as for flat panel displays for television sets and computers, and (ii) those merely requiring a single electron-producing cathode, as for x-ray sources, and electron sources for electron microscopes. In spite of the potentiality of CNTs in this field and the convincing existence of demonstrators and prototypes (by Samsung, for instance), no applications within the former categories have reached the market so far, indicating that some cost and/or technological issues are yet to be fixed. Conversely, regarding the latter category, companies such as Oxford Instruments and Medirad have commercialized miniature x-ray generators for medical applications which use nanotube-based cold cathodes developed by Applied Nanotech Inc. Also, a new cold-field emission gun for electron microscopes based on a single, small-diameter MWNT (yet thickened into a cone in order to prevent the CNT from vibrating while emitting, which is a fatal drawback for the quality of the emitted beam) is currently under development at Hitachi High Technologies (Japan) based on work carried out at the University of Toulouse (France) [8.385].

8.7.4 Flexible and Touch-Screen Displays

Nowadays, the majority of touch-screen displays in smartphones and tablets are made of Indium Tin Oxide (ITO) transparent conductive electrodes which are brittle and thus unusable for flexible displays. Chemically doped polymers exhibit both significant electrical conductivities and flexibility but demonstrate undesirable optical transmittance over the visible region [8.386]. Owing to their very high aspect ratio, CNTs increase the electrical conductivity of polymer composites with a very low percolation threshold and allow the fabrication of transparent conductive CNT-polymer films. Commercial developments by Eikos resulted in SWNT-polymer films with optoelectronic performances (90–97% visible-light transmittance and $200-500\,\Omega/\mathrm{square}$ sheet resistance) very close to ITO [8.387]. Moreover, CNTs can be deposited by cost-effective solution-based processes, a supplementary advantage over ITO coatings produced by sputtering at low pressure [8.388].

8.7.5 Nonvolatile Random Access Memory

Nonvolatile random access memories (NRAM) have recently been developed by Nantero, based on a concept by *Rueckes* et al. [8.389] which exploits a suspended SWNT crossbar array for both I/O and switchable, bistable device elements with well-defined OFF and ON states. This crossbar consists of a set of parallel SWNTs on a substrate and a set of perpendicular SWNTs that are suspended on a periodic array of supports. Each cross point in this structure corresponds to a device element with an SWNT suspended above a perpendicular nanowire. For practical manufacturing purposes, the actual switches do not rely on single SWNTs but rather on a random mesh of hundreds of SWNTs with many different intersection points (thin film of tangled CNTs patterned on silicon substrate). The devices reach switching speeds of 100 to 200 GHz, operate at orders of magnitude more cycles than flash memories, and present lower power consumption compared to dynamic random access memories (RAMs).

8.7.6 Light Absorbants

Optical properties of carpet-like deposits of CNTs (Fig. 8.15c) are being used by Surrey NanoSystems to create and sell a coating called Vantablack absorbing 99.6% of light, which is useful in optical devices for instance. Hence it is not a painting, but it is claimed to be the darkest black *color* available. This has attracted the interest of various artists to such an extent that a British (and rich) one, Anish Kapoor, bought in 2016 the exclusive rights to use Vantablack for artistic purposes. However, Frederic De Wilde, a Belgian artist, claims anteriority with a coating named NANOblck-Sqr#1, also based on CNTs, jointly developed by Rice University and NASA for the fabrication of materials with light-adsorbing surfaces.

8.7.7 Automotive and Aeronautic Industry

As reported in Sect. 8.6.3, CNTs increase the electrical conductivity of polymer composites at very low percolation threshold (below 1 wt%) due to their high aspect ratio. In the automotive industry, this property is used to enable electrostatic-assisted painting of polymer parts such as mirror housings and bumpers [8.376]. Since 2009, BASF has produced a CNT-polyoxymethylene composite fuel filter housing for the Audi A4 and A5. The high conductivity of the composite allows suppression of electrostatic charging and sparking as fuel flows through the filter. Moreover, this material is more creep-resistant than conventional polyoxymethylene and less costly than other conductive polymer composites. CNT-polymer composites are also widely used as anticorrosion coatings for metals. CNTs enhance mechanical and tribological properties of coatings while providing an electric pathway for cathodic protection [8.390]. Solvent-based zinc, aluminium and magnesium CNT-epoxy/polyamide paints for primer anticorrosion coatings were designed by Tesla Nanocoatings. CNT sheets are used in the aerospace industry to protect polymer composites against electrostatic discharge (ESD), to protect electronic components against electromagnetic interference (EMI), and to create honeycomb structures with higher stiffness than aluminum with virtually no thermal expansion, reduced weight, and improved vibrational damping properties.

8.7.8 High-Tech Goods and Clothes

Enhancement in damping ratios of CNT-polymer composites (up to 700% for MWNT-epoxy composites [8.337]) is used to improve sporting goods like baseball bats, tennis and badminton racquets, hockey sticks, racing bicycles, golf balls/clubs, skis, fly-fishing rods, and archery arrows. Easton Sports, manufacturer of sporting goods, moved new markets from wood and steel sports equipment to lightweight, high-strength CNT-polymer products. Considering the still-current difficulty of dispersing CNTs in polymers well, which is likely to generate flaws in the material from a mechanical point of view, one might wonder whether the improvement is real, or whether a minimized amount of CNTs is merely added to take benefit of the mediatic impact of using new and high-tech materials.

Far from sport issues yet a serious matter nowadays, CNT sheets are applied in light armors and projectile-protection wearables reducing the weight of the finished products. For instance, bullet-proof vests as manufactured by China Xingxing Guangzhou Imp. & Exp. Corp. (China) or AR500 Armor (USA) can weigh 25% less than their Kevlar-based equivalents, at lower cost.

8.7.9 Anodes for Li-Ion Batteries

A Li-ion battery is composed of three main components, the anode intercalated with Li^+ ions, the cathode, and the electrolyte. During charging and discharging cycles Li^+ ions diffuse between the anode and cathode through the electrolyte which is typically a lithium salt dissolved in an organic solvent. Graphite has long been the preferred anode material for commercial batteries due to its relatively high capacity, energy storage density, good cyclability, and a low redox potential for lithium. The capacity of graphite in Li-ion batteries is limited by the number of Li ions that can intercalate between individual graphene layers. Assuming a maximum of 1 Li atom for every 6 carbon atoms (LiC_6) one obtains a theoretical maximal capacity of $372\,mA\,hg^{-1}$ [8.391]. Owing to their high aspect ratio, high specific surface and high conductivity, CNTs have been shown to be excellent conductive additives for Li-ion batteries [8.392]. Li-ion storage capacity in CNTs results from the availability of the central core of the tube, the interlayer space (for MWNTs), and the interstitial space between CNTs when they are assembled in bundles [8.393]. The measured reversible Li-ion capacities for CNT-based anodes can exceed $1000\,mA\,hg^{-1}$, which is a 3-fold improvement over conventional graphite anodes [8.394]. The addition of CNTs on the graphite anode can also efficiently improve rate capability and cyclability of the resulting CNT-graphite composite electrodes [8.395]. For example, the cyclic efficiency of a graphite anode was maintained at almost 100% for up to 50 cycles by adding 10 wt% MWNTs [8.396]. CNTs are thus widely used as anode additives in commercial Li-ion batteries and more than 50% of mobile phones and notebook batteries contain CNTs [8.395]. Several CNT-producing companies such as ANS, BlueNano, Showa Denko K.K and Ube Industries provide CNT-based powders for battery electrodes.

8.7.10 Chemical Sensors

The development of CNT-based sensors has attracted intensive interest in the last several years because of their excellent sensing properties such as prompt response and high selectivity for a wide variety of analytes with detection limits reaching ppb levels [8.397, 398]. Different kinds of gas/chemical sensors, based on different working principles, have been fabricated thanks to CNTs: miniaturized ionizing gas sensors (also called *microgun* sensors), CNT thin films with variable resistance as a function of the adsorbed gas properties (chemiresistors), and CNT field-effect transistor (FET)-based sensors [8.399]. To overcome some of

the limitations posed by pristine CNT sensors (lack of specificity to different gaseous analytes, and low sensitivity towards analytes that have no affinity to CNTs), functionalization of CNTs with various methods was considered, and with a wide spectrum of materials such as conducting polymers and metal nanoparticles [8.397].

The commercialization of nanoenabled sensors is in the early stages. Research efforts are still needed in particular to control the reproducibility and specificity (chirality, diameter, and length) of commercial CNT batch characteristics [8.400, 401]. CNT-based sensors are currently being developed by large and small companies, mainly in the USA. Nanomix Incorporated (California, USA) has commercialized a CNT-based nanosensor for hydrogen detection (operating range of 2000–20 000 ppm, which is 5–50% of the lower explosive limit for hydrogen). NASA Ames Research Center is developing a low-power-consumption gas sensor based on coated (e.g., with chlorosulfonated polyethylene) or decorated (e.g., with Pd, Pt, Au, Cu, and Rh nanoparticles) SWNTs, so far tested for NO_2, NH_3, CH_4, Cl_2, HCl, toluene, benzene, acetone, formaldehyde, and nitrotoluene. Northeastern's Center for High-rate Nanomanufacturing has developed a simple and highly sensitive multibiosensor containing semiconductor SWNTs that are enzyme-immobilized for detecting D-glucose, L-lactate, and urea in sweat. The core technology platform developed by Nano Engineered Applications, Inc. (Riverside, California) is a gas sensor using SWNTs and solid-state electrical sensing, capable of real-time detection of airborne gases at the ppb level. Sensigent (Baldwin Park, California) chemical sensing technology includes CNT-based nanosensors with high sensitivity and selectivity for small molecule gases. Design West Technologies, Inc., (Southern California) proprietary CNT technology can be incorporated into existing chemical detector products as standalone chemical sensors or as a supporting orthogonal technology to detect various chemical vapors. C2Sense (Cambridge, MA) aims to provide sensors for meat spoilage detection in smart packaging. The sensing material is based on CNTs, which are functionalized with proprietary selector materials. Brewer Science (Rolla, Missouri) developed a fully integrated temperature and humidity sensor based on highly purified aqueous-based SWNT ink. It is capable of providing real-time simultaneous measurement of the temperature and rapid fluctuations of humidity in a surrounding environment.

8.7.11 Catalyst Support

Carbon-based materials make good supports in heterogeneous catalytic processes due to their ability to be tailored to the specific needs, such as high surface area, high amount of mesopores, good stability at high temperatures (under nonoxidizing atmospheres), and the possibility of controlling the chemical nature of their surfaces [8.402]. Nanosized carbon fibrous morphologies have appeared over the last decade, which show great potential for use as supports [8.403] superior to regular ones such as activated carbon, carbon blacks, or graphite [8.404]. The field of catalysis to which the specific features of CNTs could bring the most significant advancements is perhaps the oxygen reduction reaction in fuel cell electrocatalysis. Carbon materials with both high surface area and good crystallinity such as CNTs not only provide a high dispersion of the catalyst (Pt) nanoparticles, but also limit carbon oxidation at high potentials, and facilitate electron transfer, resulting in better device performance [8.405]. Moreover, CNTs have a positive effect on Pt structure, resulting in a higher catalytic activity and a higher stability than with carbon black supports [8.406]. In that sense, CNTs offer great promise for overcoming the problems of existing fuel cells, such as Pt loading. However, a problem for the commercialization of CNT-based electrodes is their higher cost compared to that of carbon blacks.

Currently, Bing Energy Inc. (Tallahassee, Florida) has commercialized a proton-exchange membrane fuel cell, comprised of highly conductive CNT buckypaper coated with Pt nanoparticles, which was developed at Florida State University to improve membrane manufacturing processes, fuel cell efficiency, and lifetime.

8.8 Toxicity and Environmental Impact of Carbon Nanotubes

It is first very important to consider that the large variety of CNTs (SWNT, DWNT, MWNT, hetero-CNTs, hybrid CNTs, etc.) and of synthesis routes (arc discharge, laser ablation, CCVD, ...) as well as the lack of standardized testing procedures make the investigation of the toxicity of CNTs very difficult, and the comparison of the already published results almost impossible [8.407]. CNTs are mostly found as bundles rather than as individual objects, or more likely as large micrometric agglomerates. All CNT materials contain various levels of residual catalyst(s), depending on the synthesis route and purification steps they have been subjected to. Usual purification treatments involve the combination of acids and oxidizing agents, which

leads to partial functionalization of the outer wall, making the treated samples more hydrophilic. SWNTs and DWNTs usually form long and flexible bundles (typically hundreds of micrometers long) whereas MWNTs are generally shorter (tens of micrometers) and more rigid. MWNTs also have generally more surface defects, which enhances their chemical reactivity. The specific surface area can range from a few tens of m^2/g in the case of densely packed MWNTs to nearly $1000\,m^2/g$ in the case of SWNTs and DWNTs (the theoretical limit being $\approx 1300\,m^2/g$ in the case of individual closed SWNTs). This is a very important parameter as the surface area has recently been shown to be the most relevant metric for the comparison of different carbon nanoparticles, even with very different morphologies [8.408].

The main exposure routes for dry CNTs are inhalation and dermal contact (also possible in the case of suspensions). Ingestion is generally not considered (would be accidental), although it is in fact more or less related to inhalation. In the case of suspensions, the main issue concerns their stability. This question has been widely studied worldwide and the general approach is the addition of a surfactant in order to stabilize the CNTs in the liquid. The main problem is that all commonly used surfactants are toxic to a certain extent and thus cannot be used in the presence of living cells or animals for in vivo or in vitro investigations, or at such low concentrations that really they no longer play the role they are supposed to play. Although a few natural surfactants have been investigated, the stability of the suspensions in the presence of living organisms is often very different (fast destabilization leading to flocculation). Injection in the bloodstream is envisaged, but would not be accidental (biological applications such as imaging, targeted cell delivery, hyperthermia, etc.). After the CNTs have entered the body, they could travel following different routes depending on the entry point (movements from one organ to another are called translocation) but also mainly on their physicochemical characteristics. Objects recognized as nonself by the immune system usually end up in the liver or the kidneys if they can be transported there, and could possibly be excreted (eliminated) from the body. In the general case, CNTs will just accumulate (biopersistance). They are usually intercepted by macrophages (cells present in all tissues and whose role is to phagocyte (engulf and then digest – when this is possible) cellular debris and pathogens as well as to stimulate lymphocytes and other immune cells to respond to the pathogens). Taking into account the small size of macrophages as compared to that of agglomerates, bundles or even individual CNTs, macrophages usually do not manage to get rid of the CNTs by phagocytose. However, they try to do so and thus release reactive oxygen species, enzymes, cytokines (interferons), etc. and agglomerate around them to isolate them from the body. Proteins present in blood and most of the biological fluids (complement system – innate immunity) will play a similar role by *labeling* the CNTs (opsonization) and possibly generating some inflammatory reactions. The complement system strongly interacts with the lymphocytes. These natural phenomena have deleterious consequences on the surrounding tissues: inflammation in a first instance, formation of granuloma (commonly observed in the lungs after exposure to CNTs). Each target organ has its own phagocyte cells (Kupffer cells in the liver, Langerhans cells in the skin, etc.).

Toxicity can be assessed both by in vitro and in vivo experiments. In the case of in vitro assays, cell cultures (usually immortalized cancer cells, but also primary cultures or even stem cells) are exposed to suspensions of CNTs. In the case of in vivo assays, the animals (mice, rats, worms, amphibians, fishes, etc.) are exposed either to aerosols (inhalation) or mainly again to suspensions of CNTs which will be administrated according to different protocols depending on the study (intratracheal instillation, injection, contact with the skin, etc.). Extrapolating the toxicity results from animals (or even worse, from cells) to humans is very delicate but the data are however very useful for the sake of comparison in a given system and with given experimental conditions. As soon as CNTs are in contact with a biological fluid, their surface chemistry is likely to be modified very quickly by adsorption of proteins (complement system, surfactants [8.409], etc.); this adsorption can be very specific [8.408, 409], and is likely to be dynamic and controlled by the affinity of the molecules for the surface of the CNTs (pristine or functionalized). It is thus obvious that the surface chemistry of the CNTs will play a very important role.

The potential use of CNTs in commercial products (Sect. 8.7) begs the question of their fate at the end of their lifecycle. If the impact of CNTs on human health has been under investigation for a few years already, it is noteworthy that environmental impact has only scarcely been taken into account. Only a few publications (less than 80) are available to date and the concentration at which ecotoxic effects are evidenced is in most cases much higher than what could be reasonably found in the environment (unless very local and specific conditions apply). Because of the potentially very high specific surface area of CNTs, they could act as vectors for pollutants adsorbed on their surface (polycyclic aromatic hydrocarbons or heavy metal ions, for example), even if themselves do not show any obvious sign of toxicity.

There is currently no consensus about the toxicity of CNTs [8.407], although about 600 papers have al-

ready been published on this topic within the last 5 years (2016 data). Despite the worldwide efforts devoted to this field of research, the huge variety of CNT types, shapes, composition, etc. still makes it very difficult to answer this simple question: *are CNTs toxic*? The *principle of precaution* should not stop all research in this area but only draw attention to a more responsible attitude for people working on their synthesis or manipulating them, and for industries willing to include them in consumer products. Gloves should be worn at all times as well as an adapted (FFP3 (filtering facepiece protection class 3) type) disposable dust mask. Wearing a lab coat is recommended to limit contamination of clothes, and CNT wastes should be burnt.

8.9 Concluding Remarks

Carbon nanotubes have been the focus of a lot of research work (and therefore a lot of funding) for more than two decades now. Although some experts initially predicted the same disappointment that followed the *fullerene era* (originally believed to be so promising, but which has resulted in no significant applications to date, in spite of a considerable investment of time and money), it is clear that applications including carbon nanotubes are now coming onto the market. It took time indeed, but that is the price to pay when introducing a new material into technology. It is an almost general rule, which accounts for the time needed for production lines to reach the requested mass-scale, reproducibility, reliability, and economic viability according to industrial standards. Taking the example of carbon fibers, first developed in the 1960s, how long did it take to see them in mass consumption, high-tech products (besides sporting goods, for which cost is less of an issue)? It is happening only now, as commercial planes (A350 from Airbus, Dreamliner from Boeing) incorporate significant amounts of carbon fibers in their structures, whereas previously only the military field had been able to afford the benefits of such a technological jump. Despite this, carbon fibers have not yet reached the general automobile field, except for luxury or race cars. In addition, carbon nanotubes have a supplementary drawback: they deal with a nano-world that most existing industrial plants are not familiar with, and not designed for. That is why most applications are currently being taken to the market by start-ups, and it will take time for those to reach economic reliability and expand to become major companies. But some will.

What are the perspectives for carbon nanotubes? They are quite positive, and it is not being overoptimistic to say so: nanotubes exhibit an extraordinary diversity of morphologies, textures, structures and nanotextures, far beyond that provided by fullerenes, and now graphene. As most of their properties have now been experimentally studied or predicted, research should focus on solving the problems related to their incorporation into the tremendous variety of devices and materials that would benefit from the CNT technology. In this regard, considering the nanotube-based nano-objects and composites described in Sect. 8.5 and Sect. 8.6 is of primary importance. Of course, this comes with some uncertainty regarding the potential toxicity related to CNTs at various points of their life cycle, but this issue concerns all nanomaterials in general, and is the most critical challenge upon which the future of nanotechnologies depends.

9. Nanowires

Mildred S. Dresselhaus, Marcie R. Black, Vincent Meunier, Oded Rabin

This chapter provides an up-to-date overview of research on inorganic nanowires, particularly metallic and semiconducting nanowires. Nanowires are one-dimensional, anisotropic structures, small in diameter, and large in surface-to-volume ratio. Their physical properties are different than those of structures of other scales and dimensionality. While the study of nanowires is particularly challenging, scientists have made immense progress in developing synthetic methodologies for the fabrication of nanowires, developing instrumentation for their characterization, and incorporating nanowires as functional elements in advanced materials and devices. The chapter is divided into three main sections addressing the synthesis, the physical properties, and the applications of nanowires. Yet, the reader will discover many links that make these aspects of nanoscience intimately interdependent.

9.1 **Synthesis** 250
9.1.1 Template-Assisted Synthesis 250
9.1.2 VLS Method for Nanowire Synthesis 255
9.1.3 Etching Methods 257
9.1.4 Other Synthesis Methods 258
9.1.5 Nanowire Alignment and Superstructures of Nanowires 260
9.2 **Characterization and Physical Properties of Nanowires** 262
9.2.1 Structural Characterization 262
9.2.2 Mechanical Properties 266
9.2.3 Transport Properties 267
9.2.4 Optical Properties 277
9.3 **Applications** 282
9.3.1 Electrical Applications 282
9.3.2 Optical Applications 284
9.3.3 Energy Applications 286
9.3.4 Chemical and Biochemical Sensing Devices 288
9.3.5 Magnetic Applications 289
9.4 **Concluding Remarks** 290
References 290

Nanowires are attracting much interest from those seeking to apply nanotechnology and (especially) those investigating nanoscience. Nanowires, unlike other low-dimensional systems, have two quantum-confined directions but one unconfined direction available for electrical conduction. This allows nanowires to be used in applications where electrical conduction, rather than tunneling transport, is required. Because of their unique density of electronic states, in the limit of small diameters nanowires are expected to exhibit significantly different optical, electrical, and magnetic properties to their bulk three-dimensional (3-D) crystalline counterparts. Increased surface area, very high density of electronic states and joint density of states near the energies of their van Hove singularities, enhanced exciton binding energy, diameter-dependent bandgap, and increased surface scattering for electrons and phonons are just some of the ways in which nanowires differ from their corresponding bulk materials. Yet the sizes of nanowires are typically large enough (> 1 nm in the quantum-confined directions) to result in local crystal structures that are closely related to their parent materials, allowing theoretical predictions about their properties to be made based on knowledge of their bulk properties.

Not only do nanowires exhibit many properties that are similar to, and others that are distinctly different from, those of their bulk counterparts, nanowires also have the advantage from an applications standpoint that material parameters critical for certain properties can be independently controlled in nanowires but not in their bulk counterparts. Certain properties can also be enhanced nonlinearly in small-diameter nanowires, by exploiting the singular aspects of the one-dimensional (1-D) electronic density of states.

Furthermore, nanowires have been shown to provide a promising framework for applying the *bottom-up*

approach [9.1] to the design of nanostructures for nanoscience investigations and for potential nanotechnology applications.

Driven by (1) these new research and development opportunities, (2) the smaller and smaller length scales now being used in the semiconductor, optoelectronics, and magnetics industries, and (3) the dramatic development of the biotechnology industry where the action is also at the nanoscale, the nanowire research field has developed with exceptional speed in the last decade. Therefore, a review of the current status of nanowire research is of significant broad interest at the present time. It is the aim of this review to focus on nanowire properties that differ from those of their parent crystalline bulk materials, with an eye toward possible applications that might emerge from the unique properties of nanowires and from future discoveries in this field.

For quick reference, examples of typical nanowires that have been synthesized and studied are listed in Table 9.1. Also of use to the reader are review articles that focus on a comparison between nanowire and nanotube properties [9.2] and the many reviews that have been written about carbon nanotubes [9.3–5], which can be considered as model one-dimensional systems.

9.1 Synthesis

In this section we survey the most common synthetic approaches that have successfully afforded high-quality nanowires of a large variety of materials (Table 9.1). In Sect. 9.1.1, we discuss methods that make use of various templates with nanochannels to confine the nanowire growth in two dimensions. In Sect. 9.1.2, we present the synthesis of nanowires by the vapor–liquid–solid mechanism and its many variations. In Sect. 9.1.3, etching methods for vertically aligned silicon nanowires are reviewed. In Sect. 9.1.4, examples of other synthetic methods of general applicability are presented. The last part of this section (Sect. 9.1.5) features several approaches that have been developed to organize nanowires into simple architectures.

9.1.1 Template-Assisted Synthesis

The template-assisted synthesis of nanowires is a conceptually simple and intuitive way to fabricate nanostructures [9.67–69]. In this context, templates are synthetic or naturally occurring host materials that contain small-diameter cylindrical pores or voids. These empty volumes are filled with a material of choice, which adopts the pore morphology, to form nanowires. In this section, commonly used templates and techniques for filling the templates to make nanowires are described.

Templates and Fabrication Thereof

In template-assisted synthesis of nanostructures, the chemical stability and mechanical properties of the template, as well as the diameter, uniformity, and density of the pores are important characteristics to consider. Templates frequently used for nanowire synthesis include anodic alumina (Al_2O_3) and ion-track–etched polymer films. Both are commercially available (as filtration membranes). Nanochannel glass, mica films, mesoporous materials, block-copolymers, inorganic nanotubes, viruses, and biopolymers have also been used as nanowire templates.

Porous anodic alumina templates are produced by anodizing pure Al films in selected acids [9.70–72]. Under carefully chosen anodization conditions, the resulting oxide film possesses a regular hexagonal array of parallel and nearly cylindrical channels, as shown in Fig. 9.1a. The self-organization of the pore structure in an anodic alumina template involves two coupled processes: pore formation with uniform diameters and pore ordering. The pores form with uniform diameters because of a delicate balance between electric field–enhanced diffusion, which determines the growth rate of the alumina, and dissolution of the alumina into the acidic electrolyte [9.73]. The pores self-order because of mechanical stress at the aluminum-alumina interface due to volume expansion during the anodization process. This stress produces a repulsive force between the pores, causing them to arrange in a close-packed lattice [9.74]. Depending on the anodization conditions, the pore diameter can be systematically varied from ≤ 10 up to 200 nm with a pore density in the range of 10^9–10^{11} pores/cm^2 [9.22, 34, 70, 71]. It has been shown by many groups that the pore size distribution and the pore ordering of the anodic alumina templates can be significantly improved by a two-step anodization technique [9.75–77], where the aluminum oxide layer is dissolved after the first anodization in an acidic solution followed by a second anodization under the same conditions. Alternatively, the locations of the pores can be controlled by pretexturing the surface of the aluminum [9.78, 79].

Track-etched polymer foils are nanowire templates produced by bombardment of polymer films in a heavy-ion accelerator followed by chemical etching [9.81]. The ion-beam bombardment creates latent tracks of

damage in the polymer. These areas are susceptible to chemical etch and can be selectively removed to create hollow channels [9.82]. This technique offers control over pore size, pore aspect ratio, pore shape, and pore density; however, the pores are randomly distributed. Track-etched polycarbonate membranes (Fig. 9.1b) are economical, easy to handle, and dissolve in organic solvents [9.83, 84]. The track-etching technique can be applied also to hard materials: irradiated single-crystal mica films etched with hydrofluoric acid afford nanochannels of diamond-shaped cross-section in a refractory host material [9.48].

Other porous materials can be used as host templates for nanowire growth, as discussed by *Ozin* [9.67]. Nanochannel glass (NCG), for example, contains a regular hexagonal array of glass capillaries similar to the pore structure in anodic alumina with a packing density as high as 3×10^{10} pores/cm^2 [9.68]. Porous Vycor glass that contains an interconnected network of pores less than 10 nm was also employed for the early study of nanostructures [9.85]. The nanochannel array template with the smallest pore diameter may have been identified in mesoporous molecular sieves termed MCM-41 [9.86] that possess hexagonally packed pores with very small channel diameters, which can be varied between 2 and 10 nm. Conducting organic filaments have been fabricated in the nanochannels of MCM-41 [9.87].

Templates for nanowire growth can be produced also using diblock copolymers, polymers that consist of two chain segments of different chemistries covalently linked to each other. When the two components are immiscible in each other, phase segregation occurs, and depending on their volume ratio, spheres, cylinders, or lamellae may self-assemble. To form self-assembled arrays of nanopores:

1. The block copolymer must adopt the cylinder morphology.
2. The cylinders must be parallel and oriented perpendicular to the surface.
3. The component in the cylinders must be etched away selectively.

With polystyrene and polymethylmethacrylate (PMMA) block copolymers (P(S-b-MMA)), by applying an electric field while the copolymer was heated above the glass transition temperature of the two constituent polymers, the self-assembled cylinders of PMMA could be aligned with their main axis perpendicular to the film [9.88]. Selective removal of the PMMA component afforded the preparation of 14 nm-diameter ordered pore arrays with a packing density of 1.9×10^{11} cm^{-3}.

To conclude the list of templates used to fabricate nanowires, we note efforts to utilize biology for the task. Biological systems can produce high-aspect-ratio structures with remarkably consistent dimensions and in high volumes. Coating these filamentous structures with inorganic materials results in useful nanowires. But unlike with the porous templates described above, the nanowire growth is not restricted in any direction; and diameter control is implemented through the process conditions. Additionally, the organic material remains trapped inside the nanowire. For example, the DNA molecule has been used as a template for growing nanometer-sized wires [9.7], as were M13 bacteriophages and the tobacco mosaic virus [9.89–92].

Nanowire Template-Assisted Growth by Pressure Injection

The pressure injection technique can be employed for fabricating highly crystalline nanowires from a low-melting point material in porous templates with robust mechanical strength. In the high-pressure injection method, the nanowires are formed by pressure-injecting the desired material in liquid form into the evacuated pores of the template. Due to the heating and pressurization processes, the templates used for the pressure injection method must be chemically stable and be able to maintain their structural integrity at high tempera-

tures and at high pressures. Anodic aluminum oxide films and nanochannel glass are two typical materials used as templates in conjunction with the pressure-injection filling technique. Metal nanowires (Bi, In, Sn, and Al) and semiconductor nanowires (Se, Te, GaSb, and Bi_2Te_3) have been fabricated in anodic aluminum oxide templates using this method [9.21, 56, 93].

The pressure P required to overcome the surface tension for the liquid material to fill pores with a diameter d_W is determined by the Washburn equation [9.94]

$$d_W = -4\frac{\gamma \cos\theta}{P} ,$$

where γ is the surface tension of the liquid, and θ is the contact angle between the liquid and the template. To reduce the required pressure and to maximize the filling factor, some surfactants are used to decrease the surface tension and the contact angle. For example, the introduction of Cu into the Bi melt can facilitate the filling of the pores in the anodic alumina template with liquid Bi and can increase the number of nanowires that are formed [9.22]. However, some surfactants might cause contamination problems and should therefore be avoided. Nanowires produced by the pressure-injection technique usually possess high crystallinity and a preferred crystal orientation along the wire axis. For example, Fig. 9.2 shows the x-ray diffraction (XRD) patterns of Bi nanowire arrays of three different wire diameters with an injection pressure of ≈ 5000 psi [9.93], showing that the major ($> 80\%$) crystal orientation of the wire axis in the 95 and 40 nm diameter Bi nanowire arrays are, respectively, normal to the (202) and (012) lattice planes, which are denoted by $[10\bar{1}1]$ and $[01\bar{1}2]$ when using a hexagonal unit cell, suggesting a wire diameter–dependent crystal growth direction. On the other hand, 30 and 200 nm Bi nanowires produced using a much higher pressure of $> 20\,000$ psi show a different crystal orientation of (001) along the wire axis [9.23], indicating that the preferred crystal orientation may also depend on applied pressure, with the most dense packing direction along the wire axis for the highest applied pressure.

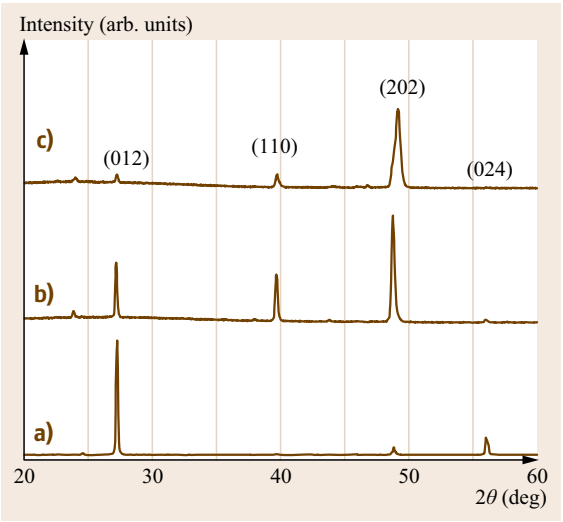

Fig. 9.2a–c XRD patterns of bismuth/anodic alumina nanocomposites with average bismuth wire diameters of **(a)** 40 nm, **(b)** 52 nm, and **(c)** 95 nm [9.93]. The Miller indices corresponding to the lattice planes of bulk Bi are indicated above the individual peaks. The majority of the Bi nanowires are oriented along the $[10\bar{1}1]$ and $[01\bar{1}2]$ directions for $d_W \geq 60$ nm and $d_W \leq 50$ nm respectively (after [9.22, 93]). The existence of more than one dominant orientation in the 52 nm Bi nanowires is attributed to the transitional behavior of *intermediate*-diameter nanowires as the preferential growth orientation is shifted from $[10\bar{1}1]$ to $[01\bar{1}2]$ with decreasing d_W

Electrochemical Deposition

The electrochemical deposition (ECD) technique has attracted increasing attention as a versatile method for fabricating nanowires in templates. Traditionally, electrochemistry has been used to grow thin films on conducting surfaces. Since electrochemical growth is usually controllable in the direction normal to the substrate surface, this method can be readily extended to fabricate 1-D or 0-D nanostructures, if the deposition is confined within the pores of an appropriate template. In the electrochemical methods, a thin conducting metal film is first coated on one side of the porous membrane to serve as the cathode for electroplating. The length of the deposited nanowires can be controlled by varying the duration of the electroplating process. The ECD method has been used to synthesize a wide variety of nanowires, such as metals (Bi [9.18, 84]; Co [9.95, 96]; Fe [9.34, 97]; Cu [9.83, 98]; Ni [9.48, 95]; Ag [9.99]; Au [9.12]); conducting polymers [9.18, 80]; superconductors (Pb [9.100]); compound semiconductors (CdS [9.28]; Bi_2Te_3 [9.25]); and even superlattice nanowires with A/B constituents (such as Cu/Co [9.83, 98]) (Table 9.1). The ECD method offers a low-cost, low-temperature, and rapid approach to template-assisted nanowire synthesis.

In the ECD process, the chosen template has to be chemically stable in the electrolyte during the electroplating process. Cracks and defects in the templates are detrimental to nanowire growth, because deposition rates are higher in the more accessible cracks, leaving most of the nanopores unfilled. Particle-track–etched polymer membranes or mica films are typical templates used in ECD employing a direct current (DC). To use

anodic aluminum oxide films in DC ECD, the insulating barrier layer, separating the pores from the bottom aluminum substrate, has to be removed and a metal film is then evaporated onto the back of the template membrane [9.101]. At the end of the ECD in anodic alumina templates, the surfaces can be polished to even out the variations in nanowire length and reveal the ends of the nanowires. Figure 9.3 presents SEM images of cross-sectional views of a Bi_2Te_3 nanowire array electrodeposited in porous anodic alumina [9.25]. The light areas are associated with Bi_2Te_3 nanowires, the dark regions denote empty pores, and the surrounding gray matrix is alumina. Optimization of the electrochemical conditions and good laboratory practices result in high pore filling factors of close to 100% for ECD methods.

It is possible to employ an alternating current (AC) electrodeposition method in porous anodic alumina templates without the removal of the barrier layer, by utilizing the rectifying properties of the oxide barrier. In AC electrochemical deposition, although the applied voltage is sinusoidal and symmetric, the current is greater during the cathodic half-cycles (deposition current) than in the anodic half-cycles (stripping current). Since no current rectification occurs at defect sites lacking the barrier layer, the deposition and stripping rates are similar and material does not effectively deposit in cracks in the template. In this fashion, metals such as Co [9.96] and Fe [9.34, 97], and semiconductors such as CdS [9.28], have been deposited into the pores of anodic aluminum oxide templates without removing the barrier layer.

In contrast to nanowires synthesized by the pressure injection method, nanowires fabricated by the ECD process are usually polycrystalline, with no preferred crystal orientation, as observed by XRD studies. However, some exceptions exist. For example, anisotropy in crystal growth rates may result in polycrystalline nanowires having a preferred wire growth orientation [9.28]. In addition, *Xu* et al. have prepared a number of single-crystal II–VI semiconductor nanowire arrays, including CdS, CdSe and CdTe, by DC ECD in anodic alumina templates using nonaqueous electrolytes [9.27, 31]. Pulsed electrodeposition techniques can achieve or improve single-crystal nanowire array growth and orientation. The use of pulsed currents is believed to be advantageous for the growth of crystalline wires because the concentration of ions in the electrolyte inside the pores can recover in the period between the electrical pulses and therefore uniform deposition conditions can be produced for each deposition pulse. Single-crystal Ag and Pb nanowires were fabricated by pulse electrodeposition [9.8, 100].

One advantage of the ECD technique is the possibility of fabricating multilayered structures within nanowires. With electrolytes that contain two or more different metal ions, by varying the cathodic potential with time, different metal layers can be controllably

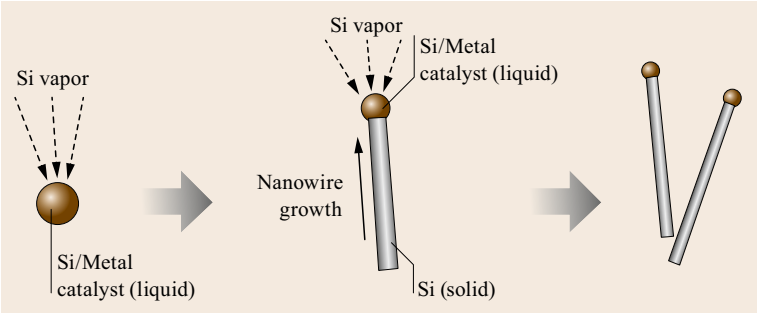

Fig. 9.5 Schematic diagram illustrating the growth of silicon nanowires by the VLS mechanism

deposited in sequence. Co/Cu multilayered nanowires have been synthesized in this way [9.83, 98]. Figure 9.4 shows transmission electron microscopy (TEM) images of a single Co/Cu nanowire about 40 nm in diameter [9.98]. The light bands correspond to Co-rich layers and the dark bands correspond to Cu-rich layers. This electrodeposition method provides a low-cost approach to preparing multilayered 1-D nanostructures.

Vapor Deposition

Vapor deposition of nanowires includes physical vapor deposition (PVD) [9.17], chemical vapor deposition (CVD) [9.38], metalorganic chemical vapor deposition (MOCVD) [9.41] and atomic layer deposition (ALD) [9.102]. Like electrochemical deposition, vapor deposition is usually capable of preparing smaller-diameter (≤ 20 nm) nanowires than pressure injection methods, since surface tension is typically not a barrier for inserting the material into the pores. The main challenge with these techniques is the deposition of material on the surface of the template blocking the pore openings before the pores are filled.

In the PVD process, the material for the nanowires is first vaporized by heat or other means, and is then introduced through the pores of the template and cooled to solidify. Using a specially designed experimental setup [9.17], nearly single-crystal Bi nanowires in anodic aluminum templates with pore diameters as small as 7 nm have been synthesized, and these Bi nanowires were found to possess a preferred crystal growth orientation along the wire axis, similar to the Bi nanowires prepared by pressure injection [9.17, 22].

In the CVD and ALD processes, reacting gas(es) decompose on the surface of the template to form elemental or compound materials. The decomposition is promoted by the CVD reactor temperature and/or a catalyst on the surface. For example, single-crystal GaN nanowires have been synthesized in anodic alumina templates through a gas reaction of Ga_2O vapor with a flowing ammonia atmosphere [9.37, 38]. Templates were filled with TiO_2 by ALD to produce an array of nanowires [9.102], but with high-aspect-ratio pores the ALD product is typically a conformal coating, that is to say, an array of nanotubes [9.103, 104]. A hybrid liquid-/gas-phase CVD approach has been used to prepare polycrystalline GaAs and InAs nanowires in a nanochannel glass array [9.41]. In this method, the nanochannels are filled with one liquid precursor (such as Me_3Ga or Et_3In) via a capillary effect and the nanowires are formed within the template by reactions between the liquid precursor and the other gas reactant (such as AsH_3).

9.1.2 VLS Method for Nanowire Synthesis

A significant number of notable modern syntheses of semiconductor nanowires are based on the so-called vapor–liquid–solid (VLS) mechanism of anisotropic crystal growth. This mechanism was first proposed for the growth of single-crystal silicon whiskers, 100 nm to hundreds of micrometers in diameter [9.105]. The proposed growth mechanism (Fig. 9.5) involves the absorption of source material from the gas phase into a liquid droplet of catalyst (a molten particle of gold on a silicon substrate in the original work [9.105]). Upon supersaturation of the liquid alloy, a nucleation event generates a solid precipitate of the source material. This seed serves as a preferred site for further deposition of material at the interface of the liquid droplet, promoting the elongation of the seed into a nanowire or a whisker, and suppressing further nucleation events on the same catalyst. Since the liquid droplet catalyzes the incorporation of material from the gas source to the growing crystal, the deposit grows anisotropically as a whisker whose diameter is dictated by the diameter of the liquid alloy droplet. The nanowires thus obtained are of high purity, except for the end containing the solidified catalyst as an alloy particle (Figs. 9.5 and 9.6a). Real-time observations of the alloying, nucleation, and elongation steps in the growth of germanium nanowires from gold nanoclusters by the VLS method were recorded by in-situ TEM [9.106].

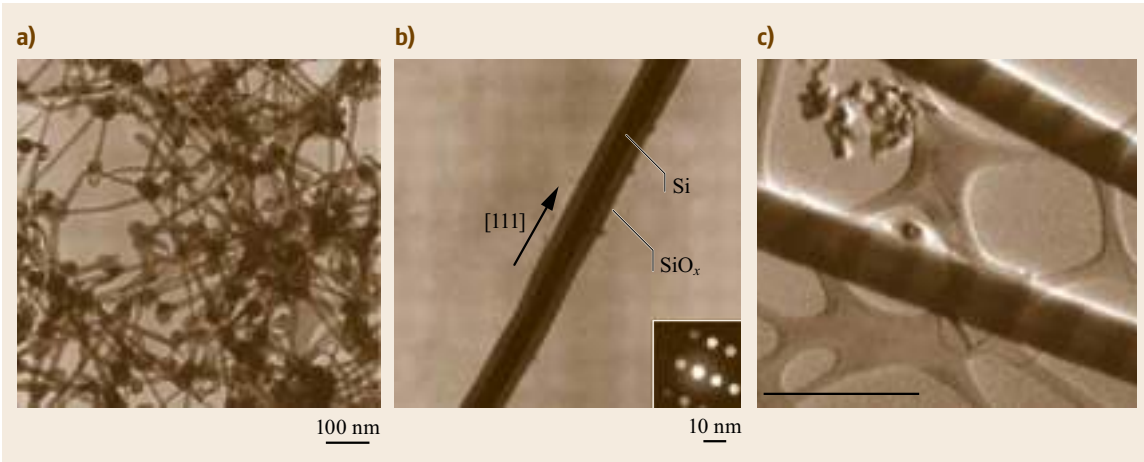

Fig. 9.6 **(a)** TEM images of Si nanowires produced after laser-ablating a $Si_{0.9}Fe_{0.1}$ target. The *dark spheres* with a slightly larger diameter than the wires are solidified catalyst clusters (after [9.58]). **(b)** Diffraction contrast TEM image of a Si nanowire. The crystalline Si core appears *darker* than the amorphous oxide surface layer. The *inset* shows the convergent beam electron diffraction pattern recorded perpendicular to the wire axis, confirming the nanowire crystallinity (after [9.58]). **(c)** Scanning transmission electron microscope (STEM) image of $Si/Si_{1-x}Ge_x$ superlattice nanowires in the bright field mode. The scale bar is 500 nm (after [9.107])

Reduction of the average wire diameter to the nanometer scale requires the generation of nanosized catalyst droplets. However, due to the balance between the liquid-vapor surface free energy and the free energy of condensation, the size of a liquid droplet, in equilibrium with its vapor, is usually limited to the micrometer range. This obstacle has been overcome by several modern methodologies:

1. Advances in the synthesis of metal nanoclusters have made monodispersed nanoparticles commercially available. These can be dispersed on a solid substrate in high dilution so that when the temperature is raised above the melting point, the liquid clusters do not aggregate [9.57].
2. Alternatively, metal islands of nanoscale sizes can self-form when a strained thin layer is grown or heat-treated on a non-epitaxial substrate [9.43].
3. Laser-assisted catalytic VLS growth is a method used to generate nanowires under non-equilibrium conditions. Using laser ablation of a target containing both the catalyst and the source materials, a plasma is generated from which catalyst nanoclusters nucleate as the plasma cools down. Single-crystal nanowires grow as long as the particle remains liquid [9.58].
4. Interestingly, by optimizing the material properties of the catalyst-nanowire system, conditions can be achieved for which nanocrystals nucleate in a liquid catalyst pool supersaturated with the nanowire material, migrate to the surface due to a large surface tension, and continue growing as nanowires perpendicular to the liquid surface [9.60]. In this case, supersaturated nanodroplets are sustained on the outer end of the nanowire due to the low solubility of the nanowire material in the liquid [9.108].

A wide variety of elemental, binary, and compound semiconductor nanowires have been synthesized via the VLS method, and relatively good control over the nanowire diameter and diameter distribution has been achieved. The nanowires are often single crystals with a preferred crystallographic orientation along the wire axis, and may be oriented with respect to the substrate by epitaxy relations [9.109, 110]. Researchers are currently focusing their attention on the controlled variation of the material properties along the nanowire axis. In this context, researchers have modified the VLS synthesis apparatus to generate compositionally modulated nanowires. GaAs/GaP–modulated nanowires have been synthesized by alternately ablating targets of the corresponding materials in the presence of gold nanoparticles [9.111]. p-Si/n-Si nanowires were grown by chemical vapor deposition from alternating gaseous mixtures containing the appropriate dopant [9.111]. $Si/Si_{1-x}Ge_x$ nanowires were grown by combining silicon from a gaseous source with germanium from a periodically ablated target (Fig. 9.6c) [9.107]. NiSi-Si nanowires have been successfully synthesized that directly incorporate a nanowire metal contact into active nanowire devices [9.112]. Finally, using an ultra-high vacuum chamber and molecular beams, InAs/InP

nanowires with atomically sharp interfaces were obtained [9.113]. These compositionally modulated nanowires are expected to exhibit exciting electronic, photonic, and thermoelectric properties.

Interestingly, silicon and germanium nanowires grown by the VLS method consist of a crystalline core coated with a relatively thick amorphous oxide layer (2−3 nm) (Fig. 9.6b). These layers are too thick to be the result of ambient oxidation, and it has been shown that these oxides play an important role in the nanowire growth process [9.59, 114]. Silicon oxides were found to serve as a special and highly selective catalyst that significantly enhances the yield of Si nanowires without the need for metal catalyst particles [9.59, 114, 115]. A similar yield enhancement was also found in the synthesis of Ge nanowires from the laser ablation of Ge powder mixed with GeO_2 [9.44]. The Si and Ge nanowires produced from these metal-free targets generally grow along the [112] crystal direction [9.116], and have the benefit that no catalyst material is found on either ends of the nanowires. Based on these observations and other TEM studies [9.44, 114, 116], an oxide-enhanced nanowire growth mechanism different from the classical VLS mechanism was proposed, where no metal catalyst is required during the laser ablation-assisted synthesis [9.114]. It is postulated that the nanowire growth is dependent on the presence of SiO (or GeO) vapor, which decomposes in the nanowire tip region into both Si (or Ge), which is incorporated into the crystalline phase, and SiO_2 (or GeO_2), which contributes to the outer coating. The initial nucleation events generate oxide-coated spherical nanocrystals. The (112) crystal faces have the fastest growth rate, and therefore the nanocrystals soon begin elongating in the perpendicular direction to form one-dimensional structures. The Si_mO or Ge_mO ($m > 1$) layers on the nanowire tips may be in or near their molten states, catalyzing the incorporation of gas molecules in a directional fashion [9.116]. Besides nanowires with smooth walls, a second morphology of chains of unoriented nanocrystals linked by oxide necks is frequently observed (indicated by an arrow in Fig. 9.7). In addition, scanning tunneling microscope (STM) studies revealed that about 1% of the wires consist of a third morphology: zigzag nanowires 3 nm in diameter and microns in length [9.117]. The recurring structure of two alternating straight wire segments, 10 and 5 nm in length respectively, whose junctions form an angle of 30°, is probably a result of alternating growth along different crystallographic orientations [9.117].

Other variations of the VLS mechanism of nanowire growth include synthesis at low temperatures where the catalysts are solid nanoparticles (i. e., vapor-solid-solid or VSS) [9.109, 118, 119] and synthesis in a liquid phase where the catalyst is suspended in a liquid solution in which the reactants are dissolved (i. e., solution–liquid–solid or SLS) [9.120].

9.1.3 Etching Methods

For applications that require uniform nanowires, specific crystallographic orientation, control of the nanowire array dimensions, and/or high-density vertical nanowires, etching methods offer a practical *top-down* alternative method to fabricate nanowire arrays. The two most common methods of making etched nanowires are reactive ion etching (RIE) and metal-assisted chemical etching (MACE). Both methods result in vertically aligned nanowire arrays with high densities. In addition, in versions of both methods, the diameter and density of the nanowires can be controlled. Furthermore, MACE and RIE etched nanowires can result in large arrays of nanowires with uniform heights. Silicon, due to its favorable properties for electronic and photonic applications and its prevalence in the semiconductor industry, is the dominant material used to make etched nanowires.

Reactive ion etching is a vacuum technique used in the semiconductor industry to etch silicon and III–V semiconductors. Energetic charged particles bombarding the substrate remove material by a combination of sputtering and chemical attack. Process engineers have long known that when process conditions are not set a certain way unpatterned regions in the RIE-etched silicon wafers will turn into black silicon [9.121]. The black silicon is in fact a dense array of vertical nanowires, also known as silicon grass. An example of silicon grass is shown in Fig. 9.8. While unwanted by the complementary metal-oxide-semiconductor (CMOS)

Fig. 9.8 A SEM image of silicon grass formed by RIE. ©IOP Publishing. Reproduced with permission. All rights reserved (after [9.121])

industry, black silicon has proven useful for making and studying nanowire arrays. Ultimately, RIE methods have been used to form patterned silicon nanowire arrays in a controllable fashion. RIE and often deep RIE (DRIE) are used in combination with a mask to pattern where nanowires form [9.122]. The ordered arrays of vertical nanowires shown in Fig. 9.9 are examples of wire arrays formed by using e-beam lithography in combination with deep RIE.

Metal-assisted chemical etching to make silicon nanowire arrays is a well explored research topic. The resulting silicon structure made from MACE is often called *black silicon*, *silicon whiskers*, *nanotexture*, *porous silicon,* or *nanowires*. Recently several reviews have covered the process and the capabilities of MACE [9.123–125]. In MACE a thin metal is deposited onto a silicon surface and then immersed into an etch solution containing hydrofluoric acid and an oxidizer. The metal catalyzes the etching of silicon. Thus silicon is etched where the metal is in contact with the silicon and is not etched where the metal is absent. As the etching progresses, the metal moves down the silicon with the etching front. In the case where the metal is put down such that there are holes in the metal, nanowires form as the metal etches the silicon around the nanowires. MACE results in very anisotropic etched structures. See Fig. 9.10 for an example of a MACE-etched array of nanowires. In this particular example, the metal was masked using a silica colloidal crystal template such that the metal was blocked from touching the silicon wherever a silica sphere was present, thus forming a nanowire [9.61].

9.1.4 Other Synthesis Methods

In this section we review several other general procedures available for the synthesis of a variety of nanowires. We focus on *bottom-up* approaches, which afford many kinds of nanowires in large numbers, and do not require highly sophisticated equipment (such as scanning microscopy or lithography-based methods), and exclude cases for which the nanowires are not self-sustained (such as in the case of atomic rows on the surface of crystals).

A solution-phase synthesis of nanowires with controllable diameters has been demonstrated [9.55, 126], without the use of templates, catalysts, or surfactants.

Instead, Gates et al. make use of the anisotropy of the crystal structure of trigonal selenium and tellurium, which can be viewed as rows of 1-D helical atomic chains. Their approach is based on the mass transfer of atoms during an aging step from a high free-energy solid phase (e.g., amorphous selenium) to a seed (e.g., trigonal selenium nanocrystal), which grows preferentially along one crystallographic axis. The lateral dimension of the seed, which dictates the diameter of the nanowire, can be controlled by the temperature of the nucleation step. Furthermore, Se/Te alloy nanowires were synthesized by this method, and Ag_2Se compound nanowires were obtained by treating selenium nanowires with $AgNO_3$ [9.127–129]. In a separate work, tellurium nanowires were transformed into Bi_2Te_3 nanowires by their reaction with $BiPh_3$ [9.130].

More often, however, the use of surfactants is necessary to promote the anisotropic 1-D growth of nanocrystals in solution. Solution-phase synthetic routes have been optimized to produce monodispersed quantum dots (zero-dimensional isotropic nanocrystals) [9.131]. Surfactants are necessary in this case to stabilize the interfaces of the nanoparticles and to retard oxidation and aggregation processes. Detailed studies on the effect of growth conditions revealed that they can be manipulated to induce a directional growth of the nanocrystals, usually generating nanorods (aspect ratio of ≈ 10), and in favorable cases, nanowires with high aspect ratios. *Heath* and *LeGoues* synthesized germanium nanowires by reducing a mixture of $GeCl_4$ and phenyl-$GeCl_3$ at high temperature and high pressure. The phenyl ligand was essential for the formation of high-aspect-ratio nanowires [9.42]. In growing CdSe nanorods [9.29], *Alivisatos* et al. used a mixture of two surfactants, whose concentration ratio influenced the shape of the nanocrystal. It is believed that different surfactants have different affinities, and different absorption rates, for the different crystal faces of CdSe, thereby regulating the growth rates of these faces. In the liquid-phase synthesis of Bi nanowires, the additive $NaN(SiMe_3)_2$ induces the growth of nanowires oriented along the [110] crystal direction from small bismuth seed clusters, while water solely retarded the growth along the [001] direction, inducing the growth of hexagonal-plate particles [9.130]. A coordinating alkyl-diamine solvent was used to grow polycrystalline PbSe nanowires at low temperatures [9.51]. Here, the surfactant-induced directional growth is believed to occur through the formation of organometallic complexes in which the bidentate ligand assumes the equatorial positions, thus hindering the ions from approaching each other in this plane. Additionally, the alkyl-diamine molecules coat the external surface of the wire, preventing lateral growth. The aspect ratio of the wires increased as the temperature was lowered in the range $10\,°C < T < 117\,°C$. Noble metal nanowires were grown by the polyol-reduction method utilizing polyvinylpyrrolidone as a surfactant [9.9–11, 54]. These nanowires have a pentagonal cross-section. The 1-D growth is a consequence of extending the twin boundaries in the dodecahedral seed nanoparticles that

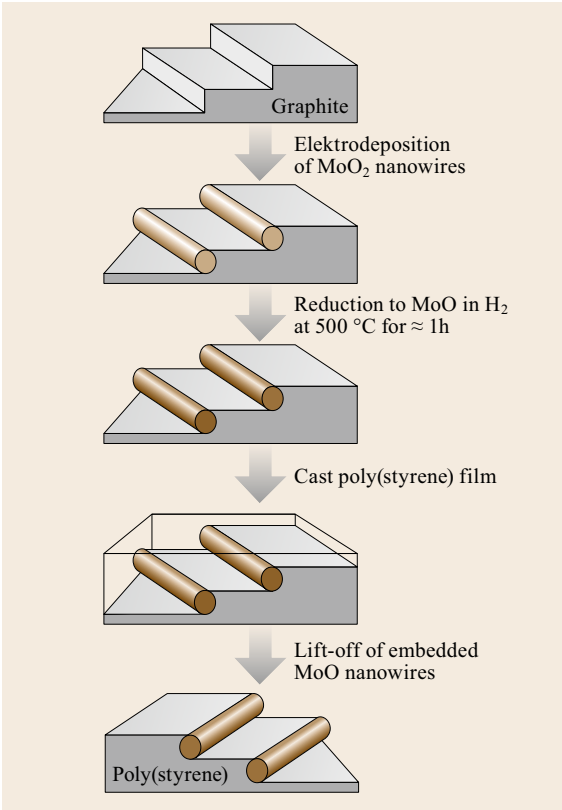

Fig. 9.11 Schematic of the electrodeposition step edge decoration of HOPG (highly oriented pyrolytic graphite) for the synthesis of molybdenum nanowires (after [9.47, 132])

form upon nucleation and passivation of the (100) surfaces by the surfactant.

Stress-induced crystalline bismuth nanowires have been grown from sputtered films of layers of Bi and CrN. The nanowires presumably grow from defects and cleavage fractures in the film, and are up to several millimeters in length with diameters ranging from 30 to 200 nm [9.15]. Other elemental and metal chalcogenide nanowires of soft, low-melting point metals (Bi, Pb, Ga) have been observed to grow from polycrystalline films under stress. This approach offers the benefits of being low-cost and free of contaminants [9.16, 133, 134].

Selective electrodeposition along the step edges in highly oriented pyrolytic graphite (HOPG) was used to obtain MoO_2 nanowires as shown in Fig. 9.11. The site selectivity was achieved by applying a low overpotential to the electrochemical cell in which the HOPG served as cathode, thus minimizing the nucleation events on less favorable sites (i. e., plateaus). While these nanowires cannot be removed from the substrate, they can be reduced to metallic molybdenum

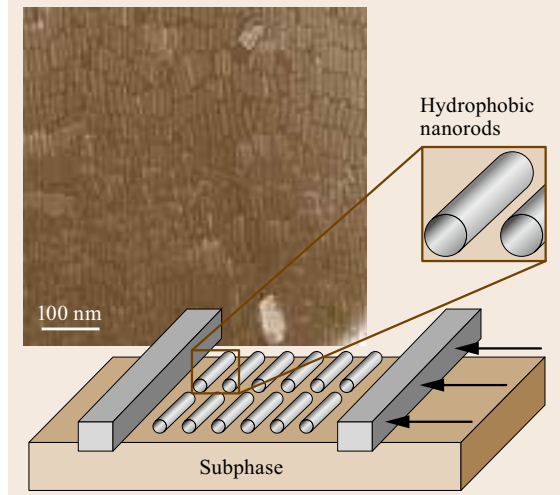

Fig. 9.12 A TEM image of a smectic phase of a $BaCrO_4$ nanorod film (*left inset*) achieved by the Langmuir–Blodgett technique, as depicted by the illustration (after [9.136])

nanowires, which can then be released as free-standing nanowires. Other metallic nanowires were also obtained by this method [9.47, 132]. In contrast to the template synthesis approaches described above, in this method the substrate only defines the position and orientation of the nanowire, not its diameter. In this context, other surface morphologies, such as self-assembled grooves in etched crystal planes, have been used to generate nanowire arrays via gas-phase shadow deposition (for example, Fe nanowires on (110)NaCl [9.36]). The cross-section of artificially prepared superlattice structures has also been used for site-selective deposition of parallel and closely spaced nanowires [9.135]. Nanowires prepared on the above-mentioned substrates have semicircular, rectangular, or other unconventional cross-sectional shapes.

9.1.5 Nanowire Alignment and Superstructures of Nanowires

Controlling the position of a nanowire in the growth process is important for preparing devices or test structures containing nanowires, especially when it involves a large array of nanowires. Post-synthesis methods to align and position nanowires include microfluidic channels [9.137], Langmuir–Blodgett assemblies [9.136], and electric-field–assisted assembly [9.138]. The first method involves the orientation of the nanowires by the liquid flow direction when a nanowire solution is injected into a microfluidic channel assembly and by the interaction of the nanowires with the side walls of

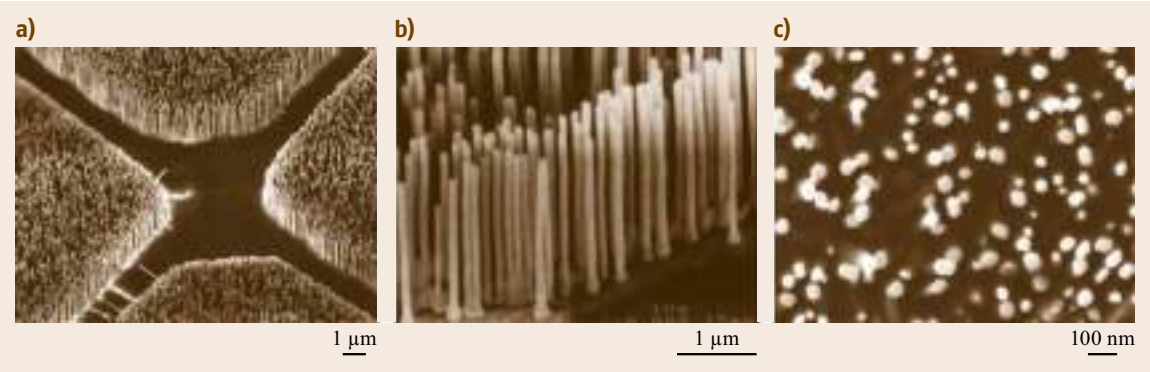

Fig. 9.13a–c SEM images of ZnO nanowire arrays grown on a sapphire substrate, where **(a)** shows patterned growth, **(b)** shows a higher-resolution image of the parallel alignment of the nanowires, and **(c)** shows the faceted side-walls and the hexagonal cross-section of the nanowires. For nanowire growth, the sapphire substrates were coated with a 1.0–3.5 nm-thick patterned layer of Au as the catalyst, using a TEM grid as the shadow mask. These nanowires have been used for nanowire laser applications (after [9.110])

the channel. The second method involves the alignment of nanowires at a liquid-gas or liquid-liquid interface by the application of compressive forces on the interface (Fig. 9.12). The aligned nanowire films can then be transferred onto a substrate and lithography methods can be used to define interconnects. This allows the nanowires to be organized with a controlled alignment and spacing over large areas. Using this method, centimeter-scale arrays containing thousands of single silicon nanowire field-effect transistors with high performance could be assembled to make large-scale nanowire circuits and devices [9.139, 140]. The third technique is based on dielectrophoretic forces that pull polarizable nanowires toward regions of high field strength [9.141, 142]. The nanowires align between two isolated electrodes that are capacitively coupled to a pair of buried electrodes biased with an AC voltage. Once a nanowire shorts the electrodes, the electric field is eliminated, preventing more nanowires from depositing. The above techniques have been successfully used to prepare electronic circuitry and optical devices out of nanowires (Sects. 9.3.1 and 9.3.2). Alternatively, alignment and positioning of the nanowires can be specified and controlled during their growth by the proper design of the synthesis method. For example, ZnO nanowires prepared by the VLS method were grown into an array in which both their position on the substrate and their growth direction and orientation were controlled [9.65]. The nanowire growth region was defined by patterning the gold film, which serves as a catalyst for the ZnO nanowire growth, employing soft lithography, e-beam lithography, or photolithography. The orientation of the nanowires was achieved by selecting a substrate with a lattice structure matching that of the nanowire material to facilitate the epitaxial growth. These conditions result in an array of nanowire posts at predetermined positions, all vertically aligned with the same crystal growth orientation (Fig. 9.13). Similarly, GaN nanowire arrays have been synthesized epitaxially on (100)$LiAlO_2$ and (111)MgO single-crystal substrates. The lattice matching conditions enabled control over the crystallographic growth directions of the nanowires. For example, GaN nanowires on (100)$LiAlO_2$ substrates grow oriented along the [110] direction, whereas (111)MgO substrates result in the growth of GaN nanowires with an [001] orientation, due to the different lattice-matching constraints [9.143]. A similar structure could be obtained by the template-mediated electrochemical synthesis of nanowires (Sect. 9.1.1), particularly if anodic alumina with its parallel and ordered channels is used. The control over the location of the nucleation of nanowires in the electrochemical deposition is determined by the pore positions and the back-electrode geometry. The pore positions can be precisely controlled by imprint lithography [9.78]. By growing the template on a patterned conductive substrate that serves as a back-electrode [9.144–146], different materials can be deposited in the pores at different regions of the template.

9.2 Characterization and Physical Properties of Nanowires

In this section we review the structure and properties of nanowires and their interrelationship. The discovery and investigation of nanostructures were spurred on by advances in various characterization and microscopy techniques that enabled material characterization to take place at smaller and smaller length scales, reaching length scales down to individual atoms. For applications, characterizing the structural properties of nanowires is especially important, so that a reproducible relationship between their desired functionality and their geometrical and structural characteristics can be established. Due to the enhanced surface-to-volume ratio in nanowires, their properties may depend sensitively on their surface conditions and geometrical configurations. Even nanowires made of the same material may possess dissimilar properties due to differences in their crystal phase, crystalline size, surface conditions, and aspect ratios, which depend on the synthesis methods and conditions used in their preparation.

9.2.1 Structural Characterization

Structural and geometric factors play an important role in determining the various attributes of nanowires, such as their electrical, optical, and magnetic properties. Therefore, various novel tools have been developed and employed to obtain this important structural information at the nanoscale. At the micrometer scale, optical techniques are extensively used for imaging structural features. Since the sizes of nanowires are usually comparable to or, in most cases, much smaller than the wavelength of visible light, traditional optical microscopy techniques are usually limited when characterizing the morphology and surface features of nanowires. Therefore, electron microscopy techniques play a more dominant role at the nanoscale. Since electrons interact with matter more strongly than photons, electron microscopy is particularly sensitive relative to x-rays for the analysis of tiny samples.

In this section we review and give examples of how scanning electron microscopy, transmission electron microscopy, scanning probe spectroscopies, and diffraction techniques are used to characterize the structure of nanowires. To provide the necessary basis for developing reliable structure-property relations, multiple characterization tools are applied to the same samples.

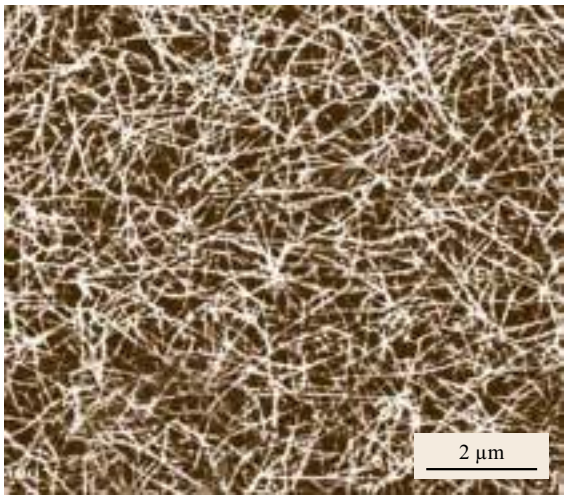

Fig. 9.14 SEM image of GaN nanowires in a mat arrangement synthesized by laser-assisted catalytic growth. The nanowires have diameters and lengths on the order of 10 nm and 10 μm respectively (after [9.39])

Scanning Electron Microscopy

SEM usually produces images down to length scales of ≈ 10 nm and provides valuable information regarding the structural arrangement, spatial distribution, wire density, and geometrical features of the nanowires. The examples of SEM micrographs shown in Figs. 9.1 and 9.3 indicate that structural features at the 10 nm to 10 μm length scales can be probed, providing information on the size, size distribution, shapes, spatial distributions, density, alignment, fill-factors, granularity, etc. As another example, Fig. 9.13a shows an SEM image of ZnO nanowire arrays grown on a sapphire substrate [9.110], which provides evidence for the non-uniform spatial distribution of the nanowires on the substrate, which was attained by patterning the catalyst film to define high-density growth regions and nanowire-free regions. Figure 9.13b, showing a higher magnification of the same system, indicates that these ZnO nanowires grow perpendicular to the substrate, are well aligned with approximately equal wire lengths, and have wire diameters in the range 20–150 nm. The SEM micrograph in Fig. 9.13c provides further information about the surface of the nanowires, showing it to be well faceted, forming a hexagonal cross-section, indicative of nanowire growth normal to the (0001) plane. Both the uniformity of the nanowires' size, their alignment perpendicular to the substrate, and their uniform growth direction, as suggested by the SEM data, are linked to the good epitaxial interface between the (0001) plane of the ZnO nanowire and the (110) plane of the sapphire substrate. (The crystal structures of ZnO and sapphire are essentially incommensurate, with the exception that the *a*-axis of

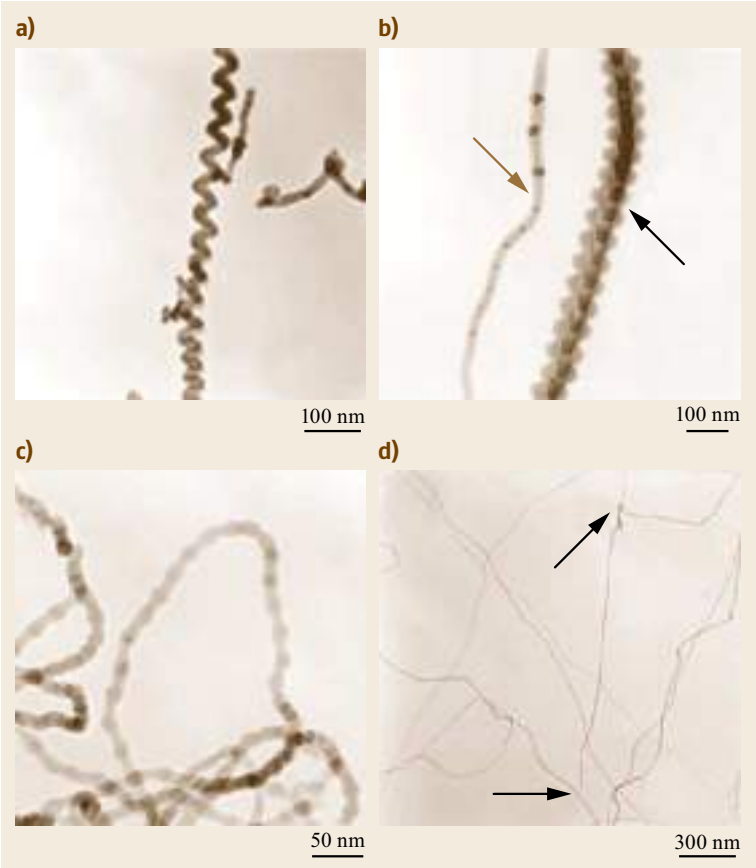

Fig. 9.15a–d TEM morphologies of four special forms of Si nanowires synthesized by the laser ablation of a Si powder target. **(a)** A spring-shaped Si nanowire; **(b)** fishbone-shaped (indicated by a *black arrow*) and frogs' egg-shaped (indicated by a *brown arrow*) Si nanowires; and **(c)** pearl-shaped nanowires. **(d)** shows polysites for the nucleation of silicon nanowires (indicated by *arrows*) (after [9.147])

ZnO and the *c*-axis of sapphire are related almost exactly by a factor of four, with a mismatch of less than 0.08% at room temperature [9.110].) The well-faceted nature of these nanowires has important implications for their lasing action (Sect. 9.3.2). The SEM image of GaN nanowires synthesized by a laser-assisted catalytic growth method [9.39] featured in Fig. 9.14 revals that random spatial orientation of the nanowire axes and a wide diameter distribution for these nanowires, in contrast to the ZnO wires in Fig. 9.13 and to arrays of well-aligned nanowires prepared by template-assisted growth (Fig. 9.3).

Transmission Electron Microscopy

TEM and high-resolution transmission electron microscopy (HRTEM) are powerful imaging tools for studying nanowires at the atomic scale, and they usually provide more detailed geometrical features than are seen in SEM images (SAED). As an example, the TEM images in Fig. 9.15a–c show four different morphologies for Si nanowires prepared by the laser ablation of a Si target: spring-shaped, fishbone-shaped, frogs' egg-shaped, and pearl-shaped nanowires [9.147].

TEM studies also yield information regarding the crystal structure, crystal quality, grain size, and crystal orientation of the nanowire axis. The crystal quality of nanowires is revealed from high-resolution TEM images with atomic resolution, along with selected area electron diffraction (SAED) patterns. For example, Fig. 9.16 shows a TEM image of one of the GaN nanowires from Fig. 9.14, indicating single crystallinity and showing (100) lattice planes, thus indicating the growth direction of the nanowire. This information is supplemented by the corresponding electron diffraction pattern in the upper right. A more comprehensive review of the application of TEM for growth orientation indexing and crystal defect characterization in nanowires is available elsewhere [9.148].

The high resolution of the TEM also permits the surface structures of the nanowires to be studied. In many cases, the nanowires are sheathed with native oxides, an amorphous oxide layer that forms during the growth process. This can be seen in Fig. 9.6b for silicon nanowires and in Fig. 9.17 for germanium nanowires [9.44], showing a mass-thickness contrast TEM image and a selected area electron diffraction pattern of a Ge nano-

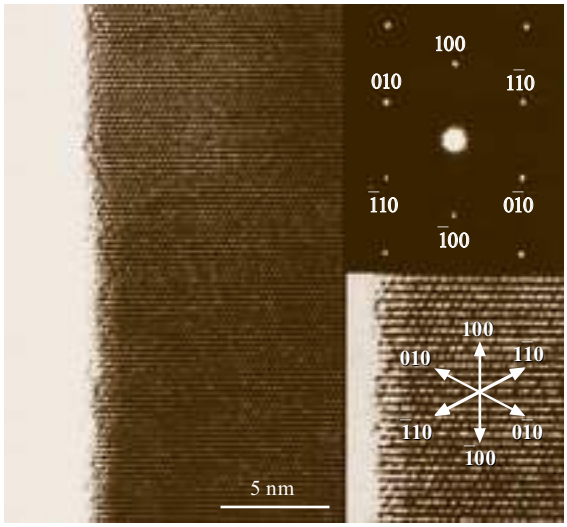

Fig. 9.16 Lattice-resolved high-resolution TEM image of one GaN nanowire (*left*) showing that (100) lattice planes are visible perpendicular to the wire axis. The electron diffraction pattern (*top right*) was recorded along the [001] zone axis. A lattice-resolved TEM image (*lower right*) highlights the continuity of the lattice up to the nanowire edge, where a thin native oxide layer is found. The directions of various crystallographic planes are indicated in the *lower right figure* (after [9.39])

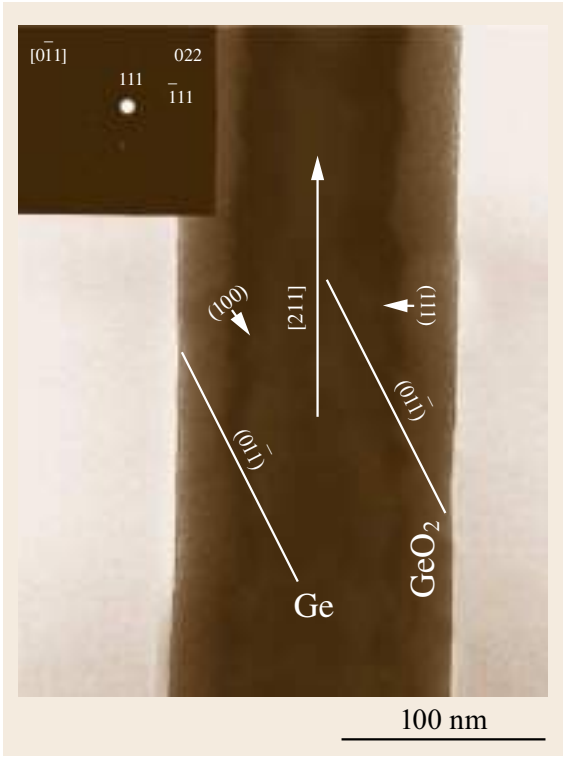

Fig. 9.17 A mass-thickness contrast TEM image of a Ge nanowire taken along the $(0\bar{1}1)$ zone axis and a selected area electron diffraction pattern (*upper left inset*) (after [9.44]). The Ge nanowires were synthesized by laser ablation of a mixture of Ge and GeO_2 powder. The core of the Ge nanowire is crystalline, while the surface GeO_2 is amorphous

wire. The main TEM image shows that these Ge nanowires possess an amorphous GeO_2 sheath with a crystalline Ge core that is oriented in the [211] direction.

Dynamical processes of the surface layer of nanowires can be studied in situ using an environmental TEM chamber, which allows TEM observations to be made while different gases are introduced or as the sample is heat treated at various temperatures, as illustrated in Fig. 9.18. The figure shows high-resolution TEM images of a Bi nanowire before and after a dynamic oxide removal process carried out within the environmental chamber of the TEM [9.149]. The amorphous bismuth-oxide layer coating the nanowire (Fig. 9.18a) is removed by exposure to hydrogen gas within the environmental chamber of the TEM, as indicated in Fig. 9.18b.

By coupling the powerful imaging capabilities of TEM with other characterization tools, such as an electron energy loss spectrometer (EELS) or an energy dispersive x-ray spectrometer (EDS) within the TEM instrument, additional properties of the nanowires can be probed with high spatial resolution. With the EELS technique, the energy and momentum of the incident and scattered electrons are measured in an inelastic electron scattering process to provide information on the energy and momentum of the excitations in the nanowire sample. Figure 9.19 shows the dependence on nanowire diameter of the electron energy loss spectra of Bi nanowires. The spectra were taken from the center of the nanowire, and the shift in the energy of the peak position (Fig. 9.19) indicates the effect of the nanowire diameter on the plasmon frequency in the nanowires. The results show that there are changes in the electronic structure of the Bi nanowires as the wire diameter decreases [9.150]. Such changes in electronic structure as a function of nanowire diameter are also observed in their transport (Sect. 9.2.2) and optical (Sect. 9.2.3) properties, and are related to quantum confinement effects.

EDS measures the energy and intensity distribution of x-rays generated by the impact of the electron beam on the surface of the sample. The elemental composition within the probed area can be determined to a high degree of precision. The technique was par-

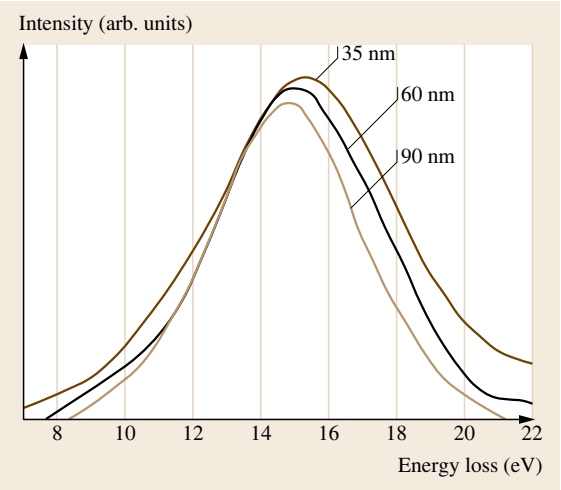

Fig. 9.19 Electron energy loss spectra (EELS) taken from the centers of bismuth nanowires with diameters of 35, 60 and 90 nm. The shift in the volume plasmon peaks is due to the effect of wire diameter on the electronic structure (after [9.150])

ticularly useful for the compositional characterization of superlattice nanowires [9.107] and core-shell nanowires [9.151] (Sect. 9.1.2).

Scanning Probe Techniques

Several scanning probe techniques, such as scanning tunneling microscopy (STM) [9.152], electric field gradient microscopy (EFM) [9.22], magnetic force microscopy (MFM) [9.49], and scanning thermal microscopy (SThM) [9.153], combined with atomic force microscopy (AFM), have been employed to study the structural, electronic, magnetic, and thermal properties of nanowires. A scanning tunneling microscope can be employed to reveal both topographical structural information, such as that illustrated in Fig. 9.20, as well as information on the local electronic density of states of a nanowire, when used in the STS (scanning tunneling spectroscopy) mode. Figure 9.20 shows STM height images (taken in the constant-current STM mode) of MoSe molecular wires deposited from a methanol or acetonitrile solution of $Li_2Mo_6Se_6$ onto Au substrates. The STM image of a single MoSe wire (Fig. 9.20a) exhibits a 0.45 nm lattice repeat distance in a MoSe molecular wire. When both STM and STS measurements are made on the same sample, the electronic and structural properties can be correlated. For example, joint STM/STS studies on Si nanowires [9.117] identified on single nanowires alternating segments grown along the [110] and [112] directions, and different I–V characteristics were measured for the [110] segments as compared with the [112] segments.

Magnetic force microscopy (MFM) has been employed to study magnetic polarization of magnetic nanowires embedded in an insulating template, such as an anodic alumina template. For example, Fig. 9.21a shows the topographic image of an anodic alumina template filled with Ni nanowires recorded in AFM mode, and Fig. 9.21b demonstrates the corresponding magnetic polarization of each nanowire in the template. This micrograph shows that an MFM probe can distinguish between spin-up and spin-down nanowires in the nanowire array, thereby providing a method for measuring magnetic dipolar interactions between wires [9.49].

X-ray Analysis

Other characterization techniques that are commonly used to study the crystal structures and chemical compositions of nanowires include x-ray diffraction and energy-dispersive x-ray spectroscopy (EDS). The peak positions in the x-ray diffraction pattern can used to determine the chemical composition and the crystal phase

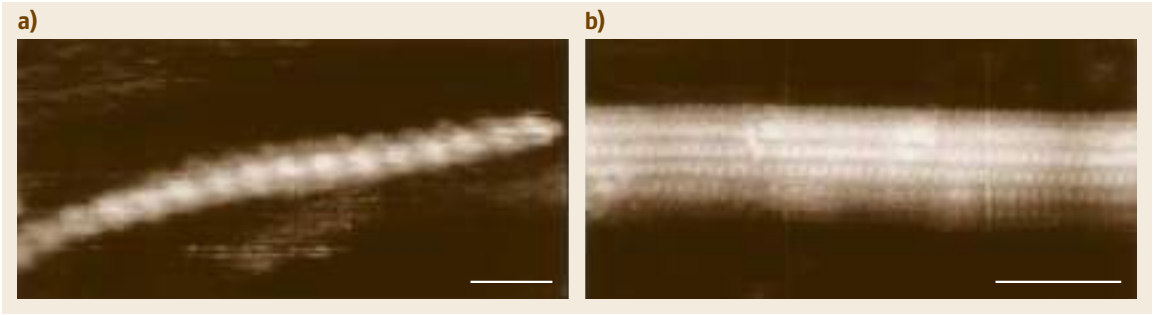

Fig. 9.20a,b STM height images, obtained in the constant-current mode, of MoSe chains deposited on an Au(111) substrate. **(a)** A single chain image, and **(b)** a MoSe wire bundle (after [9.152]). Scale bars: 1 nm

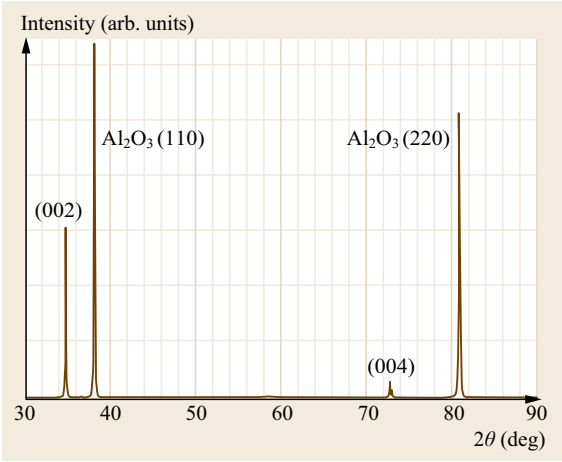

Fig. 9.22 X-ray diffraction pattern of aligned ZnO nanowires (Fig. 9.13) grown on a sapphire substrate. Only (00ℓ) diffraction peaks are observed for the nanowires, owing to their well-oriented growth orientation. Strong diffraction peaks for the sapphire substrate are found (after [9.110])

structure of the nanowires. For example, Fig. 9.2 shows that Bi nanowires have the same crystal structure and lattice constants as bulk bismuth. Both the x-ray diffraction pattern (XRD) for an array of aligned Bi nanowires (Fig. 9.2) and the SAED pattern for individual Bi nanowires [9.22] suggest that the nanowires have a common crystallographic alignment.

As another example of an XRD pattern for an array of aligned nanowires, Fig. 9.22 shows the x-ray diffraction pattern of the ZnO nanowires that are displayed in Fig. 9.13. Only (00ℓ) diffraction peaks are observed for these aligned ZnO nanowires, indicating that their preferred growth direction is [001] along the wire axis. Similarly, XRD was used to confirm the different growth directions of GaN nanowire arrays grown epitaxially on (100)$LiAlO_2$ and (111)MgO substrates [9.143].

EDS has been used to determine the chemical compositions and stoichiometry of compound nanowires or impurity contents in nanowires. However, the results from EDS analysis should be interpreted carefully to avoid systematic errors.

9.2.2 Mechanical Properties

Thermal Stability

Due to the large surface-to-volume ratio in nanowires and other nanoparticles, the thermal stability of na-

nowires is anticipated to differ significantly from that of the bulk material. Theoretical studies of materials in confined geometries show that the melting point of the material is reduced in nanostructures, as is the latent heat of fusion, and that large hysteresis can be observed in melting-freezing cycles. These phenomena have been studied experimentally in three types of nanowire systems: porous matrices impregnated with a plurality of nanowires, individual nanowires sheathed by a thin coating, and individual nanowires.

The melting-freezing of matrix-supported nanowires can be studied by differential scanning calorimetry (DSC), since large volumes of samples can thus be produced. *Huber* et al. investigated the melting of indium in porous silica glasses with mean pore diameters ranging from 6 to 141 nm [9.154]. The melting point of the pore-confined indium shows a linear dependence on inverse pore diameter, with a maximum melting point depression of 50 K. A similar shift was observed in the freezing temperature of pore-confined indium. The melting profile of the pore-confined indium in these samples is broader in temperature than for bulk indium, as expected for the heterogeneity in the pore diameter and in the indium crystal size aspect ratio within the samples.

Sheathed nanowires provide an opportunity to study the melting and recrystallization of individual nanowires. The shell layer surrounding the nanowire provides confinement to keep the liquid phase within the inner cylindrical volume. However, the shell-nanowire surface interaction should be taken into account when analyzing the phase transition thermodynamics and kinetics. *Wu* and *Yang* produced germanium nanowires coated with a thin (1−5 nm) graphite sheath, by pyrolysis of organic molecules over VLS-grown nanowires, and followed the melting and recrystallization of the germanium by variable-temperature TEM imaging [9.155]. The melting of the nanowires was followed by the disappearance of the electronic diffraction pattern. It was found that the nanowires began melting from their ends, with the melting front advancing towards the center of the nanowire as the temperature was increased. During the cool-down part of the cycle, the recrystallization of the nanowire occurred instantaneously following significant supercooling. The authors report both the largest melting point suppression recorded thus far for germanium ($\approx 300\,^{\circ}\mathrm{C}$), and a large melting-recrystallization hysteresis of up to $\approx 300\,^{\circ}\mathrm{C}$. Similarly, carbon nanotubes have been filled with various low-temperature metals [9.156]. A nanothermometer has been demonstrated using a 10 nm liquid gallium-filled carbon nanotube, showing an expansion coefficient that is linear in temperature and identical to the bulk value [9.157].

A different behavior was observed in free-standing copper nanowires [9.158]. In this system, there is little interaction between the nanowire surface and the surroundings, and the nanowire is not confined in its diameter, as in the case of the sheathed nanowires. Thermal treatment of the free-standing nanowires leads to their fragmentation into a linear array of metal spheres. Thinner nanowires are more vulnerable than thicker nanowires to the thermal treatment, showing constrictions and segmentation at lower temperatures. Analysis of the temperature response of the nanowires indicates that the nanowire segmentation is a result of the Rayleigh instability, starting with oscillatory perturbations of the nanowire diameter, leading to long cylindrical segments that become more separated and more spherical at higher temperatures. These observations indicate that annealing and melting are dominated by the surface diffusion of atoms on the entire surface of the nanowire (versus tip-initiated melting).

9.2.3 Transport Properties

The study of electrical transport properties of nanowires is important for nanowire characterization, electronic device applications, and the investigation of unusual transport phenomena arising from one-dimensional quantum effects. Important factors that determine the transport properties of nanowires include the wire diameter, material composition, surface conditions, crystal quality, and the crystallographic orientation along the wire axis for materials with anisotropic material parameters, such as the effective mass tensor, the Fermi surface, or the carrier mobility.

Electronic transport phenomena in low-dimensional systems can be roughly divided into two categories: ballistic transport and diffusive transport. Ballistic transport phenomena occur when the electrons can travel across the nanowire without any scattering. In this case, the conduction is mainly determined by the contacts between the nanowire and the external circuit, and the conductance is quantized into an integral number of universal conductance units $G_0 = 2\mathrm{e}^2/h$ [9.160, 161]. Ballistic transport phenomena are usually observed in very short quantum wires, such as those produced using mechanically-controlled break junctions (MCBJs) [9.162, 163] where the electron mean free path is much longer than the wire length and the conduction is a pure quantum phenomenon. To observe ballistic transport, the thermal energy must also obey the relation $k_\mathrm{B}T \ll \varepsilon_j - \varepsilon_{j-1}$, where $\varepsilon_j - \varepsilon_{j-1}$ is the energy separation between subband levels j and $j-1$. On the other hand, for nanowires with lengths much larger than the carrier mean free path, the electrons (or holes) undergo numerous scattering events when they travel

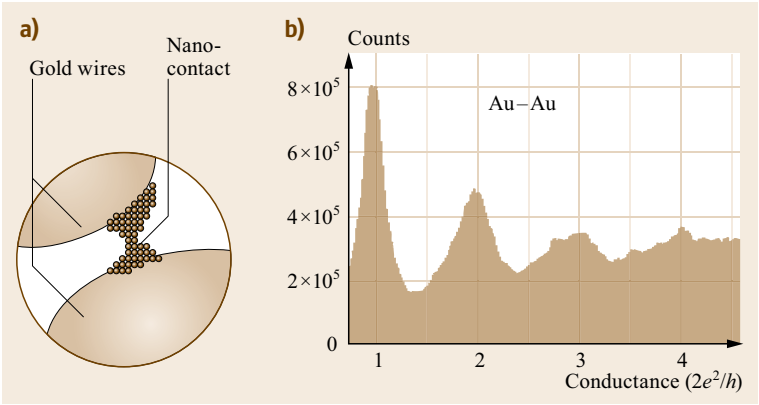

Fig. 9.23 **(a)** Schematic representation of the last stages of the contact breakage process (after [9.159]). **(b)** Histogram of conductance values built with 18 000 gold contact breakage experiments in air at room temperature, showing conductance peaks at integral values of G_0. In this experiment the gold electrodes approach and separate at 89 000 Å/s (after [9.159])

along the wire. In this case, the transport is in the diffusive regime, and the conduction is dominated by carrier scattering within the wires, due to phonons (lattice vibrations), boundary scattering, lattice and other structural defects, and impurity atoms.

Conductance Quantization in Metallic Nanowires

The ballistic transport of 1-D systems has been extensively studied since the discovery of quantized conductance in 1-D systems in 1988 [9.160, 161]. The phenomena of conductance quantization occurs when the diameter of the nanowire is comparable to the electron Fermi wavelength, which is on the order of 0.5 nm for most metals [9.164]. Most conductance quantization experiments up to the present were performed by bringing together and separating two metal electrodes. As the two metal electrodes are slowly separated, a nano-contact is formed before it breaks completely (Fig. 9.23a), and conductance in integral multiple values of G_0 is observed through these nano-contacts. Figure 9.23b shows the conductance histogram built with 18 000 contact breakage curves between two gold electrodes at room temperature [9.159], with the electrode separation up to ≈ 1.8 nm. The conductance quantization behavior is found to be independent of the contact material, and has been observed in various metals, such as Au [9.159], Ag, Na, Cu [9.165], and Hg [9.166]. For semimetals such as Bi, conductance quantization has also been observed for electrode separations as long as 100 nm at 4 K because of the long Fermi wavelength (≈ 26 nm) [9.164], indicating that the conductance quantization may be due to the existence of well-defined quantum states localized at a constriction instead of resulting from the atom rearrangement as the electrodes separate. Since conductance quantization is only observed in breaking contacts, or for very narrow and very short nanowires, most nanowires of practical interest (possessing lengths of several micrometers) lie in the diffusive transport regime, where the carrier scattering is significant and should be considered.

I–V Characterization of Semiconducting Nanowires

The electronic transport behavior of nanowires may be categorized based on the relative magnitudes of three length scales: carrier mean free path ℓ_W, the de Broglie wavelength of electrons λ_e, and the wire diameter d_W. For wire diameters much larger than the carrier mean free path ($d_W \gg \ell_W$), the nanowires exhibit transport properties similar to bulk materials, which are independent of the wire diameter, since the scattering due to the wire boundary is negligible compared to other scattering mechanisms. For wire diameters comparable to or smaller than the carrier mean free path ($d_W \approx \ell_W$ or $d_W < \ell_W$), but still much larger than the de Broglie wavelength of the electrons ($d_W \gg \lambda_e$), the transport in nanowires is in the classical finite size regime, where the band structure of the nanowire is still similar to that of bulk, while the scattering events at the wire boundary alter their transport behavior. For wire diameters comparable to the electronic wavelength $d_W \approx \lambda_e$, the electronic density of states is altered dramatically and discrete subbands are formed due to the quantum confinement effect at the wire boundary. In this regime, the transport properties are further influenced by the change in the band structure. Therefore, transport properties for nanowires in the classical finite size and quantum size regimes are highly diameter-dependent.

Researchers have investigated the transport properties of various semiconducting nanowires and have demonstrated their potential for diverse electronic devices, such as for p-n diodes [9.167, 168], field effect transistors [9.167], memory cells, and switches [9.169] (Sect. 9.3.1). So far, the nanowires studied in this context have usually been made from conventional semiconducting materials, such as group IV and III–V

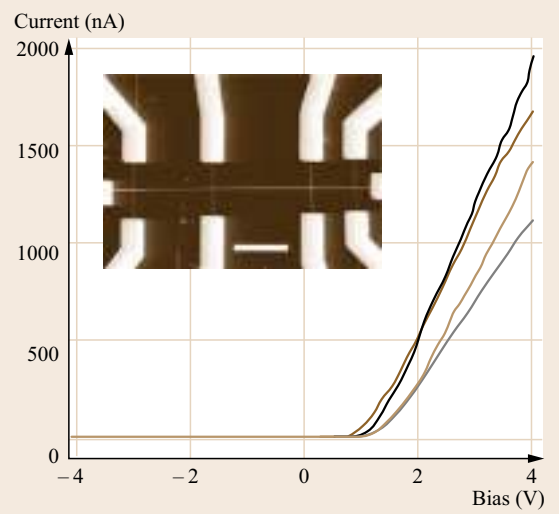

Fig. 9.24 *I–V* behavior for a 4(p) by 1(n) crossed p-Si/n-GaN junction array shown in the *inset*. The *four curves* represent the *I–V* response for each of the four junctions, showing similar current rectifying characteristics in each case. The length scale bar between the two middle junctions is 2 μm (after [9.167]). The p-Si and n-GaN nanowires are 10−25 and 10−30 nm in diameter respectively

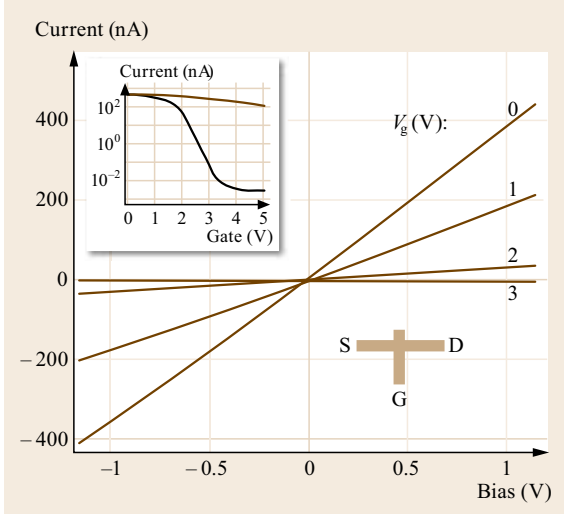

Fig. 9.25 Gate-dependent *I–V* characteristics of a crossed nanowire field-effect transistor (FET). The n-GaN nanowire is used as the nanogate, with the gate voltage indicated (0, 1, 2, and 3 V). The *inset* shows the current versus V_{gate} for a nanowire gate (*lower curve*) and for a global back-gate (*top curve*) when the bias voltage is set to 1 V (after [9.167])

compound semiconductors, via the VLS growth method (Sect. 9.1.2), and their nanowire properties have been compared to their well-established bulk properties. Interestingly, the physical principles for describing bulk semiconductor devices also hold for devices based on these semiconducting nanowires with wire diameters of tens of nanometers. For example, Fig. 9.24 shows the current-voltage (*I–V*) behavior of a four-by-one crossed p-Si/n-GaN junction array at room temperature [9.167]. The long horizontal wire in the figure is a p-Si nanowire (10−25 nm in diameter) and the four short vertical wires are n-GaN nanowires (10−30 nm in diameter). Each of the four nanoscale cross-points independently forms a p-n junction with current rectification behavior, as shown by the *I–V* curves in Fig. 9.24. The junction behavior (for example, the turn-on voltage) can be controlled by varying the oxide coating on these nanowires [9.167].

Huang et al. have demonstrated nanowire junction diodes with a high turn-on voltage (≈ 5 V) by increasing the oxide thickness at the junctions. The high turn-on voltage enables the use of the junction in a nanoscale field-effect transistor (FET), as shown in Fig. 9.25 [9.167] where *I–V* data for a p-Si nanowire are presented, for which the n-GaN nanowire with a thick oxide coating is used as a nanogate. By varying the nanogate voltage, the conductance of the p-Si nanowire can be changed by more than a factor of 10^5 (lower curve in the inset), whereas the conductance changes by only a factor of ten when a global back-gate is used (top curve in the inset of Fig. 9.25). This behavior may be due to the thin gate dielectric between the crossed nanowires and the better control of the local carrier density through a nanogate. Based on the gate-dependent *I–V* data from these p-Si nanowires, it is found that the mobility of the holes in the p-Si nanowires may be higher than that for bulk p-Si, although further investigation is required for complete understanding.

Because of the enhanced surface-to-volume ratios of nanowires, their transport behavior may be modified by changing their surface conditions. For example, researchers have found that by coating n-InP nanowires with a layer of redox molecules, such as cobalt phthalocyanine, the conductance of the InP nanowires may change by orders of magnitude upon altering the charge state of the redox molecules to provide bistable nanoscale switches [9.169]. The resistance (or conductance) of some nanowires (such as Pd nanowires) is also very sensitive to the presence of certain gases (e.g., H_2) [9.170, 171], and this property may be utilized for sensor applications to provide improved sensitivity compared to conventional sensors based on bulk material (Sect. 9.3.4).

Although it remains unclear how the size effect may influence the transport properties and device performance of semiconducting nanowires, many of the

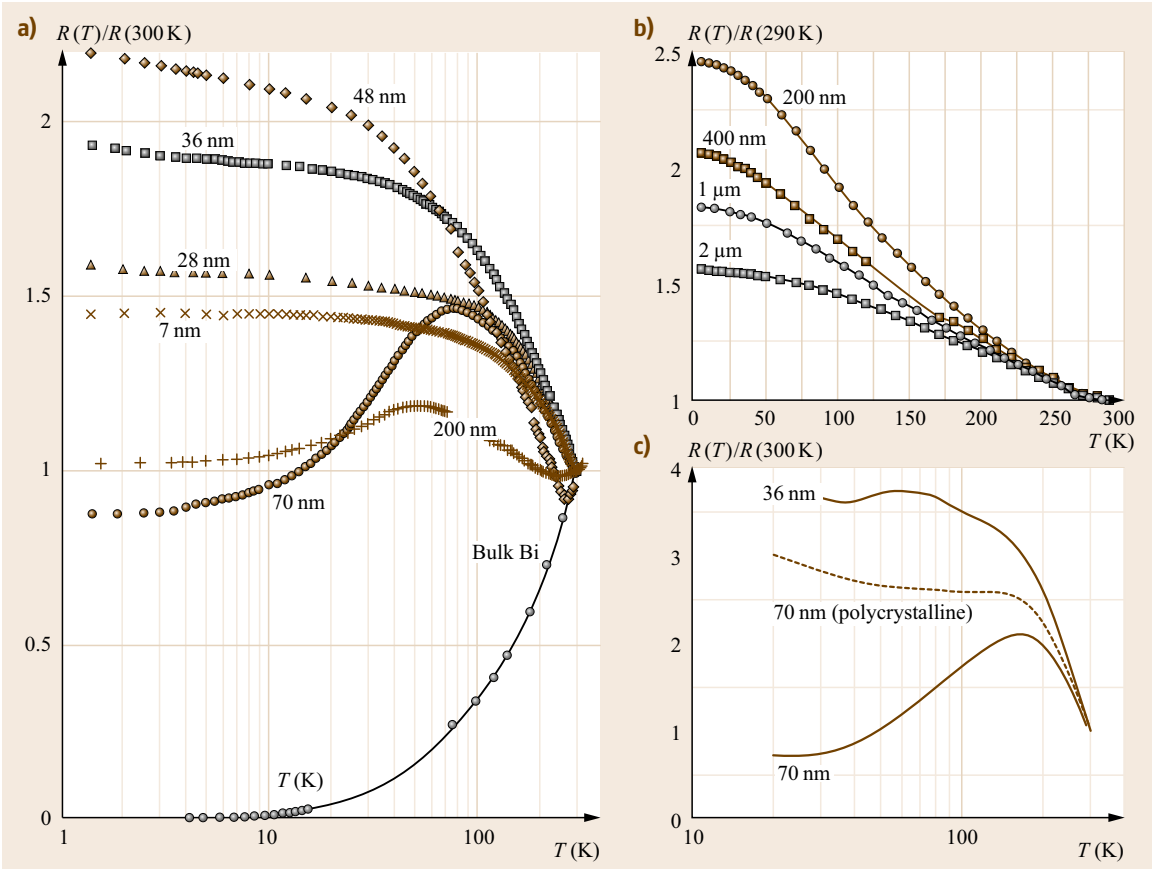

Fig. 9.26 **(a)** Measured temperature dependence of the resistance $R(T)$ normalized to the room temperature (300 K) resistance for bismuth nanowire arrays of various wire diameters d_W (after [9.17]). **(b)** $R(T)/R(290\,K)$ for bismuth wires of larger d_W and lower mobility (after [9.19]). **(c)** Calculated $R(T)/R(300\,K)$ of 36 and 70 nm bismuth nanowires. The *dashed curve* refers to a 70 nm polycrystalline wire with increased boundary scattering (after [9.93])

larger-diameter semiconducting nanowires are expected to be described by classical physics, since their quantization energies $\hbar^2/(2m_e d_W^2)$ are usually smaller than the thermal energy $k_B T$. By comparing the quantization energy with the thermal energy, the critical wire diameter below which quantum confinement effects become significant is estimated to be 1 nm for Si nanowires at room temperature, which is much smaller than the sizes of many of the semiconducting nanowires that have been investigated so far. By using material systems with much smaller effective carrier masses m_e (such as bismuth), the critical diameter for which such quantum effects can be observed increases, thereby facilitating the study of quantum confinement effects. It is for this reason that the bismuth nanowire system has been studied so extensively. Furthermore, since the crystal structure and lattice constants of bismuth nanowires are the same as for 3-D crystalline bismuth, it is possible to carry out detailed model calculations to guide and to interpret transport and optical experiments on bismuth nanowires. For these reasons, bismuth can be considered a model system for studying 1-D effects in nanowires.

Temperature-Dependent Resistance Measurements

Although nanowires with electronic properties similar to their bulk counterparts are promising for constructing nanodevices based on well-established knowledge of their bulk counterparts, it is expected that quantum size effects in nanowires will likely be utilized to generate new phenomena absent in bulk materials, and thus provide enhanced performance and novel functionality for certain applications. In this context, the transport properties of bismuth (Bi) nanowires have been extensively studied, both theoretically [9.172] and experimentally [9.17, 19, 93, 173–175] because of their promise for enhanced thermoelectric performance.

Transport studies of ferromagnetic nanowire arrays, such as Ni or Fe, have also received much attention because of their potential for high-density magnetic storage applications [9.176].

As mentioned in the previous section, the very small electron effective mass components and the long carrier mean free paths in Bi facilitate the study of quantum size effects in the transport properties of nanowires. Quantum size effects are expected to become significant in bismuth nanowires with diameters smaller than 50 nm [9.172], and the fabrication of crystalline nanowires with this diameter range is relatively easy.

Figure 9.26a shows the T dependence of the resistance $R(T)$ for Bi nanowires ($7\,\text{nm} \leq d_W < 200\,\text{nm}$) synthesized by vapor deposition and pressure injection [9.17], illustrating quantum effects in their temperature-dependent resistance. In Fig. 9.26a, the $R(T)$ behavior of Bi nanowires is dramatically different from that of bulk Bi, and is highly sensitive to the wire diameter. Interestingly, the $R(T)$ curves in Fig. 9.26a show a non-monotonic trend for large-diameter (70 and 200 nm) nanowires, although $R(T)$ becomes monotonic with T for small-diameter ($\leq 48\,\text{nm}$) nanowires. This dramatic change in the behavior of $R(T)$ as a function of d_W is attributed to a unique semimetal-semiconductor transition phenomena in Bi [9.93], induced by quantum size effects. Bi is a semimetal in bulk form, in which the T-point valence band overlaps with the L-point conduction band by 38 meV at 77 K. As the wire diameter decreases, the lowest conduction subband increases in energy and the highest valence subband decreases in energy. Model calculations predict that the band overlap should vanish in Bi nanowires (with their wire axes along the trigonal crystallographic direction) at a wire diameter $\approx 50\,\text{nm}$ [9.172].

The resistance of Bi nanowires is determined by two competing factors: the carrier density that increases with T, and the carrier mobility that decreases with T. The non-monotonic $R(T)$ for large-diameter Bi nanowires is due to a smaller carrier concentration variation at low temperature ($\leq 100\,\text{K}$) in semimetals, so that the electrical resistance is dominated by the mobility factor in this temperature range. Based on the semiclassical transport model and the established band structure of Bi nanowires, the calculated $R(T)/R(300\,\text{K})$ for 36 and 70 nm Bi nanowires is shown by the solid curves in Fig. 9.26c to illustrate different $R(T)$ trends for semiconducting and semimetallic nanowires respectively [9.93]. The curves in Fig. 9.26c exhibit trends consistent with experimental results. The condition for the semimetal-semiconductor transition in Bi nanowires can be experimentally determined, as shown by the measured resistance ratio $R(10\,\text{K})/R(100\,\text{K})$ of Bi nanowires as a function of wire diameter [9.177] in Fig. 9.27. The maximum in the resistance ratio $R(10\,\text{K})/R(100\,\text{K})$ at $d_W \approx 48\,\text{nm}$ indicates the wire diameter for the transition of Bi nanowires from a semimetallic phase to a semiconducting phase. The semimetal-semiconductor transition and the semiconducting phase in Bi nanowires are examples of new transport phenomena resulting from low dimensionality that are absent in the bulk 3-D phase. These phenomena further increase the possible benefits of exploiting properties of nanowires for desired applications.

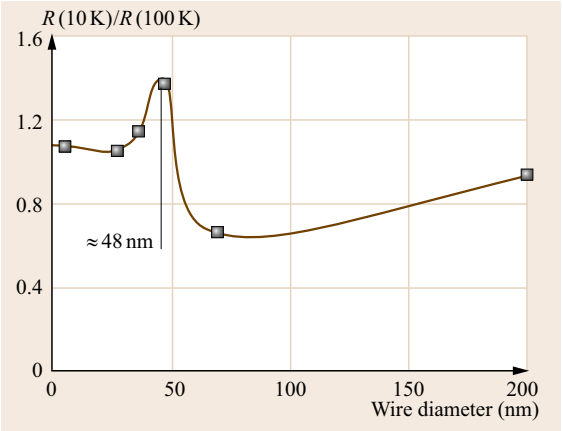

Fig. 9.27 Measured resistance ratio $R(10\,\text{K})/R(100\,\text{K})$ of a Bi nanowire array as a function of diameter. The *peak* indicates the transition from a semimetallic phase to a semiconducting phase as the wire diameter decreases (after [9.178])

It should be noted that good crystal quality is essential for observing the quantum size effect in nanowires, as shown by the $R(T)$ plots in Fig. 9.26a. Fig. 9.26b shows the normalized $R(T)$ measurements of Bi nanowires with larger diameters (200 nm–2 μm) prepared by electrochemical deposition [9.19]. These nanowires possess monotonic $R(T)$ behaviors, quite different from those of the corresponding nanowire diameters shown in Fig. 9.26a. The absence of the resistance maximum in Fig. 9.26b is due to the lower crystalline quality for nanowires prepared by electrochemical deposition, which tends to produce polycrystalline nanowires with a much lower carrier mobility. This monotonic $R(T)$ curve for semimetallic Bi nanowires with a higher defect level is also confirmed by theoretical calculations, as shown by the dashed curve in Fig. 9.26c for 70 nm wires with increased grain boundary scattering [9.179].

The theoretical model developed for Bi nanowires not only provides good agreement with experimental results, but it also plays an essential role in understanding the influence of the quantum size effect, the boundary scattering, and the crystal quality on their electrical

properties. While the electronic density of states may be significantly altered due to quantum confinement effects, various scattering mechanisms related to the transport properties of nanowires can be accounted for by Matthiessen's rule. Furthermore, the transport model has also been generalized to predict the transport properties of Te-doped Bi nanowires [9.93], Sb nanowires [9.180], and BiSb alloy nanowires [9.181], and good agreement between experiment and theory has also been obtained for these cases.

For nanowires with diameters comparable to the phase-breaking length, their transport properties may be further influenced by localization effects. It has been predicted that in disordered systems, the extended electronic wavefunctions become localized near defect sites, resulting in the trapping of carriers and giving rise to different transport behavior. Localization effects are also expected to be more pronounced as the dimensionality and sample size are reduced. Localization effects on the transport properties of nanowire systems have been studied on Bi nanowires [9.182] and Zn nanowires [9.63]. Figure 9.28 shows the measured $R(T)/R(300\,\mathrm{K})$ of Zn nanowires fabricated by vapor deposition in porous silica or alumina [9.63]. While 15 nm Zn nanowires exhibit an $R(T)$ behavior with a T^1 dependence as expected for a metallic wire, the $R(T)$ of 4 nm Zn nanowires exhibits a temperature dependence of $T^{-1/2}$ at low temperatures, consistent with 1-D localization theory. Thus, due to this localization effect, the use of nanowires with very small diameters for transport applications may be limited.

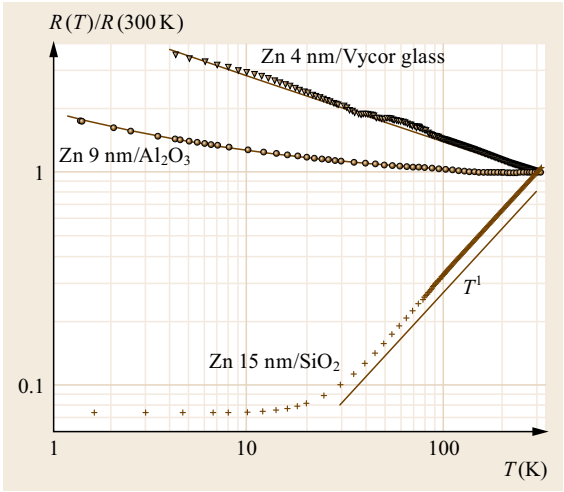

Fig. 9.28 Temperature dependence of the resistance of Zn nanowires synthesized by vapor deposition in various porous templates (after [9.63]). The data are given as *points*, the *full lines* are fits to a T^1 law for 15 nm diameter Zn nanowires in an SiO_2 template, denoted by Zn/SiO_2. Fits to a combined T^1 and $T^{-1/2}$ law were made for the smaller nanowire diameter composite samples denoted by Zn (9 nm)/Al_2O_3 and Zn 4 nm/Vycor glass

Magnetoresistance

Magnetoresistance (MR) measurements for characterizing nanowires yield a great deal of information about the effects of wire boundary, doping and annealing on electron scattering, and about localization effects in nanowires [9.175]. For example, at low fields the MR data show a quadratic dependence on the B field from which carrier mobility estimates can be made (Fig. 9.29 at low B field).

Figure 9.29 shows the longitudinal magnetoresistance ($\boldsymbol{B}$ parallel to the wire axis) for 65 and 109 nm Bi nanowire samples (before thermal annealing) at 2 K. The MR maxima in Fig. 9.29a are due to the classical size effect, where the wire boundary scattering is reduced as the cyclotron radius becomes smaller than the wire radius in the high field limit, resulting in a decrease in resistivity. This behavior is typical for the longitudinal MR of Bi nanowires in the diameter range of 45–200 nm [9.17, 174, 175, 183], and the peak position B_m moves to lower B field values as the wire diameter increases, as shown in Fig. 9.29c [9.183], where B_m varies linearly with $1/d_\mathrm{W}$. The condition for the occurrence of B_m is approximately given by $B_\mathrm{m} \approx 2c\hbar k_\mathrm{F}/(ed_\mathrm{W})$, where k_F is the wave vector at the Fermi energy. The peak position B_m is found to increase linearly with increasing temperature in the range of 2–100 K, as shown in Fig. 9.29b [9.183]. As T is increased, phonon scattering becomes increasingly important, and therefore a higher magnetic field is required to reduce the resistivity associated with boundary scattering sufficiently to change the sign of the MR. Likewise, increasing the grain boundary scattering is also expected to increase the value of B_m at a given T and wire diameter.

The presence of the peak in the longitudinal MR of nanowires requires a high crystal quality with long carrier mean free paths along the nanowire axis, so that most scattering events occur at the wire boundary instead of at a grain boundary, at impurity sites, or at defect sites within the nanowire. *Liu* et al. have investigated the MR of 400 nm Bi nanowires synthesized by electrochemical deposition [9.84], and no peak in the longitudinal MR is observed. The absence of a magnetoresistance peak may be attributed to a higher defect level in the nanowires produced electrochemically and to a large wire diameter, much longer than the carrier mean free path. The negative MR observed for the Bi nanowire arrays above B_m (Fig. 9.29) shows that wire boundary scattering is a dominant scattering process for the longitudinal magnetoresistance, thereby estab-

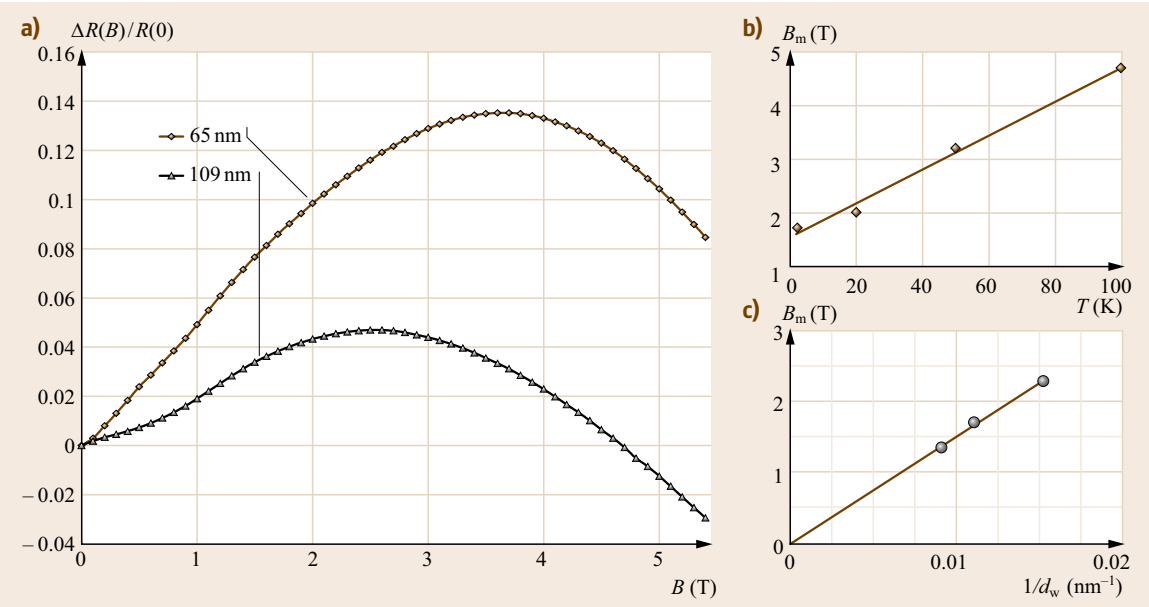

Fig. 9.29 **(a)** Longitudinal magnetoresistance, $\Delta R(B)/R(0)$, at 2 K as a function of B for Bi nanowire arrays with diameters of 65 and 109 nm before thermal annealing. **(b)** The peak position B_m as a function of temperature for the 109 nm diameter Bi nanowire array after thermal annealing. **(c)** The peak position B_m of the longitudinal MR (after thermal annealing) at 2 K as a function of $1/d_W$, the reciprocal of the nanowire diameter (after [9.183])

lishing that the mean free path is larger than the wire diameter.

In addition to the longitudinal magnetoresistance measurements, transverse magnetoresistance measurements (***B*** perpendicular to the wire axis) have also been performed on Bi nanowire array samples [9.17, 175, 183], where a monotonically increasing B^2 dependence over the entire range $0\,\mathrm{T} \leq B \leq 5.5\,\mathrm{T}$ is found for all Bi nanowires studied. This is expected, since the wire boundary scattering cannot be reduced by a magnetic field perpendicular to the wire axis. The transverse magnetoresistance is also found to be always larger than the longitudinal magnetoresistance in nanowire arrays.

The Shubnikov–de Haas (SdH) quantum oscillatory effect, which results from the passage of the quantized Landau levels through the Fermi energy as the field strength varies, should, in principle, provide the most direct measurement of the Fermi energy and carrier density. For example, *Heremans* and *Thrush* have demonstrated that SdH oscillations can be observed in Bi nanowire samples with diameters down to 200 nm [9.184], and they have demonstrated that Te doping can be used to raise the Fermi energy in Bi nanowires. Such information on the Fermi energy is important because, for certain applications based on nanowires, it is necessary to place the Fermi energy near a subband edge where the density of states has a sharp feature. However, due to the unusual 1-D geometry of nanowires, other characterization techniques that are commonly used in bulk materials to determine the Fermi energy and the carrier concentration (such as Hall effect measurement) cannot be applied to nanowire systems.

Thermal Conductivity of Nanowires

The thermal conductivity in nanowires can be significantly reduced as the dimensions of the nanowire become comparable to the phonon mean free path and the phonon wavelength [9.185]. The confinement in the nanowire may modify the phononphonon density of states, while defects in the nanowire enhance scattering. The most dominant suppression of thermal conductivity is achieved when multiple mechanisms operate to impede phonon transport at various length scales: atomic point-defects scatter high-frequency phonons, and interfaces and grain boundaries scatter primarily low-to-mid frequency phonons. Silicon nanowires with smooth and rough surfaces [9.186–188], segmented Si/SiGe nanowires [9.189], and indium gallium zinc oxide nanowires [9.190] have been selected as testbeds for fundamental studies. The enhancement of a new mechanism of phonon scattering in nanowires is evident by the lower thermal conductivity and by the change in its temperature dependence [9.185].

Measurements of the thermal conductivity of nanowires have been carried out on nanowire arrays embed-

ded in a matrix and individual free-standing nanowires. The former provides data of relevance to device performance, while only the latter can provide reliable data that are not distorted by thermal transport via the matrix or substrate and by sample polydispersity. Single-nanowire thermal measurements are very challenging and are now possible thanks to technological developments in the micro- and nanofabrication of miniature thermal sensors [9.191], and the use of nanometer-size thermal scanning probes [9.153, 192, 193]. In a typical fabricated device, shown in Fig. 9.30, a nanowire is suspended across a gap between two SiN_x membranes supported by long beams. On the membranes, metal lines form heating elements, resistive temperature sensors, and electrodes. Using a heat flow model, the thermal conductivity $\kappa(T)$ of the individual suspended nanowires can be extracted from the sensor data [9.194].

The experiments show that the thermal conductivity of small-diameter homogeneous nanowires may be more than one order of magnitude smaller than in the bulk, mainly due to the effect of strong phonon boundary scattering [9.195]. Phonon confinement effects may eventually become important in nanowires with even smaller diameters. The most extensive experimental thermal conductivity measurements have been done on Si nanowires [9.186], where $\kappa(T)$ measurements have been made on nanowires in the diameter range of 22−115 nm. As d_W decreases a large decrease is observed in the peak of $\kappa(T)$, associated with Umklapp processes, indicating a growing importance of boundary scattering and a corresponding decreasing importance of phonon-phonon scattering (Fig. 9.31). At the smallest wire diameter of 22 nm, a linear $\kappa(T)$ dependence is found experimentally, consistent with a linear T dependence of the specific heat for a 1-D system, and a temperature-independent mean free path and sound velocity. Introduction of scattering elements through alloying and composition modulation, such as in Si/SiGe superlattice nanowires, pushed the thermal conductivity values further down [9.189]. Remarkably, surface roughness, observed in some Si nanowires fabricated by the MACE method (Sect. 9.1.3), also reduces $\kappa(T)$ by an order of magnitude, such that 50 nm diameter rough Si nanowires have thermal conductivity values lower than 2 $Wm^{-1}K^{-1}$ at room temperature [9.188].

Model calculations for $\kappa(T)$ based on a radiative heat transfer model have been carried out for Si nanowires [9.196–198]. These results show that the predicted $\kappa(T)$ behavior for Si nanowires is similar to that observed experimentally in the range of 37 nm $\leq d_W \leq$ 115 nm regarding both the functional form of $\kappa(T)$ and the magnitude of the relative decrease in the maximum thermal conductivity as a function of

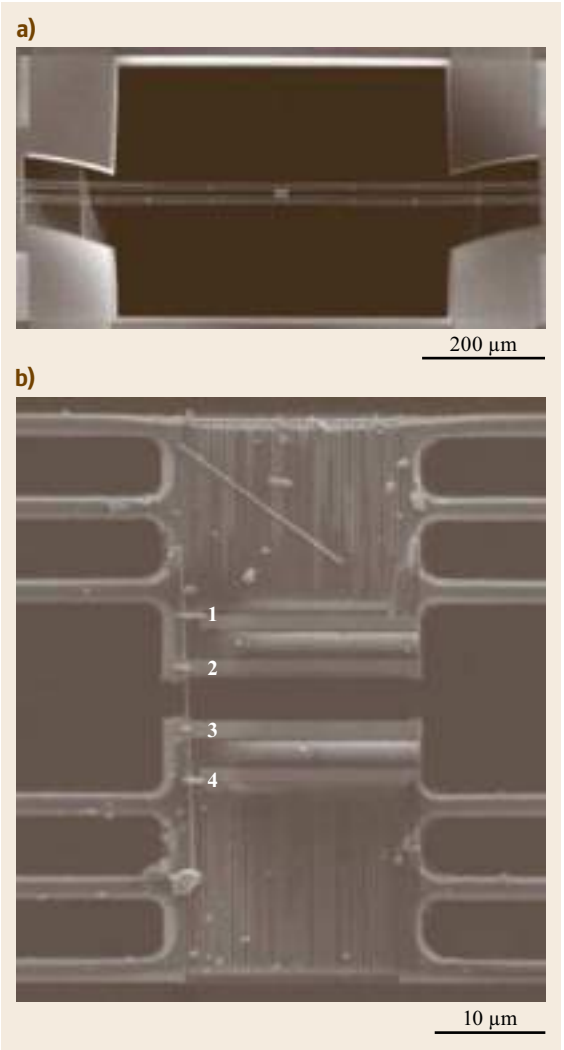

Fig. 9.30a,b Microfabricated device for the measurement of the thermal conductivity and thermoelectric properties of individual nanowires. **(a)** Low magnification view of the full length of the microscale device. **(b)** High magnification view of the probed nanowire and metalization lines on the membranes. d_W. However, the model calculations often overestimate κ_{max}, with agreement improved by using the full phonon dispersion relations. Furthermore, the model calculations (Fig. 9.31) do not reproduce the experimentally observed linear T dependence for the 22 nm nanowires, but rather predict a 3-D behavior for both the density of states and the specific heat in 22 nm nanowires [9.196, 199]. *Kazan* et al. resolved the discrepancies by considering also optical phonon decay and an angle-dependent specularity function for the boundary scattering, and

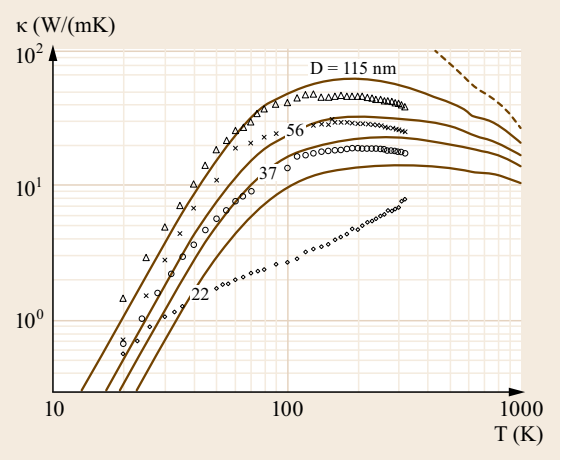

Fig. 9.31 Predicted thermal conductivities of Si nanowires of various diameters (*solid lines*) and the corresponding experimental data (symbols, from [9.186]) (after [9.196])

they were able to model both the diameter and surface roughness effects [9.200].

Thermal conductance measurements on GaAs nanowires below 6 K show a power law dependence, but the T dependence becomes somewhat less pronounced below ≈ 2.5 K [9.192]. This deviation from the power law temperature dependence led to a more detailed study of the quantum limit for the thermal conductance. To carry out more detailed experiments, a mesoscopic phonon resonator and waveguide device were constructed that included four ≈ 200 nm wide and 60 nm thick silicon nitride nanowire-like nano-constrictions (Fig. 9.32a), and this was used to establish the quantized thermal conductance limit of $g_0 = \pi^2 k_B^2 T/(3h)$ (Fig. 9.32b) for ballistic phonon transport [9.201, 202].

For temperatures above 0.8 K, the thermal conductance in Fig. 9.32b follows a T^3 law, but as T is further reduced, a transition to a linear T dependence is observed, consistent with a phonon mean free path of $\approx 1\,\mu$m, and a thermal conductance value approaching $16g_0$, corresponding to four massless phonon modes per channel and four channels in their phonon waveguide structure (Fig. 9.32a). Ballistic phonon transport occurs when the thermal phonon wavelength (380 nm for the experimental structure) is somewhat greater than the width of the phonon waveguide at the waveguide constriction.

Thermoelectric Properties

Nanowires are predicted to hold great promise for thermoelectric applications [9.172, 203], due to their unique band structure compared to their bulk counterparts and the expected reduction in thermal conductivity associated with enhanced boundary scattering (see Sect. 9.2.3, *Thermal Conductivity of Nanowires* above). Due to the sharp density of states function at the 1-D subband edges (where the van Hove singularities occur), nanowires are expected to exhibit enhanced Seebeck coefficients compared to their bulk counterparts. Since the Seebeck coefficient measurement is intrinsically independent of the number of nanowires contributing to the signal, the measurements on nanowire arrays of uniform wire diameter are, in principle, as accurate as single-wire measurements. Individual nanowire measurements, on the other hand, allow for the simultaneous determination of the Seebeck coefficient S, the thermal conductivity κ, and the electrical conductivity σ (and thus, the power factor $S^2\sigma$ and the figure-of-merit $ZT = S^2\sigma T\kappa^{-1}$), as well as electrostatic gating of semiconductor nanowires for detailed stud-

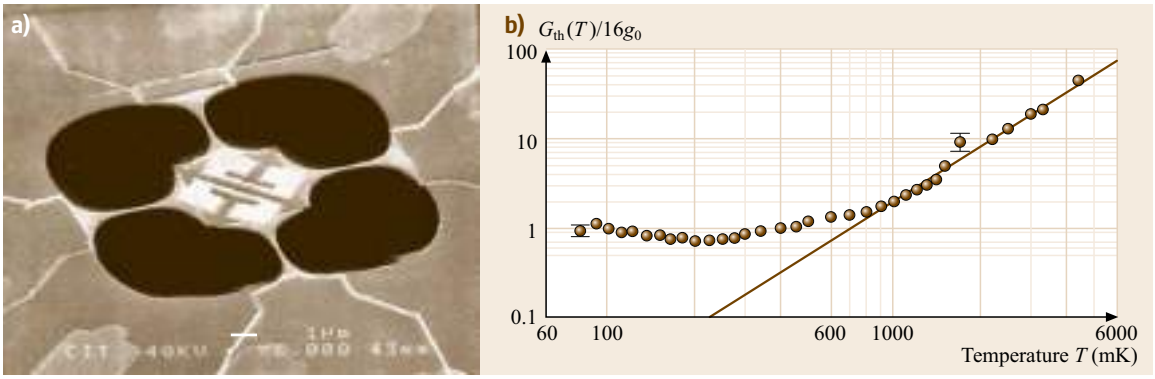

Fig. 9.32 **(a)** Suspended mesoscopic phonon device used to measure ballistic phonon transport. The device consists of a $4\times4\,\mu m^2$ *phonon cavity* (*center*) connected to four Si_3N_4 beams, 60 nm thick and less than 200 nm wide at the narrowest point. ies of carrier concentration effects on thermoelectric properties.

Many nanowire systems have demonstrated enhanced Seebeck coefficient values as the diameter of the nanowire is reduced. Measured Seebeck coefficients $S(T)$ may also display a temperature dependence different than the bulk, indicative of carrier localization, enhanced scattering, or quantum confinement effects. In the well-known $Bi_{1-x}Sb_x$ thermoelectric material systems, $S(T)$ values are enhanced in arrays of nanowires with diameters of 40 and 65 nm (but not 200 nm), and by alloying with isoelectronic Sb [9.179]. Thermopower enhancement is attributed to the semimetal-semiconductor transition induced by quantum confinement and to Sb alloying effects in $Bi_{1-x}Sb_x$ nanowires [9.204]. *Heremans* et al. have observed a substantial increase in the thermopower of Bi in tiny nanowires in Bi(15 nm)/silica and Bi(9 nm)/alumina disordered nanocomposites [9.63]. The enhancement is due to the sharp density of states near the Fermi energy in a 1-D system. Measurements on individual or a small number of Si nanowires also showed dramatic enhancement of the Seebeck coefficient near and below room temperature, showing that non-traditional thermoelectric materials can become technologically relevant in nanowire form [9.187, 188]. This is particularly important in light of the poor mechanical properties, low abundance, and toxicity of some of the materials traditionally used for thermoelectrics. Since the Seebeck coefficient is a function of the carrier density, modulation of $S(T, V_G)$ is observed in individual electrostatically-gated nanowires (Sb_2Te_3 [9.205]; PbSe [9.206]; InAs [9.207, 208]), offering an additional strategy for tuning the thermoelectric properties. At cryogenic temperatures, the $S(V_G)$ function shows distinct peaks. The interpretation of these peaks is still under debate; the features may originate from the quantization in the band structure (subband formation) or from nanowire nonuniformities.

For applications in cooling and power generation, enhancing only the thermopower is not sufficient. In fact, in all the nanowire examples quoted above, the enhanced thermopower is accompanied by a significant reduction of the electrical conductivity, detrimental to the power factor $S^2\sigma$. Theoretical work demonstrates that quantum confinement in nanowires effectively reduces that density-of-states for electrons and holes in two-band semiconductors. As a result, as the nanowire diameter decreases, a decrease in the power factor is expected (Fig. 9.33) [9.209, 210]. This trend is reversed in small-diameter nanowires where electrons in the single lowest subband dominate transport ($d < 37$ nm for InSb, see Fig. 9.33). At this strongly confined regime, the power factor goes as d^{-2}; however, electron scattering and localization effects put a cap on the benefits of size reduction. The notable breakthroughs in low-dimensional systems for thermoelectric applications are related to the high figure-of-merit values that were achieved by drastically reducing the thermal conductivity while maintaining the power factor only slightly below bulk values. In smooth- and rough-edge silicon nanowires, reduction of the thermal conductivity by two orders of magnitude led to ZT values of up to 0.6 at 300 K (compare to 0.01 for bulk silicon) [9.187, 188]. Further improvements will likely involve materials with more complex band structures [9.204, 211] and more complex geometries [9.212].

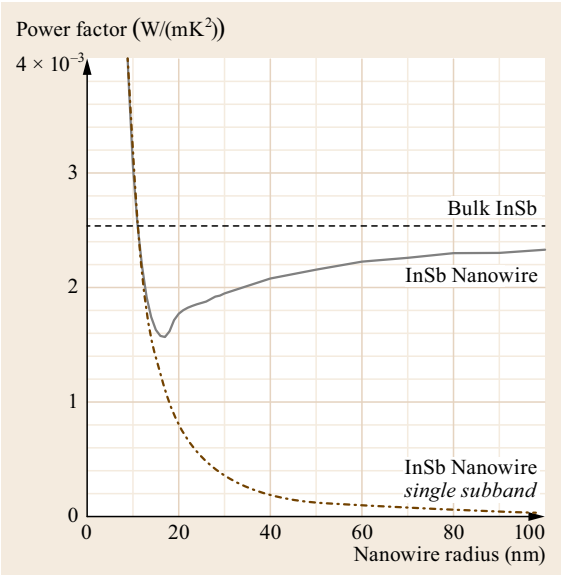

Fig. 9.33 Calculated thermoelectric power factor for n-type InSb nanowires (*solid line*). The power factor surpasses the bulk value (*dashed line*) only for very narrow nanowires, where electrons in one subband dominate transport. The *dash-dotted* line illustrates the size dependence of the power factor in a model considering just one subband (adapted from [9.209])

In 3-D systems, the electronic contribution to κ is proportional to σ in accordance with the Wiedemann–Franz law, and normally materials with high S have a low σ. Hence an increase in the electrical conductivity (for example by electron donor doping) results in an adverse variation in both the Seebeck coefficient (decreasing) and the thermal conductivity (increasing). These two trade-offs set the upper limit for increasing ZT in bulk materials, with the maximum ZT remaining ≈ 1 at room temperature for the 1960–1995 time frame.

The high electronic density of states in quantum-confined structures is proposed as a promising possibil-

ity to bypass the Seebeck/electrical conductivity tradeoff and to control each thermoelectric-related variable independently, thereby allowing for increased electrical conductivity, relatively low thermal conductivity, and a large Seebeck coefficient simultaneously [9.213]. The quantum size effect in nanowires can be combined with other parameters to tailor the band structure and electronic transport behavior (for instance, Sb alloying in Bi) to further optimize ZT. For example, Fig. 9.34 shows the predicted ZT for p-type $Bi_{1-x}Sb_x$ alloy nanowires as a function of wire diameter and Sb content x [9.204]. The occurrence of a local ZT maximum in the vicinity of $x \approx 0.13$ and $d_W \approx 45$ nm is due to the coalescence of the energies of ten valence bandextrema in the nanowire and the resulting unusually high density of states for holes, which is a phenomenon absent in bulk $Bi_{1-x}Sb_x$ alloys. For nanowires with very small diameters, it is speculated that localization effects will eventually limit the enhancement of ZT. However, in bismuth nanowires, localization effects are not significant for wires with diameters larger than 9 nm [9.63]. In addition to 1-D nanowires, ZT values as high as ≈ 2 have also been experimentally demonstrated in macroscopic samples containing PbSe quantum dots (0-D) [9.214] and stacked two-dimensional (2-D) films [9.195].

Quantum Wire Superlattices

The studies on superlattice nanowires, which possess a periodic modulation in their material composition along the wire axis, have attracted much attention recently because of their promise in various applications, such as thermoelectrics [9.107, 215], nanobarcodes (Sect. 9.3.2) [9.216], nanolasers (Sect. 9.3.2) [9.111], one-dimensional waveguides, and resonant tunneling diodes [9.113, 217]. Figure 9.35a shows a schematic structure of a superlattice nanowire consisting of interlaced quantum dots of two different materials, as denoted by A and B. Various techniques have been developed to synthesize superlattice nanowire structures with different interface conditions, as mentioned in Sects. 9.1.1 and 9.1.2.

In this superlattice nanowire structure, the electronic transport along the wire axis is made possible by the tunneling between adjacent quantum dots, while the uniqueness of each quantum dot and its 0-D characteristic behavior is maintained by the energy difference of the conduction or valence bands between quantum dots of different materials (Fig. 9.35b), which provides some amount of quantum confinement. *Björk* et al. have observed interesting nonlinear I–V characteristics with a negative differential resistance in one-dimensional heterogeneous structures made of InAs and InP, where InP serves as the potential barrier [9.113, 217]. The nonlinear I–V behavior is associated with the double barrier resonant tunneling process in one-dimensional structures, demonstrating that transport phenomena occur in superlattice nanowires via tunneling, and the possibility of controlling the electronic band structure of the superlattice nanowires by carefully selecting the constituent materials. These structures are especially attractive for thermoelectric applications, because the interfaces between the nanodots can reduce the lattice thermal conductivity by blocking the phonon conduction along the wire axis, while electrical conduction may be sustained and even benefit from the unusual electronic band structures due to the periodic potential perturbation.

9.2.4 Optical Properties

Optical methods provide a convenient tool for measuring the electronic structures of nanowires, since optical

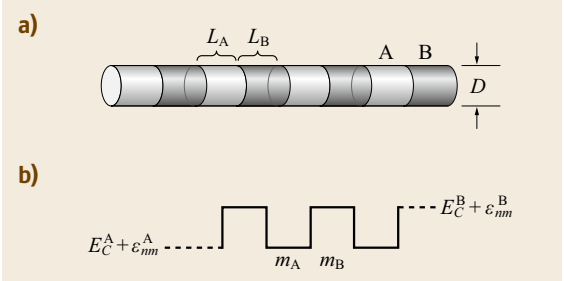

Fig. 9.35 (a) Schematic diagram of superlattice (segmented) nanowires consisting of interlaced nanodots A and B of the indicated length and wire diameter. **(b)** Schematic potential profile of the subbands in the superlattice nanowire (after [9.215])

measurements require minimal sample preparation (for example, contacts are not required) and are sensitive to quantum effects. A variety of optical techniques have shown that the properties of nanowires are different from those of their bulk counterparts. For example, optical spectra of 1-D systems often show intense features at specific energies near singularities in the joint density of states that are formed under strong quantum confinement conditions.

Although optical methods are an extremely important tool for characterizing nanowires, the interpretation of these measurements for nanowires is not always straightforward. The wavelength of light used to probe the sample is usually smaller than the wire length, but larger than the wire diameter. Hence, the probe light used in an optical measurement cannot be focused solely onto the wire, and the wire and the substrate on which the wire rests (or host material, if the wires are embedded in a template) are probed simultaneously.

In this section we discuss the determination of the dielectric function for nanowires from optical measurements. We then discuss various optical techniques with appropriate examples that sensitively differentiate nanowire properties from those also found in the parent bulk material. Finally, phonon confinement effects are reviewed.

The Dielectric Function

The observable optical properties of materials can be related to their complex dielectric function [9.218, 219]. Since nanowire diameters are typically smaller than the wavelength of light, photons at visible or infrared wavelengths *see* a dielectric function for the composite nanowire array/substrate system that is different from that of the nanowire itself. Effective medium theories [9.220, 221] can be applied to model the nanowire and substrate as one continuous composite with a single complex dielectric function $(\epsilon_1 + \mathrm{i}\epsilon_2)$, where the real and imaginary parts of the dielectric function ϵ_1 and ϵ_2 are related to the index of refraction (n) and the absorption coefficient (K) by the relation $\epsilon_1 + \mathrm{i}\epsilon_2 = (n + \mathrm{i}K)^2$. One commonly observed consequence of effective medium theory is the lower (higher) energy of the plasma frequency (when $\epsilon_1(\omega)$ becomes zero), when the magnitude of the dielectric function of the host materials is larger (smaller) than that of the nanowire [9.222].

The dielectric function of the nanowires and the substrate can be separated out by using effective medium theory in reverse. Since the dielectric function of the host material is often known, and the dielectric function of the composite material can be measured (using reflection and transmission measurements in combination with either the Kramer–Kronig relations or Maxwell's equations), the complex dielectric function of the nanowires can be deduced. As an example, this technique was used to determine the frequency dependence of the real and imaginary parts of the dielectric function $\epsilon_1(\omega)$ and $\epsilon_2(\omega)$ for an array of parallel bismuth nanowires filling the pores of an alumina template [9.223].

If both the dielectric permittivity and the magnetic permeability are negative, the material will display a negative index of refraction. A material with a negative index of refraction has interesting physics and can be used to make a lens that is not limited by the diffraction limit [9.224]. Such materials are artificially designed composites with components of subwavelength dimensions, often metallic and magnetic (nano)wires. Negative refraction is also observed in hyperbolic metamaterials, where the permeability is positive and the permittivity tensor has both positive and negative components. Parallel metallic nanowires in a dielectric matrix satisfy this condition [9.225]. Negative refraction at visible light was first realized using a silver nanowire array in porous anodic alumina [9.226].

Characteristic Optical Properties of Nanowires

Reflection and transmission measurements are often used for nanowire characterization. Infrared spectroscopy, for example, can be used to determine the plasma frequency, free carrier density, and donor impurity concentration as a function of temperature. This is especially useful for nanowire research, since Hall effect measurements cannot be made on nanowires. For example, the bandgap of gallium nitride and its temperature dependence were determined by infrared spectroscopy in nanowires in the 10–50 nm range in comparison to bulk values [9.227].

Another common method used to study nanowires is photoluminescence spectrum (PL) or fluorescence spectroscopy. PL has been used to study many properties of nanowires, such as the optical gap behavior, oxygen vacancies in ZnO nanowires [9.66], strain in Si nanowires [9.229], and quantum confinement effects in InP and Si nanowires [9.228, 230]. Figure 9.36 shows the photoluminescence spectrum of InP nanowires as a function of wire diameter, thereby providing direct information on the effective bandgap. As the wire diameter of an InP nanowire is decreased so that it becomes smaller than the bulk exciton diameter of 19 nm, quantum confinement effects set in, and the bandgap is increased. This results in an increase in the PL peak energy. The smaller the effective mass, the larger the quantum confinement effects. When the shift in the peak energy as a function of nanowire diameter (Fig. 9.36) is analyzed using an effective mass model, the reduced effective mass of the ex-

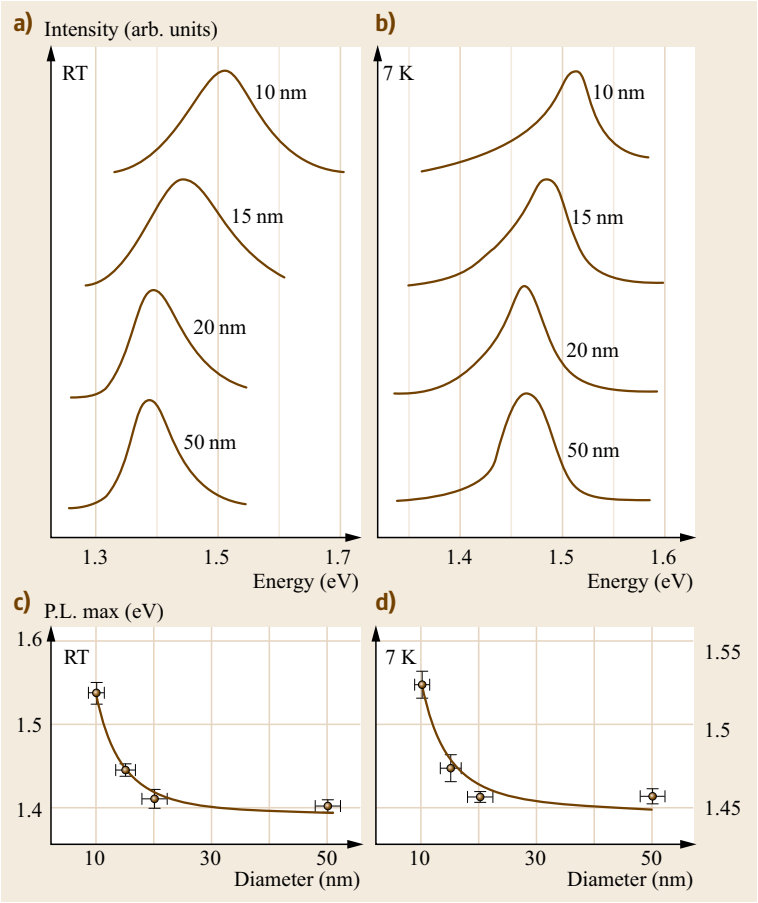

Fig. 9.36 Photoluminescence of InP nanowires of varying diameters at 7 K (**b**,**d**) and room temperature (**a**,**c**) showing quantum confinement effects of the exciton for wire diameters of less than 20 nm (after [9.228])

citon is deduced to be $0.052m_0$, which agrees quite well with the literature value of $0.065m_0$ for bulk InP. Although the line widths of the PL peak for the small-diameter nanowires (10 nm) are smaller at low temperature (7 K), strong quantum confinement and bandgap tunability effects persist at room temperature and thus are significant for photonics applications of nanowires (Sect. 9.3.2).

The resolution of photoluminescence (PL) optical imaging of a nanowire is, in general, limited by the wavelength of light. However, when a sample is placed very close to the detector, the light is not given a chance to diffract, and so samples much smaller than the wavelength of light can be resolved. This technique is known as near-field scanning optical microscopy (NSOM) and has been used to successfully image nanowires [9.231]. For example, Fig. 9.37 shows the topographical (a) and (b) NSOM PL images of a single ZnO nanowire.

Magneto-optics can be used to measure the electronic band structure of nanowires. For example, magneto-optics in conjunction with photoconductance has been proposed as a tool to determine band parameters of nanowires, such as the Fermi energy, electron effective mass, and the number of subbands to be considered [9.232]. Since different nanowire subbands have different electrical transmission properties, the electrical conductivity changes when light is used to excite electrons to higher subbands, thereby providing a method for studying the electronic structure of nanowires optically. Magneto-optics can also be used to study the magnetic properties of nanowires in relation to bulk properties [9.36, 233]. For example, the surface magneto-optical Kerr effect has been used to measure the dependence of the magnetic ordering temperature of Fe-Co alloy nanowires on the relative concentration of Fe and Co [9.233], and it was used to find that, unlike in the case of bulk Fe-Co alloys, cobalt in nanowires inhibits magnetic ordering. Nickel nanowires were found to have a strong increase in their magneto-optical activity with respect to bulk nickel. This increase is attributed to the plasmon resonance in the wires [9.234].

Nonlinear optical properties of nanowires have received particular attention since the nonlinear behavior

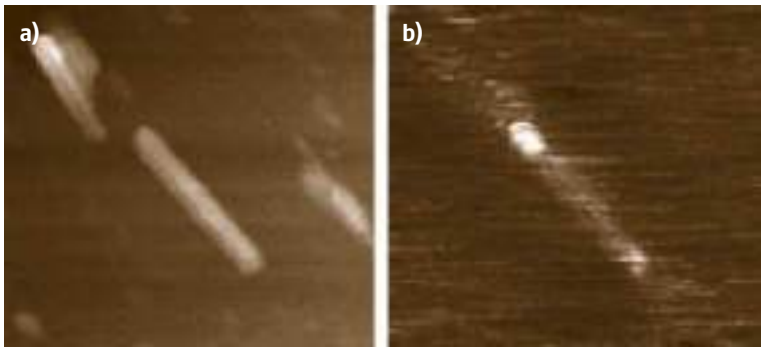

Fig. 9.37 **(a)** Topographical and **(b)** photoluminescence (PL) near-field scanning optical microscopy (NSOM) images of a single ZnO nanowire waveguide (after [9.231])

is often enhanced compared to bulk materials and the nonlinear effects can be utilized for a number of applications. One such study measured the second harmonic generation (SHG) and third harmonic generation (THG) in a single nanowire using near-field optical microscopy [9.235]. ZnO nanowires were shown to have strong SHG and THG effects that are highly polarization sensitive, and this polarization sensitivity can be explained on the basis of optical and geometrical considerations. Some components of the second harmonic polarization tensor are found to be enhanced in nanowires while others are suppressed as the wire diameter is decreased, and such effects could be of interest for device applications. It was also shown that the second-order nonlinearities are mostly wavelength-independent for $\lambda < 400\,\text{nm}$, which is in the transparent regime for ZnO, below the onset of bandgap absorption, and this observation is also of interest for device applications.

Reflectivity and transmission measurements have also been used to study the effects of quantum confinement and surface effects on the low-energy indirect transition in bismuth nanowires [9.236]. *Black* et al. investigated an intense and sharp absorption peak in bismuth nanowires, which is not observed in bulk bismuth. The energy position E_p of this strong absorption peak increases with decreasing diameter. However, the rate of increase in energy with decreasing diameter $|\partial E_\text{p}/\partial d_\text{W}|$ is an order of magnitude less than that predicted for either a direct interband transition or for intersubband transitions in bismuth nanowires. On the other hand, the magnitude of $|\partial E_\text{p}/\partial d_\text{W}|$ agrees well with that predicted for an indirect L-point valence to T-point valence band transition (Fig. 9.38). Since both the initial and final states for the indirect L–T point valence band transition downshift in energy as the wire diameter d_W is decreased, the shift in the absorption peak results from a difference between the effective masses and not from the actual value of either of the masses. Hence the diameter dependence of the absorption peak energy is an order of magnitude less for a valence-to-valence band indirect transition than for a direct interband L-point transition. Furthermore, the band-tracking effect for the indirect transition gives rise to a large value for the joint density of states, thus accounting for the high intensity of this feature. Figure 9.38 shows the experimentally observed transmission spectrum in bismuth nanowires of $\approx 45\,\text{nm}$ diameter (a), and the simulated optical transmission from an indirect transition in bismuth nanowires of $\approx 45\,\text{nm}$ diameter is also shown for comparison in (b). The indirect L–T point valence band transition mechanism [9.237] is also consistent with observations of the effect on the optical spectra of a decrease in the nanowire diameter and of n-type doping of bismuth nanowires with Te.

Phonon Confinement Effects

Phonons in nanowires are spatially confined by the nanowire cross-sectional area, crystalline boundaries, and surface disorder. These finite size effects give rise to phonon confinement, causing an uncertainty in the phonon wavevector, which typically gives rise to a frequency shift and lineshape broadening. Since zone center phonons tend to correspond to maxima in the phonon dispersion curves, the inclusion of contributions from a broader range of phonon wave vectors results in both a downshift in frequency and an asymmetric broadening of the Raman line, which develops a low-frequency tail. These phonon confinement effects have been theoretically predicted [9.238, 239] and experimentally observed in GaN [9.240], as shown in Fig. 9.39 for GaN nanowires with diameters in the range 10–50 nm. The application of these theoretical models indicates that broadening effects should be noticeable as the wire diameter in GaN nanowires decreases to $\approx 20\,\text{nm}$. When the wire diameter decreases further to $\approx 10\,\text{nm}$, the frequency downshift and asymmetric Raman line broadening effects should become observable in the Raman spectra for the GaN nanowires but are not found in the corresponding spectra for bulk GaN.

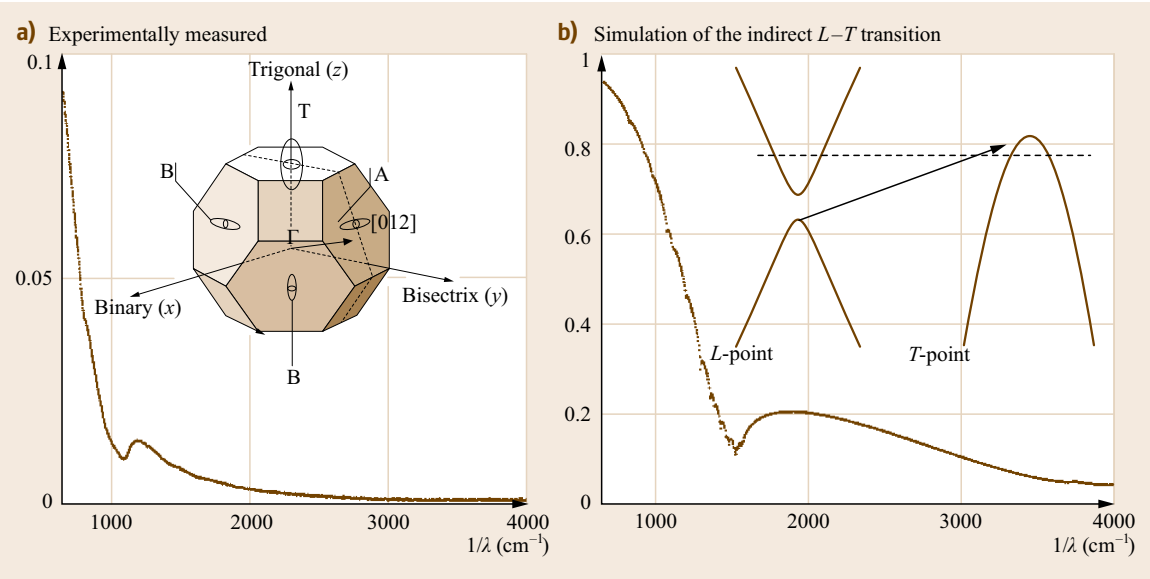

Fig. 9.38 **(a)** The measured optical transmission spectra as a function of wavenumber $(1/\lambda)$ of a $\approx 45\,\text{nm}$ diameter bismuth nanowire array. **(b)** The simulated optical transmission spectrum resulting from an indirect transition of an L-point electron to a T-point valence subband state. The *insert* in **(a)** shows the bismuth Brillouin zone, and the locations of the T-point hole and the three L-point electron pockets, including the nondegenerate A, and the doubly degenerate B pockets. The *insert* in **(b)** shows the indirect L–T point electronic transition induced by a photon with an energy equal to the energy difference between the initial and final states minus the phonon energy (about $100\,\text{cm}^{-1}$) needed to satisfy conservation of energy in a Stokes process (after [9.237])

The experimental spectra in Fig. 9.39 show the four $A_1 + E_1 + 2E_2$ modes expected from symmetry considerations for bulk GaN crystals. Two types of quantum confinement effects are observed. The first type is the observation of the downshift and the asymmetric broadening effects discussed above. Observations of such downshifts and asymmetric broadening have also been reported in 7 nm-diameter Si nanowires [9.241]. A second type of confinement effect found in Fig. 9.39 for GaN nanowires is the appearance of additional Raman features not found in the corresponding bulk spectra and associated with combination modes, and a zone boundary mode. Resonant enhancement effects were also observed for the $A_1(\text{LO})$ phonon at $728\,\text{cm}^{-1}$ at higher laser excitation energies [9.240].

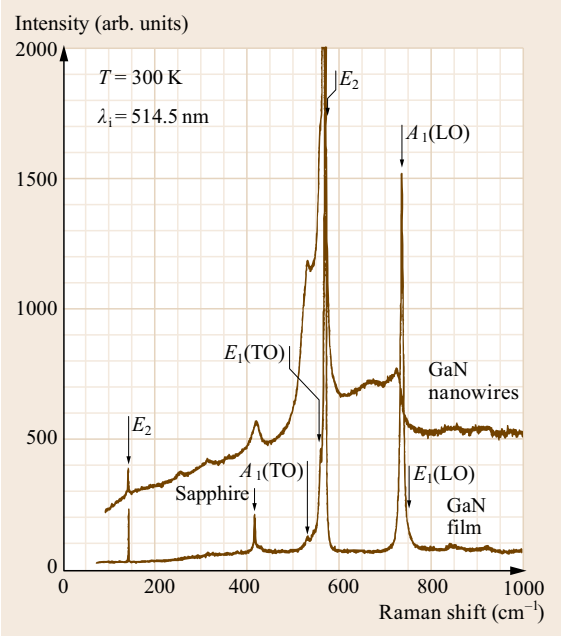

Fig. 9.39 Room-temperature Raman scattering spectra of GaN nanowires and of a 5 μm-thick GaN epilayer film with green (514.5 nm) laser excitation. The Raman scattering response was obtained by dividing the measured spectra by the Bose–Einstein thermal factor (after [9.240]) ►

9.3 Applications

In the preceding sections we have reviewed many of the central characteristics that make nanowires in some cases similar to and in some cases very different from their parent materials. We have also shown that some properties are diameter dependent, and these properties are therefore tunable during synthesis. Thus, nanowires offer a new toolbox of materials for engineers to design systems that could benefit in unprecedented ways from both the unique and tunable properties of nanowires and the small sizes of these nanostructures. As the synthetic methods for the production of nanowires continue to mature (Sect. 9.1) and nanowires are made in reproducible and cost-effective ways, the number of applications utilizing nanowires will continue to expand. This is a timely development, as the semiconductor industry will soon be reaching what seems to be its limit in feature size reduction, and approaching a classical-to-quantum size transition. At the same time, the field of biotechnology is expanding through the availability of tremendous genome information and innovative screening assays. Since nanowires are similar in size to the shrinking electronic components and to cellular biomolecules, it is only natural for nanowires to be good candidates for applications in these fields. Commercialization of nanowire devices, however, will require reliable mass production, effective assembly techniques, and quality control methods.

In this section, applications of nanowires to electronics (Sect. 9.3.1), optics (Sect. 9.3.2), energy (Sect. 9.3.3), chemical and biochemical sensing (Sect. 9.3.4), and magnetic media (Sect. 9.3.5) are discussed.

9.3.1 Electrical Applications

Nanowires are uniquely suited for some electrical applications. They are nano-sized in two dimensions and have one dimension that is not confined, providing a path for electrical conduction without the need for tunneling or carrier hopping. The microelectronics industry continues to face technological and economic challenges as the device feature size is decreased, especially below 20 nm. The self-assembly of nanowires might present a way to construct unconventional devices that do not rely on improvements in photolithography and, therefore, do not necessarily imply increasing fabrication costs. In addition, unlike traditional silicon processing, different semiconductors can be used simultaneously in nanowire devices to produce diverse functionalities. Not only can wires of different materials be combined, but a single wire can be made of different materials. For example, junctions of GaAs and GaP nanowire segments show rectifying behavior [9.111], thus demonstrating that good electronic interfaces between two different semiconductors can be achieved in the synthesis of multicomponent nanowires.

Electronic devices made from nanowires could also hold advantages due to their unique morphology. For example, in bulk field-effect transistors (FETs), the depletion layer formed below the source and drain region results in a source-drain capacitance that limits the operation speed. However, in nanowires, the source-drain contact can be wrapped around the semiconductor wire and thus the depletion layer can be limited to the nanowire volume inside the contact. Thus, depending on the device design, the source-drain capacitance in nanowires could be greatly minimized and possibly eliminated.

Device functionalities common in conventional semiconductor technologies, such as p-n junction diodes [9.167], field-effect transistors [9.169], logic gates [9.167], and light-emitting diodes [9.111, 242], have been demonstrated in nanowires, showing their promise as building blocks that could be used to construct complex integrated circuits by employing the *bottom-up* paradigm. In fact, as of June 2017 there are over 8000 US patent and patent applications containing the words *nanowire* and *transistor*. Several approaches have been investigated to form nanowire diodes (Sect. 9.2.2). For example, Schottky diodes can be formed by contacting a GaN nanowire with Al electrodes [9.168]. Furthermore, p-n junction diodes can be formed at the crossing of two nanowires, such as the crossing of n- and p-type InP nanowires doped by Te and Zn respectively [9.242], or Si nanowires doped by phosphorus (n-type) and boron (p-type) [9.243]. In addition to the crossing of two distinctive nanowires, heterogeneous junctions have also been constructed inside a single wire, either along the wire axis in the form of a nanowire superlattice [9.111], or perpendicular to the wire axis by forming a core-shell structure of silicon and germanium [9.151]. These various nanowire junctions not only possess current rectifying properties (Fig. 9.24) expected of bulk semiconductor devices, but they also exhibit electroluminescence (EL) that may be useful for optoelectronic applications, as shown in Fig. 9.40 for the electroluminescence of a crossed junction of n- and p-type InP nanowires [9.242] (see also Sect. 9.3.2).

The conductance of a semiconductor nanowire can be significantly modified by applying voltage at a third gate terminal, implying the utilization of nanowires in field-effect transistors (FETs). This gate terminal can either be the substrate [9.39, 244–247], a separate metal contact located close to the nanowire [9.248],

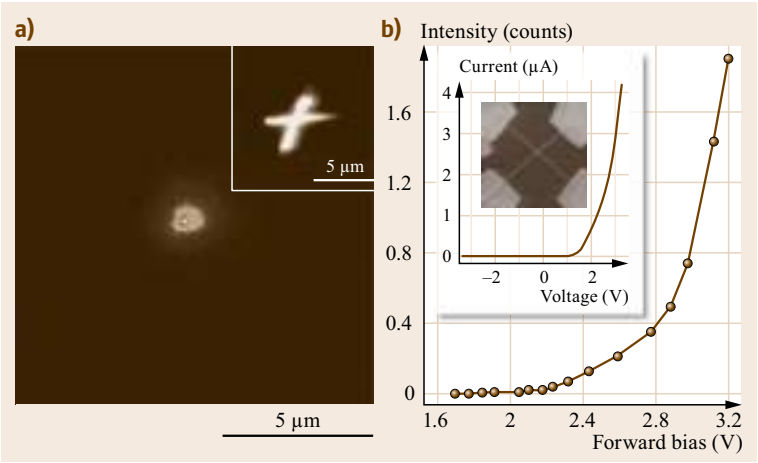

Fig. 9.40a,b Optoelectrical characterization of a crossed nanowire junction formed between 65 nm n-type and 68 nm p-type InP nanowires. **(a)** Electroluminescence (EL) image of the light emitted from a forward-biased nanowire p-n junction at 2.5 V. *Inset*, photoluminescence (PL) image of the junction. **(b)** EL intensity as a function of operation voltage. *Inset*, the SEM image and the *I–V* characteristics of the junction (after [9.242])

or another nanowire with a thick oxide coating in the crossed nanowire junction configuration [9.167]. Various logic devices performing basic logic functions have been demonstrated using nanowire junctions [9.167], as shown in Fig. 9.41 for the OR and AND logic gates constructed from two-by-one and one-by-three nanowire p-n junctions respectively. By functionalizing nanowires with redox-active molecules to store charge, nanowire FETs were demonstrated with two-level [9.169] and with eight-level [9.249] memory effects, which may be used for non-volatile memory or as switches. In another advance, In_2O_3 nanowire FETs with high-k dielectric materials were demonstrated, and substantially enhanced performance was obtained due to the highly efficient coupling of the gate [9.250]. A vertical FET with a surrounding gate geometry has also been demonstrated, which has the potential for high-density nanoscale memory and logic devices [9.251]. In addition, nanowire transistors were made without conventional doping [9.252, 253]. In these devices the gate surrounds the nanowire and fully or partially depletes the nanowire, thus controlling the carrier transport between the source and drain. These nanowire transistors were used in field-programmable logic arrays (FPGA), using an order of magnitude less area and operating power compared to conventional CMOS designs [9.252].

One challenge in making wrap-around transistors is finding a low-cost way to make the gate contact. For the application of tactile imaging, *Wu* et al. demonstrated the use of piezotronic ZnO nanowires that do not require a wrap-around gate [9.254]. The pressure applied to a ZnO nanowire in an array leads to a change in the polarization of immobile ions in the crystal that are present at the interface of the metal contact and the nanowire. This allows pressure to be sensed electrically without needing a gate terminal in each device.

Nanowires have also been proposed for applications associated with electron field emission [9.255, 256], such as flat panel displays, because of their small diameter and large curvature at the nanowire tip, which may reduce the threshold voltage for electron emission [9.257]. In this regard, the demonstration of very high field emission currents from the sharp tip ($\approx$ 10 nm radius) of a Si cone [9.255], from carbon nanotubes [9.258], from Si nanowires inside a carbon nanotube [9.259], and from Co nanowires [9.260], has stimulated interest in this potential area of application for nanowires.

Although the application of nanowires to thermoelectrics appears very promising, these materials are still in the research phase of the development cycle and are far from being commercialized. One challenge for thermoelectric devices based on nanowires lies in finding a suitable host material that will not reduce ZT too much due to the unwanted heat conduction through the host material. Therefore, the host material should have a low thermal conductivity and occupy a volume fraction in the composite material that is as low as possible, while still providing the quantum confinement and the support for the nanowires. In addition, the technology to scale up the sequential bonding of individual nanowires by dopant type (p-type to n-type to p-type, and so on) still needs to be developed.

Meshes of nanowires in the percolation limit have a combination of mechanical, electrical, and optical properties that make them useful for displays and tactile devices. Silver nanowire meshes, in particular, are being tested as transparent conduction films since their properties were shown to be similar to those of state-of-the-art indium tin oxide (ITO) [9.261]. These films are prepared from Ag nanowire suspensions, allowing for inkjet printing and low-temperature processing.

The *inset* shows the SEM image (scale bar: 1 μm) of an assembled AND gate and the symbolic electronic circuit. **(d)** The output voltage of the circuit in **(c)** versus the four possible logic address level inputs (after [9.167])

9.3.2 Optical Applications

Nanowires also hold promise for optical applications. One-dimensional systems exhibit a singularity in their joint density of states, allowing quantum effects in nanowires to be optically observable, sometimes even at room temperature. Since the density of states of a nanowire in the quantum limit (small wire diameter) is highly localized in energy, the available states quickly fill up with electrons as the intensity of the incident light is increased. This filling up of the subbands, as well as other effects that are unique to low-dimensional materials, lead to strong optical nonlinearities in quantum wires. Quantum wires may thus yield optical switches with a lower switching energy and increased switching speed compared to currently available optical switches.

Light-emitting diodes (LEDs) have been achieved in junctions between a p-type and an n-type nanowire (Fig. 9.40) [9.242] and in superlattice nanowires with p-type and n-type segments [9.111]. The light emission was localized to the junction area, and was polarized in the superlattice nanowire. An electrically driven laser was fabricated from CdS nanowires. The devices were fabricated by patterning a metal contact onto an n-type CdS nanowire, which resided on a p^+ silicon wafer. The cleaved ends of the wire formed the laser cavity, so that in forward bias, the light characteristic of lasing was observed at the end of the wire [9.262]. LEDs have also been achieved with core-shell structured nanowires made of n-GaN/InGaN/p-GaN [9.263].

Light emission from quantum wire p-n junctions is especially interesting for laser applications, because quantum wires can form lasers with lower excitation thresholds than their bulk counterparts and they also exhibit decreased sensitivity of performance to temperature [9.264]. Furthermore, the emission wavelength can be tuned for a given material composition by simply altering the geometry of the wire.

Lasing action has been reported in ZnO nanowires with wire diameters that are much smaller than the wavelength of the light emitted ($\lambda = 385\,\mathrm{nm}$) [9.110] (Fig. 9.42). Since the edges and lateral surfaces of ZnO nanowires are faceted (Sect. 9.2.1), they form optical cavities that sustain desired cavity modes. Compared to conventional semiconductor lasers, the exciton laser action employed in zinc oxide nanowire lasers exhibits a lower lasing threshold ($\approx 40\,\mathrm{kW/cm^2}$) than their 3-D counterparts ($\approx 300\,\mathrm{kW/cm^2}$). In order to utilize exciton confinement effects in the lasing action, the exciton binding energy ($\approx 60\,\mathrm{meV}$ in ZnO) must be greater than the thermal energy ($\approx 26\,\mathrm{meV}$ at 300 K). Decreasing the wire diameter increases the excitation binding energy and lowers the threshold for lasing. PL NSOM imaging confirmed the waveguiding properties of the anisotropic and the well-faceted structure of ZnO nanowires, limiting the emission to the tips of the ZnO nanowires [9.231]. Time-resolved studies have illuminated the dynamics of the emission process [9.265].

Lasing nanowires were also obtained with other materials systems, such as ZnS nanowires in anodic aluminum oxide templates [9.266], GaN nanowires

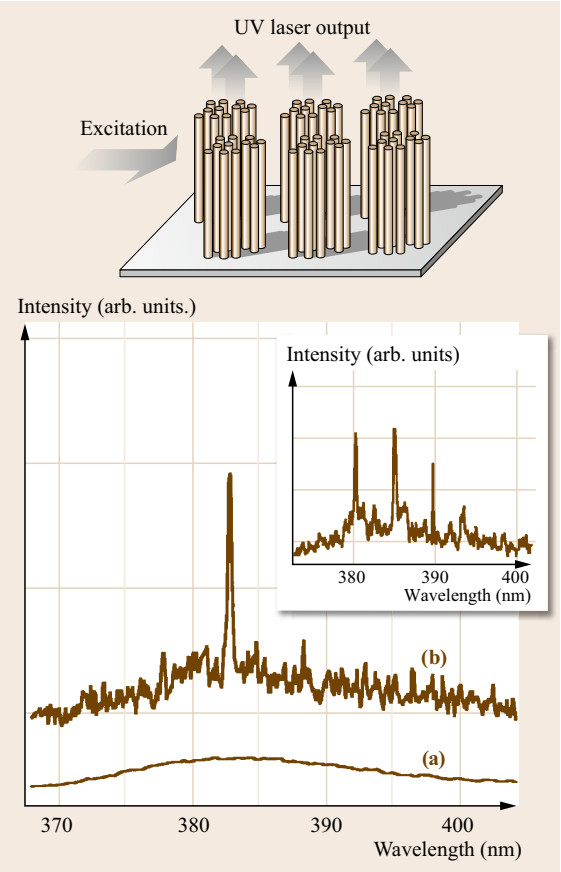

Fig. 9.42 A schematic of lasing in ZnO nanowires and the PL spectra of ZnO nanowires at two excitation intensities. The emission spectrum of trace (a) is taken below the lasing threshold (20 kW/cm^2) and the spectrum of trace (b) above it (100 kW/cm^2) (after [9.110])

[9.267], and a low-lasing-threshold, self-organized GaN(core)/AlGaN(shell) structure [9.268].

Nanowires have also been demonstrated to have good waveguiding properties. Quantitative studies of cadmium sulfide (CdS) nanowire structures show that light propagation takes place with only moderate losses through sharp and even acute angle bends. In addition, active devices made with nanowires have shown that efficient injection into and modulation of light through nanowire waveguides can be achieved [9.269]. By linking ZnO nanowire light sources to SnO_2 waveguides, the possibility of optical integrated circuitry is introduced [9.270].

Nanowire photodetectors were also proposed. ZnO nanowires were found to display a strong photocurrent response to ultraviolet (UV) light irradiation [9.271]. The conductivity of the nanowire increased by four orders of magnitude compared to the dark state. The response of the nanowire was reversible, and selective to photon energies above the bandgap, suggesting that ZnO nanowires could be good candidates for optoelectronic switches.

Nanowires have been also proposed for another type of optical switching. Light with its electric field normal to the wire axis excites a transverse free carrier resonance inside the wire, while light with its electric field parallel to the wire axis excites a longitudinal free carrier resonance inside the wire. Since nanowires are highly anisotropic, these two resonances occur at two different wavelengths and thus result in absorption peaks at two different energies. Gold nanowires dispersed in an aqueous solution align along the electric field when a DC voltage is applied. The energy of the absorption peak can be toggled between the transverse and longitudinal resonance energies by changing the alignment of the nanowires under polarized light illumination using an electric field [9.272, 273]. Thus, electro-optical modulation is achieved.

Nanowires may also be used as barcode tags for optical readout. Nanowires containing gold, silver, nickel, palladium, and platinum were fabricated [9.216] by electrochemical filling of porous anodic alumina, so that each nanowire consisted of segments of various metal constituents. Thus many types of nanowires can be made from a handful of materials, and identified by the order of the metal segments along their main axis, and the length of each segment. Barcode readout is possible by reflectance optical microscopy. The segment length is limited by the Rayleigh diffraction limit, and not by synthesis limitations, and thus can be as small as 145 nm. Figure 9.43a shows an optical image of many Au-Ag-Au-Ag barcoded wires, where the silver segments show higher reflectivity. Figure 9.43b is a backscattering mode field electron SEM (FE-SEM) image of a single nanowire, highlighting the composition and segment length variations along the nanowire.

Nanowires have found applications in solar cells or photovoltaics. Both the large surface area and the high conductivity along the length of nanowires are favorable for their use in photovoltaics. An early example involved n-type nanorods for inorganic-organic solar cells [9.274], which offer promise from a manufacturing and cost-effectiveness standpoint. In a hybrid nanocrystal-organic solar cell, the incident light forms bound electron-hole pairs (excitons) in both the inorganic nanocrystal and in the surrounding organic medium. These excitons diffuse to the inorganic-organic interface and disassociate to form an electron and a hole. Since conjugated polymers usually have poor electron mobilities, the inorganic phase is chosen to have a higher electron affinity than the organic phase so that the organic phase carries the holes and the

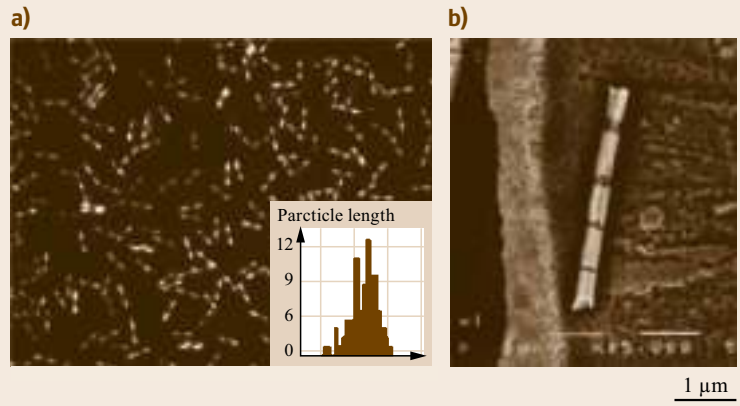

Fig. 9.43 (a) An optical image of many short barcoded Au-Ag-Au-Au wires and (b) an FE-SEM image of an Au/Ag barcoded wire with multiple strips of varying length. The *insert* in (a) shows a histogram of the particle lengths for 106 particles in this image (after [9.216])

semiconductor carries the electrons. The separated electrons and holes drift to the external electrodes through the inorganic and organic materials respectively. However, only those excitons formed within an exciton diffusion length from an interface can dissociate before recombining, and therefore the distance between the dissociation sites limits the efficiency of a solar cell. A solar cell prepared from a composite of CdSe nanorods inside poly(3-ethylthiophene) [9.274] yielded monochromatic power efficiencies of 6.9% and power conversion efficiencies of 1.7% under air mass AM1.5 (AM) illumination. The nanorods provide a large surface area with good chemical bonding to the polymer for efficient charge transfer and exciton dissociation. Furthermore, they provide a good conduction path for the electrons to reach the electrode. Their enhanced absorption coefficient and their tunable bandgap are also characteristics that can be used to enhance the energy conversion efficiency of solar cells.

Inorganic solar cells have the highest efficiencies to date, and nanowire photovoltaics can be an avenue for reduced cost and improved efficiency, by reducing material usage, increasing light absorption, and reducing recombination. Sol Voltaics AB is working to commercialize nanowire solar cells using a low-cost process based on VLS-grown vertical nanowire arrays with built-in axial p-n junctions [9.275, 276]. Devices of InP nanowires and GaAs nanowires achieved 13.8% and 15.3% efficiencies respectively. Silicon nanowires have also been used to make high-efficiency solar cells. Vertically aligned silicon nanowire arrays for solar cells are often made by either MACE or RIE (Sect. 9.1.3). Many studies on silicon nanowires put the p-n junction radially inside the wires [9.277]. These nanowire solar cells may be able to circumvent the Shockley–Queisser limit [9.278]. In radially doped nanowires, the solar-cell junction runs down the nanowire axis, and due to their small diameter, photocarriers are always generated near the junction. Thus in radially doped nanowires, hot carriers can be extracted out of the cell before they relax to the band edge.

Solar cells with silicon nanowire arrays on bulk silicon and the junction inside the bulk silicon are being commercialized by Advanced Silicon Group [9.279]. This cell design combines some of the advantages of nanowire cells with traditional silicon photovoltaics. In particular, these nanowire cells (sometimes called black silicon cells) have very low reflection and efficiently trap light inside the solar cell, with both effects leading to improved efficiency. Since the nanowires are smaller than the wavelength of light, the incident light sees an effective medium (Sect. 9.2.4) [9.280]. By tapering the wires, the index of refraction can be graded leading to a very low reflection of light. In black silicon cells, the junction is placed below the nanowires. It is formed by standard doping in the bulk single-crystal silicon substrate. Such pristine junctions are critical for low carrier recombination, low dark current, and thus high-efficiency cells. Pristine junctions are more challenging to create in the radial nanowire cell design.

9.3.3 Energy Applications

Energy Storage

Nanowires have been researched for energy application. Electrochemical and photoelectrochemical systems benefit from the nanowire array high surface area and one-dimensional conductivity. Individual nanowires can be used as in-situ electrochemical probes to explore intrinsic electrochemical processes and behaviors at the nanoscale.

Silicon has the highest lithium-ion absorption capacity of any known anode material for lithium ion batteries, but it expands and contracts by four times its volume when charged and discharged. This extensive expansion leads to pulverization of the electrode mate-

rial and the capacity of the anode quickly degrades with cycling. Nanowires allow for expansion and contraction during lithiation and delithiation in the radial direction while maintaining the structural integrity of the anode. In addition, compared to silicon nanoparticles, nanowires allow for conduction down the nanowire axis [9.281]. *Mai* et al. reported the characterization of single nanowire anode capacity fading in Li ion–based energy storage devices [9.282], while *Oleshko* et al. incorporated all the battery components in a single heterostructure nanowire for a detailed structural and electrochemical performance study using in-situ multimode analytical STEM imaging [9.283]. Several companies are commercializing silicon nanowire anodes including Nexeon, Advanced Silicon Group, Silexta, and Amprius [9.284–286]. Complete nanowire nanobattery arrays embedded in porous anodic alumina were demonstrated; however, these employed vanadium oxide chemistry [9.287].

Qui and coauthors used TiO_2 passivated InP nanowire arrays to create a photocatalytic system that reduces CO_2 with water to produce methanol [9.288]. More recently, the importance of uniformity of the nanowires in photocatalytic reactions was demonstrated with individual Si nanowire devices [9.289].

Nanowire-based capacitors can be readily produced as arrays in templates, for example by ALD [9.290]. Synthesis of individual nanowire capacitors as coaxial heterostructures by CVD offers extensive material flexibility. Following this approach, *Ajayan* et al. demonstrated the fabrication of single-nanowire capacitors made of a Cu-Cu_2O-C nanowire with capacitance values up to $140\,\mu F/cm^2$, well above the values reported for metal-insulator-metal micro-/nanocapacitors [9.291].

Piezoelectric Generators

Mechanical energy is abundant in the environment and in industrial processes but such energy is usually wasted, be it in the form of mechanical vibration, hydraulic pressure, or air flow, among others. One way to harvest these forms of energy is through the piezoelectric effect, which converts mechanical energies into electricity. This effect is well known at the macroscale in bulk materials such as lead zirconate titanate (PZT) and lead magnesium niobate-lead titanate (PMN–PT). The development of energy nanogenerators, which convert mechanical energy into electricity using one-dimensional piezoelectric materials, now enables the harvesting of small-scale mechanical energy, which can, in turn, be used to charge electrochemical systems or to power low-consumption microdevices [9.292, 293]. *Wang* and *Song* reported the first piezoelectric nanogenerators in 2006. In this seminal work, an output voltage pulse of several millivolts was obtained after bending a ZnO nanowire with an AFM tip [9.294]. With the ultimate objective of improving energy conversion efficiency and output power for practical applications, much research in optimizing materials [9.295–297] and system design [9.298, 299] continues to be performed in the field of nanowire-based technology [9.300, 301].

The major types of piezoelectric nanogenerator structures include the vertically aligned nanowire networks, the laterally aligned nanowire arrays, and the nanowire-based nanocomposites. The fundamental working principle applicable to the various realizations of vertically aligned nanowire arrays, hinges on the electromechanical coupling of the semiconductor behavior and the piezoelectric property of the piezoelectric nanowire. In this case, the application of external stress induces the appearance of a piezoelectric potential along the nanowire, which affects the details of the Schottky barrier at the interface between the nanowire and metallic pads. This, in turn, accounts for the flow of electrons between the metallic electrodes, through the closed circuit, to ensure thermodynamic equilibrium. In addition to the original ZnO-based device, AFM tip-induced lateral bending was also demonstrated for nanowires with other chemical compositions such as GaN, CdS, InN, and ZnS [9.302–306]. To avoid the use of an AFM tip, simplify the fabrication process, and improve the device stability, *Xu* and coworkers proposed a vertical nanowire array integrated nanogenerator (VING), which is created by packaging an array of vertically aligned ZnO nanowires with polymethyl methacrylate (PMMA) and by connecting the nanowire with top and bottom flat electrodes [9.307]. ZnO VINGs are currently among the most popular nanogenerators. Moving beyond ZnO (which has a relatively low piezoelectric constant and therefore yields low-performance nanogenerators), researchers are also exploring more efficient nanowire perovskite piezoelectric materials such as $Pb(Zr, Ti)O_3$ (PZT) [9.308]. This path is promising but suffers from a number of difficulties that are absent in ZnO-based VINGs, namely a more difficult synthesis process and the limited flexibility of the substrate typically used for materials growth.

The first lateral type of piezoelectric nanogenerator (where deformation is always induced by laterally bending the nanowires via the substrate or by applying a pressure in the radial nanowire direction) was demonstrated by *Wang* et al. in 2007 [9.309]. This device is based on the voltage generation of an individual $BaTiO_3$ nanowire under periodic tensile mechanical load. The nanofabrication process of the flexural stage involves complex and expensive steps due to the need to manipulate materials of extremely small sizes. In con-

trast, laterally integrated nanogenerators (LINGs) using a flexible polymer substrate are not only easier to fabricate but also feature improved performance [9.310]. In addition to ZnO, LINGs were made using other nanowire materials, such as potassium sodium niobate, which have the advantage of displaying a much higher piezoelectric constant and a lower free charge carrier density (which reduces stray screening responsible for lower piezoelectric response), and of being biocompatible [9.311]. The field of LINGs is still fairly recent and much effort is being made to simplify the fabrication processes, including the development of a scalable sweeping-printing method for fabricating flexible devices with ZnO nanowire arrays [9.312], or a one-step fabrication of ZnO nanowire networks [9.307]. Notably, the development of electrospinning techniques has enabled the use of ultralong piezoelectric nanofibers and large-scale LING fabrication [9.313, 314].

A novel type of piezoelectric nanogenerator based on nanowire-polymer composites has been explored to simplify the fabrication process compared to that of VINGs and LINGs. In this case, the nanogenerator assembly consists of four functional layers: top and bottom electrodes, flexible substrate, and a nanowire-composite layer. This multilayer structure is reminiscent of that of conventional piezoelectric ceramics. While the composite may feature piezoelectric properties inferior to those of ceramics, the presence of the polymer matrix significantly enhances the flexibility of the device. Compared to VINGs and LINGs, where the device fabrication is largely dictated by the assembly process of the nanowire arrays, the nanowire-composite design can be easily obtained by directly mixing as-synthesized nanowires with the polymer matrix such as polydimethylsiloxane (PDMS). *Hu* et al. realized large output nanogenerators by rational unipolar assembly of conical ZnO nanowires [9.315] and similar structures were also reported for composites of $NaNbO_3$ or GaN nanowires mixed with PDMS [9.296, 316].

Although much effort has already been made in promoting the practical application of piezoelectric nanogenerators, a number of critical issues remain to be fully resolved. This includes issues related to the integration of nanogenerators for high-output power sources, the structural design for increasing the energy harvesting efficiency in different practical conditions, and the need for improved stability and reliability [9.300].

9.3.4 Chemical and Biochemical Sensing Devices

Sensors for chemical and biochemical substances with nanowires as the sensing probe are a very attractive application area for nanowires based on a variety of materials and specific applications. Nanowire sensors will potentially be smaller and more sensitive, demand less power, and react faster than their macroscopic counterparts. Arrays of nanowire sensors could, in principle, achieve nanometer-scale spatial resolution and therefore provide accurate real-time information regarding not only the concentration of a specific analyte but also its spatial distribution. Such arrays could be very useful, for example, for dynamic studies on the effects of chemical gradients on biological cells.

The operation of many sensors made with nanowires, nanotubes, or nano-contacts is based on the reversible change in the conductance of the nanostructure upon absorption of the agent to be detected. The increased sensitivity and faster response time of nanowires are a result of the large surface-to-volume ratio and the small cross-section available for conduction channels, thus increasing the interaction between stray fields and the charge carriers. In the bulk, on the other hand, the abundance of charges can effectively shield external fields, and the volume of material can afford many alternative conduction channels. Therefore, a stronger chemical stimulus and longer response time are necessary to observe changes in the physical properties of a 3-D sensor in comparison to a nanowire.

It is often necessary to modify the surface of the nanowires to achieve a strong interaction with the analytes that need to be detected. Surface modifications utilize the self-assembly, chemisorption, or chemical reactivity of selected organic molecules and polymers towards metal and oxide surfaces. Examples include thiols on gold, isocyanides on platinum, and siloxanes on silica. These surface coatings regulate the binding and chemical reactivity of other molecules towards the nanowire in a predictable manner [9.317].

Cui et al. placed silicon nanowires made by the VLS method (Sect. 9.1.2) between two metal electrodes and modified the silicon oxide coating of the wire through the addition of molecules that are sensitive to the analyte to be detected [9.318]. For example, a pH sensor was made by covalently linking an amine-containing silane to the surface of the nanowire. Variations in the pH of the solution into which the nanowire was immersed caused protonation and deprotonation of the $-NH_2$ and the $-SiOH$ groups on the surface of the nanowire. The variation in surface charge density regulates the conductance of the nanowire; due to the p-type characteristics of a silicon wire, the conductance increases with the addition of negative surface charge. The combined acid and base behavior of the surface groups results in an approximately linear dependence of the conductance on pH in the pH range 2–9, thus leading to a direct-readout pH meter. This same type of approach was used for the detection of

the binding of biomolecules, such as streptavidin using biotin-modified nanowires (Fig. 9.44). This nanowire-based device has high sensitivity and could detect streptavidin binding down to a concentration of 10 pM (10^{-12} mol). Subsequent results demonstrated the capabilities of these functionalized Si nanowire sensors as DNA sensors down to the femtomolar range [9.319].

A similar approach was used by *Favier* et al., who made a nanosensor for the detection of hydrogen from of an array of palladium nanowires between two metal contacts [9.53]. They demonstrated that nanogaps were present in their nanowire structure, and upon absorption of H_2 and formation of Pd hydride, the nanogap structure would close and improve the electrical contact, thereby increasing the conductance of the nanowire array. The response time of these sensors was 75 ms, and they could operate in the range 0.5–5% H_2 before saturation occurred.

A mechanical sensing paradigm typically employs the nanowires as oscillating cantilevers and detects shifts in their mechanical resonance frequency (related to changes in cantilever mass) upon chemical binding events. As above, molecular binding specificity is achieved through functionalization of the nanowire surface. Using a 103 µm-long ZnO nanowire, *Wang* et al. measured a 26 pg weight with ≈ 10% error and 1.2 pg sensitivity [9.320]. These conditions allow for the detection of small nanoparticles (e.g., in aerosols). Single-macromolecule detection was demonstrated through a multimode frequency analysis in a sophisticated doubly clamped nanoelectromechanical resonator [9.321, 322].

Nanowires can act as waveguides to deliver optical signals in the near field and improve signal-to-noise ratio and spatial resolution in spectroscopic measurements [9.323]. *Yang* et al. utilized a tin oxide nanowire to guide the optical signal from a laser passing through the sample. Light scattered by the end of the nanowire was detected in the far field to obtain the PL or Raman spectrum of the analyte. Tin oxide nanowires were further used as a probe to poke through a cell's membrane and collect PL light from the cytoplasm, demonstrating a nanoscale endoscope [9.324]. The device sensed the position of luminescent quantum dots artificially positioned in the cell. Waveguiding in silver nanowires through excitation of surface plasmon polaritons has also been employed to sense molecules through surface-enhanced Raman scattering and other plasmonic effects [9.325].

9.3.5 Magnetic Applications

It has been demonstrated that arrays of single-domain magnetic nanowires can be prepared with controlled nanowire diameter and length, aligned along a common direction and arranged in a close-packed ordered array (Sect. 9.1), and that the magnetic properties (coercivity, remanence, and dipolar magnetic interwire interaction) can be controlled to achieve a variety of magnetic applications [9.49, 88].

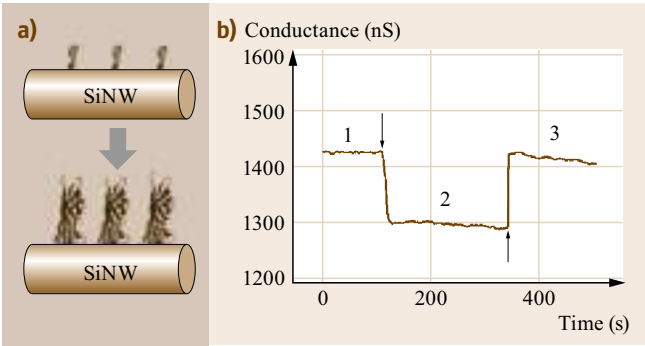

Fig. 9.44 **(a)** Streptavidin molecules bind to a silicon nanowire functionalized with biotin. The binding of streptavidin to biotin causes the nanowire to change its electrical resistance. **(b)** The electrical conductance of a biotin-modified silicon nanowire exposed to streptavidin in a buffer solution (regions 1 and 3) and with the introduction of a solution of antibiotin monoclonal antibody (region 2) (after [9.318])

The most interesting of these applications is for magnetic storage, where the large nanowire aspect ratio (length/diameter) is advantageous for preventing the onset of the *superparamagnetic* limit at which the magnetization direction in the magnetic grains can be reversed by the thermal energy $k_B T$, thereby resulting in loss of recorded data in the magnetic recording medium. The magnetic energy in a grain can be increased by increasing either the volume or the anisotropy of the grain. If the volume is increased, the particle size increases, so the resolution is decreased. For spherical magnetized grains, the superparamagnetic limit at room temperature is reached at 70 Gbit/in^2. In nanowires, the anisotropy is very large and yet the wire diameters are small, so that the magnetostatic switching energy can easily be above the thermal energy while the spatial resolution is large. For magnetic data storage applications, a large aspect ratio is needed for the nanowires in order to maintain a high coercivity, and a sufficient separation between nanowires is needed to suppress interwire magnetic dipolar coupling. Thus nanowires can form stable and highly dense magnetic memory arrays with packing densities in excess of 10^{11} wires/cm^2.

Developments in the controlled movement of domain walls in magnetic nanowires by short pulses of spin-polarized current show the possibility of nonvolatile memory devices with performance and relia-

bility comparable to conventional solid-state memory but at the affordability of conventional magnetic storage [9.326]. For instance, the racetrack memory design is a device made up of an array of horizontally or vertically oriented magnetic nanowires arranged on a silicon chip where individual spintronic read/write processes can operate on a train of tens of domain walls, thereby storing a series of data bits in each nanowire.

Moving beyond information storage, magnetic logic architectures, known as *domain-wall logic*, have the advantage of not requiring the use of transistors and therefore do not show significant heating associated with data switching [9.327]. A domain wall is a mobile interface between regions of magnetization aligned in opposite directions. In particular, a submicrometer planar nanowire made from a soft magnetic material such as Permalloy has been demonstrated as an excellent system featuring domain walls [9.328–330]. The large shape anisotropy of a nanowire provides a preferred magnetization alignment along the axis of the nanowires, leading to a robust binary information encoding. The role of the magnetic domain wall is to provide a transition edge in a changing signal. A logical *1* is defined as the magnetization pointing in the direction of propagation of domain walls and a logical *0* as the magnetization in the opposite direction. It was shown that cusp-shaped planar nanowires can be used to reverse the direction of magnetization, thereby providing the basis for the logical NOT operation [9.331]. Other basic logic functions, especially those with two-input functions, such as AND or OR, are also possible and are necessary elementary operations for computational applications. More complex logic circuits also require functions such as a fan-out structure, which creates two identical copies of an input signal and a cross-over structure, which makes it possible for two signals to pass over each other without interference [9.332].

9.4 Concluding Remarks

In this chapter, we reviewed the synthesis, characterization, and physical properties of nanowires, placing particular emphasis on nanowire properties that differ from those of their bulk counterparts and potential applications that might result from the special structures and properties of nanowires.

We have shown that the field of nanowire research continues to develop very rapidly year after year, driven by the development of a variety of complementary nanowire synthesis methods and effective tools for measuring nanowire structures and properties (Sects. 9.1 and 9.2). At present, much of the progress is at the demonstration-of-concept level, with many gaps in knowledge remaining to be elucidated, theoretical models to be developed, and new nanowire systems to be explored. Having demonstrated that many of the most interesting discoveries to date relate to nanowire properties not present in their bulk material counterparts, we can expect future research emphasis to be increasingly focused on smaller-diameter nanowires, where new unexplored physical phenomena related to quantum confinement effects are more likely to be found. We can also expect the development of applications to follow, some coming sooner and others later. Many promising applications are now at the early demonstration stage (Sect. 9.3), but are moving ahead rapidly because of their promise of new functionality not previously available in the fields of electronics, optoelectronics, biotechnology, magnetics, and energy conversion and generation, among others. Many exciting challenges remain in advancing both the nanoscience and the nanotechnological promise already demonstrated by the nanowire research described in this review.

Acknowledgments. In loving memory of our advisor, mentor, and friend Dr. Millie Dresselhaus who passed away during the production of this handbook.

10. Nanoribbons

Toshiaki Enoki, Shintaro Sato

Graphene nanoribbons have intriguing electronic structures, which are large edge geometry dependent. Armchair-edged graphene nanoribbons, which are energetically stable, have a ribbon-width-dependent intrinsic energy gap, while zigzag-edged ones have spin-polarized nonbonding edge states in the vicinity of the edge region. The edge state is the origin of electronic, magnetic and chemical activities. These features of the electronic structures can be characterized using microprobe techniques such as scanning tunneling microscopy/spectroscopy (STM/STS), atomic force microscopy (AFM), transmission electron microscopy (TEM), Raman spectroscopy, x-ray absorption, angle-resolved photoemission spectroscopy, electron transport, and magnetic measurements. Graphene nanostructures are synthesized using top-down and bottom-up methods, in the latter of which graphene nanostructures with atomically precise edges can be created. The presence of bandgap, which varies depending on the ribbon width and the edge geometry, makes graphene an important candidate for electronics device applications. The spin-polarized edge states localized in the vicinity of edges in zigzag-edged nanoribbons are expected to be utilized for spintronics applications.

10.1 Graphene Nanoribbons

A one-atom-thick two-dimensional carbon sheet called graphene was first isolated from graphite in 2004 [10.1]. It consists of a two-dimensional honeycomb lattice of carbon atoms and is regarded to be an infinite-size polycyclic aromatic hydrocarbon molecule derived by fusing benzene molecules in a two-dimensional manner. Graphene is just a precursor sheet from which carbon nanotubes [10.2, 3] or fullerenes [10.2] are created by cutting it into appropriate shapes as shown in Fig. 10.1. Here a carbon nanotube is formed by rolling up a rectangular-shaped graphene sheet into a cylinder, while a fullerene such as C_{60} is obtained by folding an appropriately cut graphene sheet into a ball with all the edges being closed. By cutting a graphene sheet, we can create a variety of nanographenes (graphene nanostructures) having different sizes and shapes. Among these, ribbon-shaped ones are called graphene nanoribbons (GNRs) (Fig. 10.2). As naturally deduced in chemistry, nanographenes are considered as nanosized polycyclic aromatic hydrocarbon molecules. What distinguishes nanographenes from fullerenes and carbon nanotubes is the presence of open edges in the former.

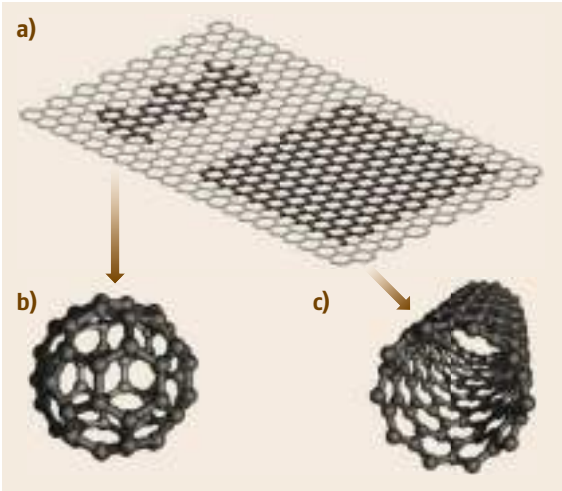

Fig. 10.1a–c Nanographene (**a**), fullerene (**b**) and carbon nanotube (**c**)

The presence of open edges having different geometries crucially contributes to a variety of properties in nanographenes.

The valence electrons, which play an important role in the physical and chemical properties, consist of π-electrons of constituent carbon atoms forming an sp^2-bond network. The π-electrons in an infinite-size graphene is described effectively in terms of massless Dirac fermion in relativistic quantum mechanics running in a two-dimensional honeycomb lattice in physics [10.4–6]. In chemistry we can discuss the behavior of the π-electrons in graphene in terms of aromaticity similarly to those in polycyclic aromatic hydrocarbon molecules [10.5, 6]. Here *Clar*'s aromatic sextet rule can phenomenologically explain their properties comprehensively [10.7, 8]. In graphene nanoarchitects such as carbon nanotubes, fullerenes and nanographenes, the electronic structure of π-electrons, which is modified from graphene, governs their physical and chemical properties. In particular, the electronic structure of nanographene is derived simply by cutting infinite graphene into nanofragments or increasing the number of constituent benzene rings to the nanodimension in polycyclic aromatic hydrocarbon molecules. The electronic structure of nanographene can be obtained by introducing a boundary condition, which is given from the open edges, in the massless Dirac fermion in physics, and also by extending the electronic structure of polycyclic aromatic molecules to the nanodimension in chemistry.

When we cut a graphene sheet, there are two fundamental directions, that is, armchair and zigzag directions, as shown in Fig. 10.2a. Rotating the cutting direction by 30° changes the armchair-zigzag direction to zigzag-armchair direction. Cutting a graphene sheet along these two fundamental directions and subsequently terminating the edge carbon atoms using foreign chemical species such as hydrogen gives two types of edges; that is, armchair edge and zigzag edge [10.5, 6], as exhibited in Fig. 10.2a. By cutting a graphene sheet into nanofragments in general directions, various edge geometries are created, in which armchair edge and zigzag edge are extreme cases. Accordingly, the edge of an arbitrary-shaped nanographene can be described in terms of a combination of armchair and zigzag edges. In the case of graphene nanoribbons, we have two types of ribbons as typical cases; armchair nanoribbon (AGNR) and zigzag nanoribbon (ZGNR) as given in Fig. 10.2b,c respectively. By cutting along an arbitrary direction between armchair and zigzag directions, nanoribbons having chiral edges are created. We can create wiggled nanoribbons depending on how we cut a graphene sheet. The electronic structure, which determines the physical and chemical properties, is essentially different between armchair and zigzag nanoribbons. Armchair nanoribbons are energetically stable with an intrinsic energy gap being opened due to aromatic stability, whereas zigzag nanoribbons are

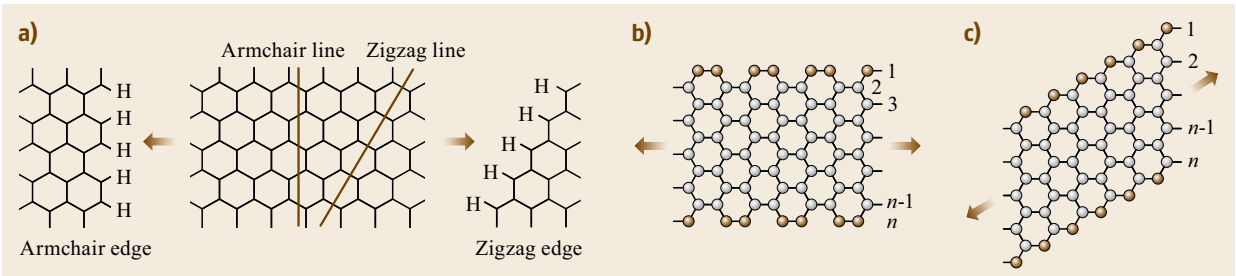

Fig. 10.2 (**a**) Cutting a graphene sheet along the armchair and zigzag directions gives an armchair edge and a zigzag edge respectively. (**b**) Armchair-edged graphene nanoribbon. (**c**) Zigzag-edged graphene nanoribbon. The ribbon width is defined in terms of the number (n) of C−C dimer chains and the number (n) of zigzag chains for armchair and zigzag nanoribbons, respectively; the ribbons are named n-AGNR and n-ZGNR

unstable as they are less aromatic. Interestingly, spin-polarized nonbonding π-electron states localized in the vicinity of zigzag edges are created, which are the origin of electronic, magnetic and chemical activities [10.5, 9]. Therefore, the presence of armchair and zigzag nanoribbons together with chiral-edged nanoribbons brings about a variety of physical and chemical properties.

Apart from edge geometry, how we terminate edge carbon atoms gives rise to another variety in the electronic structures, as functional groups we use in terminating edge carbon atoms affect the electronic structures [10.10]. For example, terminating them with hydrogen atoms gives an electronic structure different from terminating with carbonyl groups. Substituting constituent carbon atoms with heteroatoms such as boron or nitrogen atoms in nanoribbons also brings about a large change in the electronic structure.

There are two fundamental methods in preparing graphene nanoribbons; that is, the top-down method and the bottom-up method [10.5]. In the top-down method, we employ electron beam lithography or microprobe techniques such as scanning tunneling microscopy and atomic force microscopy for cutting graphene sheets into nanoribbons [10.11, 12]. Cutting a carbon nanotube can also create graphene nanoribbons, where zigzag, armchair and chiral tubes of different diameters can be utilized to produce nanoribbons having different edge geometries and widths [10.13]. The drawback in the top-down method is edge roughness, which is unavoidable. In the bottom-up method, precursor monomer molecules are polymerized typically on a metal substrate, which works as catalyst, to prepare nanoribbons. The bottom-up method can create atomically precise edges [10.14]. In addition to this, depending on which precursor monomer we employ, nanoribbons having a variety of edge geometries and chemistries can be obtained. Accordingly the bottom-up method is expected to be available in preparing nanoribbon-based molecular electronics devices.

The variety of electronic properties is a source of various functionalities in nanographenes such as graphene nanoribbons. Therefore, nanographenes will be an important base material for future molecular electronics/spintronics devices. Incorporating atomically precise nanoribbons into electronics devices brings about carbon-based molecular devices in the next generation.

10.2 Electronic and Magnetic Properties

Nanographene has open edges, which importantly contribute to modifying the electronic structure from infinite graphene. Here we have two fundamental edges; armchair and zigzag edges as shown in Fig. 10.2. The modification depends crucially on the edge geometry. We can discuss the electronic structures of nanographene and their edge geometry dependence in terms of both physics and chemistry languages, as they are in between infinite graphene and polycyclic aromatic hydrocarbon molecules, with which physicists and chemists are relatively familiar.

In chemistry, we have *Clar*'s aromatic sextet rule, which is an important phenomenological rule for discussing the electronic and chemical properties of polycyclic aromatic hydrocarbon molecules [10.7, 8]. Using this rule, we can discuss the energetic stability of polycyclic aromatic molecules by tiling aromatic sextets (Fig. 10.3a), which are benzene in the resonance state with all six carbon atoms singly bonded to the surrounding, on a molecule concerned. According to Clar's rule, the most stable structure is that having a maximal number of sextets tiled. We can employ this rule also for nanographenes as they are classified as polycyclic aromatic hydrocarbon molecules, whose sizes are in the nanodimension. Figure 10.3 shows Clar's representations of infinite graphene and several examples of armchair-edged and zigzag-edged polycyclic aromatic molecules. In infinite graphene having a two-dimensional honeycomb hexagonal lattice, aromatic sextets are tiled in every three hexagon ring and the tiled sextets form a $\sqrt{3} \times \sqrt{3}$ superlattice as shown in Fig. 10.3b. It should be noted that there are three Clar's representations degenerate in infinite graphene. So the sextets are migrating between the three states. This is the reason why infinite graphene is electrically conductive from the chemistry aspect.

When a graphene is cut, an edge is created, resulting in a modification of the arrangement of sextets. Figure 10.3c exhibits examples of armchair-edged aromatic molecules, that is, armchair-edged graphene nanofragments. We have large numbers of sextets in these fragments, and consequently their energetic stability (aromatic stability) is confirmed on the basis of Clar's aromatic rule. Note that there is no degeneracy in the Clar's representations, and, instead, only a unique Clar's representation exists for armchair-edged fragments, resulting in the localization of sextets. The localization of sextets suggests that armchair-edged nanographenes are electrically less conductive in contrast to the highly conductive properties of infinite graphene.

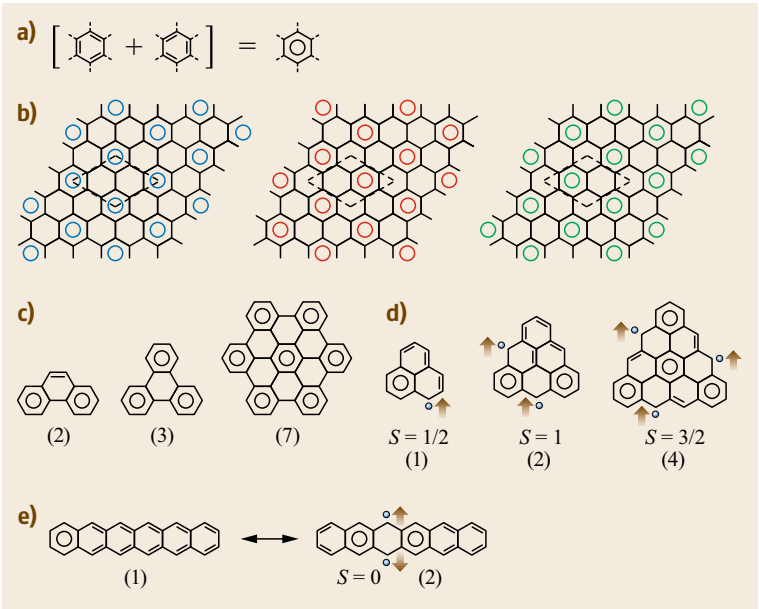

Fig. 10.3 **(a)** Clar's sextet. Clar's representations of **(b)** infinite graphene, **(c)** armchair-edged molecules, **(d)** zigzag-edged triangular molecule and **(e)** zigzag-edged linear molecule. In an infinite graphene, three Clar's representations are degenerate with sextets being arranged in a $\sqrt{3} \times \sqrt{3}$ superlattice (*dotted rhombus*) **(b)**. The *dot with an arrow* denotes an unpaired electron having a spin $S = 1/2$ in **(d,e)**. The number in the parenthesis and S indicate the number of sextets and the total spin respectively in **(c–e)**

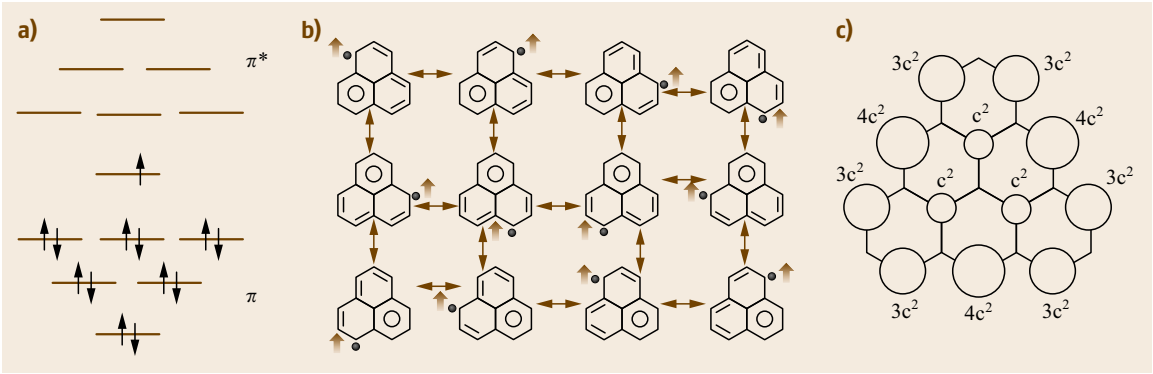

Fig. 10.4 **(a)** The electronic structure of a triangle molecule with three benzene rings fused (phenalene) (*left* molecule in Fig. 10.3d), **(b)** 12 degeneracy of Clar's representations in phenalene and **(c)** the spatial distribution of the local density of states of the nonbonding π-electron state (edge state) in triangulene consisting of six benzene rings. The nonbonding π-state is half-filled with an unpaired electron having $S = 1/2$ in **(a)**. The *arrow with a dot* denotes an unpaired electron in **(b)**

The situation is completely different in zigzag-edged fragments compared to armchair-edged ones, as shown in Fig. 10.3d,e, with examples of triangle and linear fragments respectively. Zigzag-edged nanographenes have small numbers of sextets, suggesting less energetic stability. In addition, there are unpaired electrons remaining in the edge region as shown in Fig. 10.3d,e. An unpaired electron occupies a nonbonding π-electron state in single occupancy between the π-valence states and the π^*-conduction states, as shown in Fig. 10.4a. In the case of triangle nanographenes, the spins $s = 1/2$ of unpaired electrons are arranged in parallel owing to the Hund rule, forming a ferromagnetic state (Fig. 10.3d). In contrast, the spins of two unpaired electrons in linear nanographene are arranged in antiparallel, forming a closed shell singlet state, or antiferromagnetic state in other words (Fig. 10.3e). Accordingly zigzag-edged nanographenes are magnetic due to the presence of nonbonding states half-filled with unpaired electrons. It should be noted that there exist many Clar's representations degeneratein zigzag-edged nanographenes, as can be understood from the presence of 12 representations in a fragment with three hexagons fused in triangle shape in Fig. 10.4b. Sextets migrate between 12 states, resulting in the creation of electrical conductive properties. The unpaired electron also migrates around the

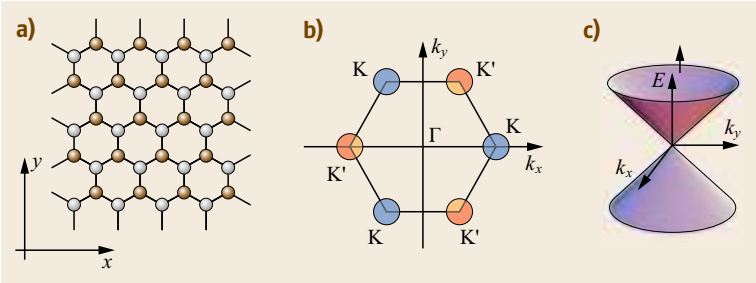

Fig. 10.5 **(a)** The two-dimensional hexagonal bipartite lattice of graphene, which has two independent sublattices; A and B sublattices denoted by *filled* and *open circles* respectively. **(b)** The hexagonal Brillouin zone of graphene with two independent reciprocal lattice points K and K′. **(c)** The electronic structure of graphene expressed with the Dirac cones of valence π- and conduction π^*-band, which correspond to the lower cone and upper inverted cone, respectively. The *arrow* shown on the Dirac cone indicates the pseudospin. Two independent sets of Dirac cones are placed at K and K′ points

zigzag-shaped peripheral region. Note that calculation proves the unpaired electron mostly populates in the vicinity of zigzag edges, as can be seen in Fig. 10.4c. Owing to this reason, the nonbonding π-state is called the edge state [10.9].

Next let us discuss the electronic structures of nanographenes in the physics aspect [10.4, 15]. The two-dimensional honeycomb hexagonal lattice of graphene is a bipartite lattice, which consists of two independent sublattices (A sublattice and B sublattice), as given in Fig. 10.5a. Here, the electron running in the hexagonal bipartite lattice can be described effectively in terms of massless Dirac fermion in relativistic quantum mechanics, as expressed in the Weyl equation with linear dependence on momentum $\boldsymbol{p}$

$$\boldsymbol{H} = v_{\mathrm{F}}\boldsymbol{\sigma}\boldsymbol{p}\,, \tag{10.1}$$

where v_{F} is the Fermi velocity given by

$$v_{\mathrm{F}} = \frac{3\gamma_0 a_{\mathrm{CC}}}{2\hbar} \approx \frac{1}{300}c$$

with a_{CC}, the C–C bond length (0.142 nm) and γ_0, the transfer integral (3.16 eV), representing the strength of the C–C interaction of π-electron, and $\boldsymbol{\sigma}$ is the Pauli matrix of a pseudospin. The Fermi velocity is estimated as $v_{\mathrm{F}} \approx (1/300)c$ (with speed of light c), which is 1000 km/s. Consequently the electrons on the graphene sheet run very fast. This is the reason why graphene is interesting for future fast electronics devices. The Pauli matrix $\boldsymbol{\sigma}$ represents a pseudospin, which is not a real spin, but is effectively converted from the structure degree of two in the bipartite lattice. In the Weyl equation, the application of magnetic field $\boldsymbol{B}$ modifies momentum as $\boldsymbol{p} \to \boldsymbol{p} - e\boldsymbol{A}$, where the gauge field $\boldsymbol{A}$ is related to the magnetic field applied; $\boldsymbol{B} = \nabla \times \boldsymbol{A}$ [10.15]. Consequently the pseudospin becomes susceptible to the magnetic field applied. The electronic structure of graphene expressed in the Weyl equation is exhibited in Fig. 10.5c. The valence π- and conduction π^*-bands having linear $\boldsymbol{p}$ $(= \hbar\boldsymbol{k})$ dependence are called Dirac cones. The bottom of the conduction band and the top of the valence band touch each other at a point called the Dirac point. The Dirac point is located at the Fermi level when graphene is neutral in charge. The absence of an energy gap between the valence and conduction bands gives zero-gap semiconductor features to infinite graphene. The structural degree of freedom two is conserved in the momentum space. So there are two independent reciprocal lattice points K and K′ in the hexagonal Brillouin zone in graphene as shown in Fig. 10.5b. Accordingly two independent sets of Dirac cones, which are called K and K′ valleys, exist at K and K′ points.

When an edge is created by cutting a graphene sheet, the edge works as a boundary condition for the electron in graphene, modifying the electronic structure depending on the edge geometry. Let us examine the scattering process of the electron at the edges [10.15]. Figure 10.6a,b exhibits the scattering processes of the electron at armchair and zigzag edges respectively. In the case of the scattering process at an armchair edge shown in Fig. 10.6a, the momentum $\hbar k_x$ is changed to $-\hbar k_x$ (see also Fig. 10.5b for the coordinates). This is a transition from the K valley to the K′ one, or the K′ valley to K one, that is, the intervalley transition. Consequently the scattered wave can be described in terms of a linear combination of the wave functions of the K valley and K′ valley, as given in the following

$$\psi_{\mathrm{B}}(R_{\mathrm{B}}) \propto \left(-\exp\left(-\mathrm{i}KR_{\mathrm{B}}\right) + \exp\left(\mathrm{i}K'R_{\mathrm{B}}\right)\right), \tag{10.2}$$

for a site R_{B} belonging to sublattice B. This suggests that the two wave functions are subjected to an interference. The electron wave interference brings about the formation of a standing wave, that can be seen in the absence of degeneracy in the Clar's representations in

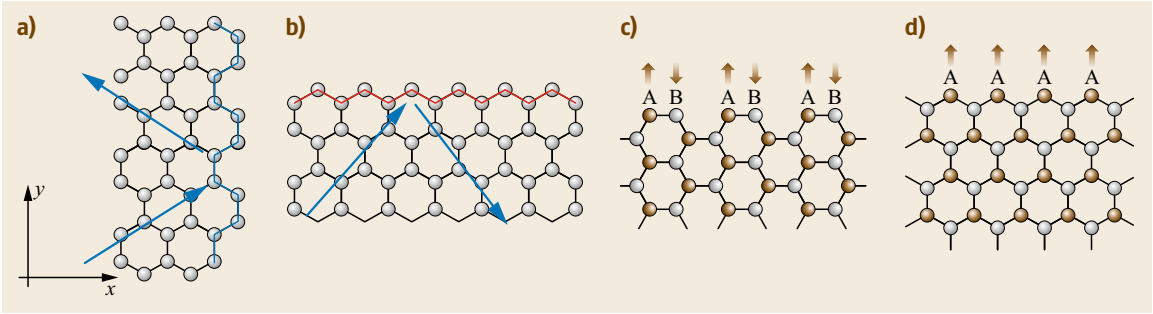

Fig. 10.6a–d The scattering processes of the electron at **(a)** armchair and **(b)** zigzag edges. Sublattice symmetry in armchair **(c)** and zigzag **(d)** edges

armchair-edged nanographenes. In other words, a single unique Clar's representation is the consequence of the formation of a standing wave. The standing wave formation makes armchair-edged nanographenes energetically stabilized together with the formation of an energy gap between the valence and conduction bands.

In zigzag-edged nanographene, the situation is in sharp contrast to that in armchair-edged nanographene. The momentum change is given as $\hbar k_y \rightarrow -\hbar k_y$ in the scattering process at a zigzag edge as shown in Fig. 10.6b. This is the transition from K valley to K one or K′ valley to K′ one, that is, only one valley participates in the transition process (intravalley transition). Accordingly there is no electron wave interference, a standing wave being absent in zigzag-edged nanographenes. What happens in zigzag-edge nanographene can be more clearly understood by comparing sublattice symmetry between armchair- and zigzag-edged nanographenes. Figure 10.6c,d shows the arrangements of A and B sublattices in the vicinity of armchair and zigzag edges. In an armchair edge, A and B sublattices are always paired the same to the interior region, the sublattice symmetry being conserved. In contrast, a zigzag edge consists of only one of the sublattices, A or B, that is, A-B symmetry is broken in the zigzag edge. In general, broken symmetry works to create a gauge field, which is lattice distortion-induced gauge field $\boldsymbol{A}_{\mathrm{q}}$. In the case of armchair edge, in which A-B symmetry is conserved, $\boldsymbol{A}_{\mathrm{q}} = 0$, whereas it becomes finite, ensuring that the pseudospin works to give a magnetic degree of freedom to zigzag-edged nanographene [10.15]. In other words the pseudospin behaves as real spin, that is equivalent to the spin of an unpaired electron, which occupies the nonbonding π-electron state in the chemistry aspect. We can count the number of spins N_{S} created in zigzag edges, in which A-B symmetry is broken, using *Lieb*'s theorem [10.16] given as follows

$$N_{\mathrm{S}} = |N_{\mathrm{A}} - N_{\mathrm{B}}| \,, \tag{10.3}$$

using which the total spin S is given in the following equation

$$S = \frac{1}{2}|N_{\mathrm{A}} - N_{\mathrm{B}}| \,. \tag{10.4}$$

Here N_{A} and N_{B} denote the numbers of sites in A and B sublattices, respectively.

As we discussed above, the formation of a standing wave in armchair-edged nanographenes and the presence of a nonbonding π-electron state in zigzag-edged ones are confirmed from both chemistry and physics aspects. Now we discuss the electron structures of these two types of nanographenes using local density approximation (LDA) calculations. Figure 10.7 shows the band structures of armchair- and zigzag-edged graphene nanoribbons (AGNR and ZGNR respectively) whose edge carbon atoms are monohydrogenated, together with the calculated spatial distribution of the local density of states and the corresponding Clar's representations. The electronic structure of an armchair-edged graphene nanoribbon (Fig. 10.7a) has an energy gap (E_{g}) between the valence and conduction bands in contrast to the absence of an energy gap in infinite graphene. The presence of an energy gap is responsible for the energetic stability of armchair-edged nanoribbons. The spatial distribution of the local density of states shown in Fig. 10.7b indicates the formation of a standing wave with a $\sqrt{3} \times \sqrt{3}$ superlattice as a signature of sextet localization (Fig. 10.7c). Therefore armchair-edged nanoribbons are subjected to aromatic stability, similar to Kekulé molecules in polycyclic aromatic hydrocarbons. The magnitude of an energy gap has a decreasing trend accompanied by an oscillation upon the increase in the ribbon width as shown in Fig. 10.8, and it is extrapolated to zero as the width becomes infinite. The aromatic stability declines upon the increase in the ribbon width. The oscillating behavior can be expressed as follows

$$E_{\mathrm{g}}^{3p+1} > E_{\mathrm{g}}^{3p} > E_{\mathrm{g}}^{3p+2} \,,$$

for widths of $n = 3p+1$, $n = 3p$ and $n = 3p+2$, where

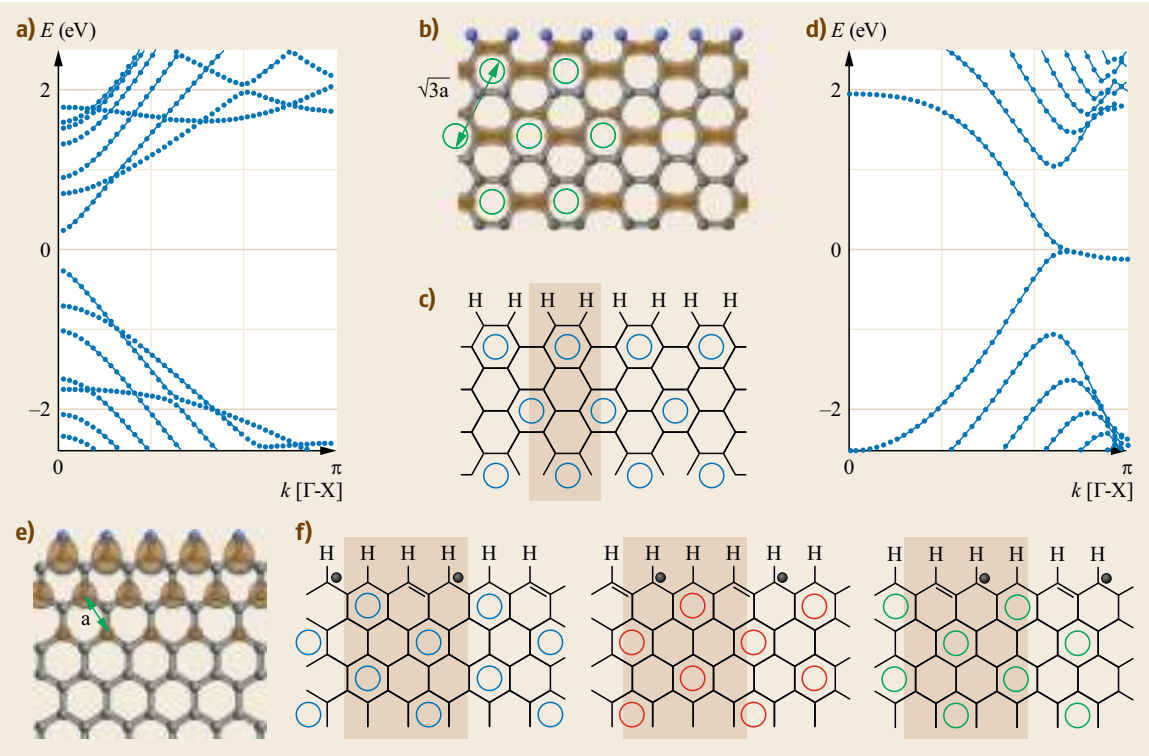

Fig. 10.7a–f The electronic structures of armchair-edged **(a–c)** and zigzag-edged graphene nanoribbons **(d–f)**, whose edge carbon atoms are monohydrogenated. **(a,d)** Calculated band structures, **(b,e)** calculated spatial distributions of the local density of states with LDA in the vicinity of the Fermi level (0–0.1 V), **(c,f)** Clar's representations. The Fermi level E_F is located at 0 eV in **(a)** and **(d)**. The ribbon widths are $n = 15$ and 10 respectively for armchair-edged and zigzag-edged nanoribbons (15-AGNR and 10-ZGNR)

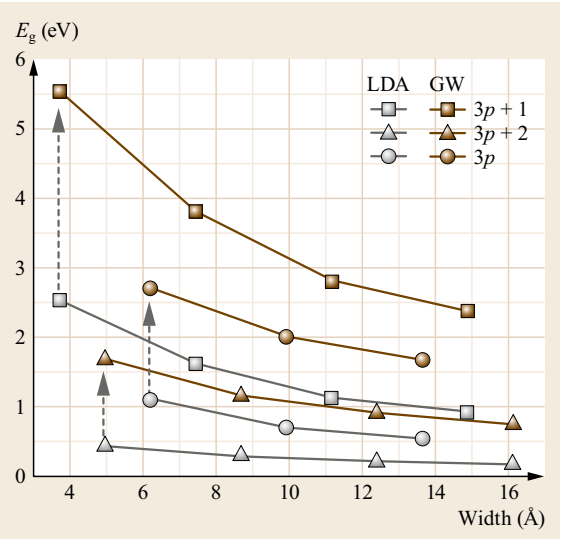

Fig. 10.8 Variation in energy gap E_g with the width of armchair-edged graphene nanoribbons. Three families of armchair graphene nanoribbons are represented by different symbols. Values for members of the same family of armchair nanographenes are connected by *solid lines* as guides to the eye. *Open symbols* represent bandgaps calculated by LDA; *solid symbols* represent the corresponding quasiparticle bandgaps obtained by the GW method. *Dashed arrows* indicate the self-energy correction for the narrowest ribbon in each of the three families (after [10.17]) ◄

the ribbon width is spanned by n C–C dimer chains, and p is an integer [10.17, 18]. The oscillating behavior is just the consequence of the change in aromaticity related to how aromatic sextets are tiled on nanoribbons. The electron correlation works to enhance the bandgap as can be seen in the calculation with the GW method in Fig. 10.8.

A zigzag-edged graphene nanoribbon has no gap, and instead it features the presence of a nonbonding π-electron state (edge state) as shown in Fig. 10.7d. A flat band having no energy dispersion between the valence and conduction bands is assigned to the edge

state in Fig. 10.7d. The spatial distribution of the edge states is found to be localized well in the vicinity of the zigzag edge region as can be seen in Fig. 10.7e. The Clar's representations are triply degenerate as confirmed in Fig. 10.7f. The sextet migration is further evidence for the absence of energy gap. In the edge, every three carbon atom has an unpaired electron with spin $s = 1/2$, which migrates between the three edge carbon atoms. Accordingly Clar's rule suggests the presence of a magnetic moment $1/3\,\mu_B$/C atom. The creation of a nonbonding edge state together with the absence of an energy gap indicates that zigzag-edged graphene nanoribbons are energetically unstable or less aromatic in other words. Note that the electron correlation effect works to create an energy gap even in zigzag-edged graphene nanoribbons [10.17] despite simple tight binding theory predicting the absence of a gap [10.9].

10.3 Characterizations

In Sect. 10.2, we discussed the electronic structures of graphene nanoribbons (GNR) having different edge geometries. Here structural and electronic characterizations of these nanoribbons are presented on the basis of what we learned in Sect. 10.2, in terms of several characterization techniques.

Microprobe techniques such as scanning tunneling microscopy (STM), scanning tunneling spectroscopy (STS) and atomic force microscopy (AFM) are powerful in characterizing both detailed atomic arrangements and electronic structures in graphene nanostructures. We can get information on the formation of standing waves in armchair edges and the presence of nonbonding edge states in zigzag edges. Figure 10.9 shows the results of STM observations in the vicinities of armchair and zigzag edges whose edge carbon atoms

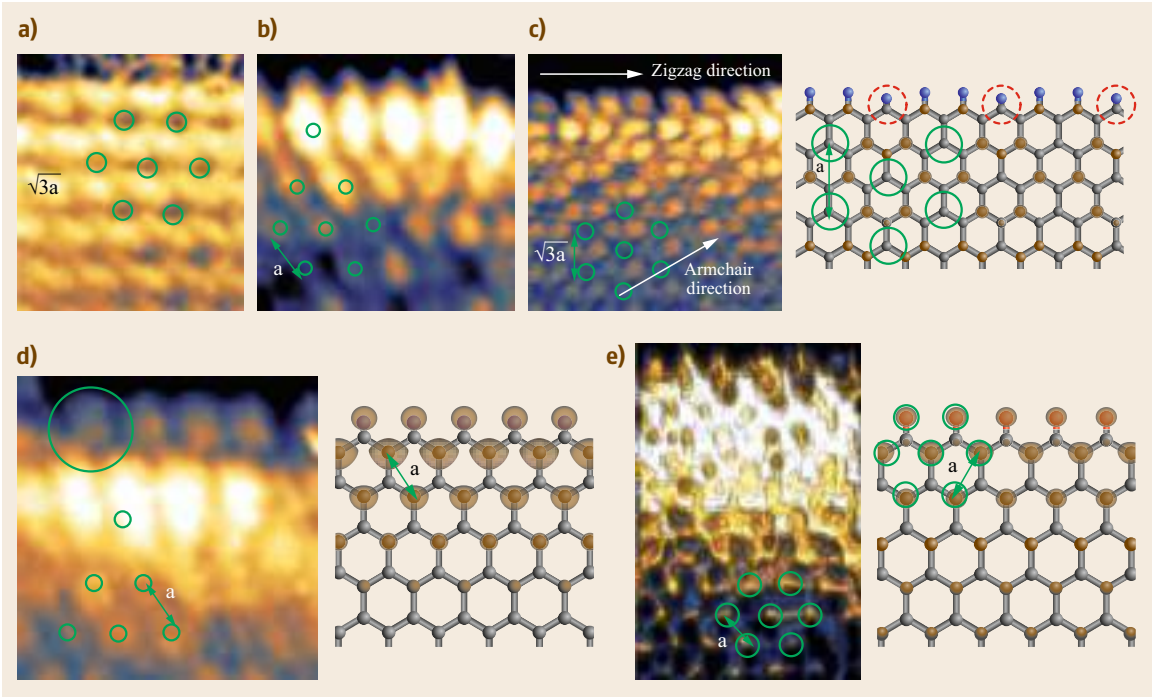

Fig. 10.9a–e STM images of armchair and zigzag edges. **(a)** Monohydrogenated armchair edge, **(b)** monohydrogenated zigzag edge, **(c)** zigzag edge in which every three edge carbon atom is dihydrogenated with others remaining monohydrogenated, **(d)** dihydrogenated zigzag edge and **(e)** zigzag edge terminated with carbonyl group (imaging conditions: $V_s = 0.1$ V, $I = 0.9$ nA for **(a,c,d)**, $V_s = 0.1$ V, $I = 0.7$ nA for **(b)**, $V_s = 0.2$ V for **(e)**). For **(c–e)**, the spatial distribution mapping of the local density of states calculated with LDA in the vicinity of the Fermi level (0–0.1 V) are also shown with *brown circles* on the right side of the STM images for comparison. The *green circles* with a and $\sqrt{3}a$ denote the periodicities of the graphene unit cell and the $\sqrt{3}\times\sqrt{3}$ superlattice respectively. The *large green circle* around the zigzag edge denotes the two hydrogen atoms terminating the edge carbon atom in **(d)**. The sites encircled with *red dotted lines* indicate the two hydrogen atoms terminating the edge carbon atoms in **(c)**

are terminated with different chemical species [10.10]. In the vicinity of a monohydrogenated armchair edge shown in Fig. 10.9a, a $\sqrt{3}\times\sqrt{3}$ superlattice is observed, which is the signature of a standing wave formed in an armchair edge. In contrast to the armchair edge, the bright spots assigned to edge states are observed in the vicinity of monohydrogenated zigzag edges in Fig. 10.9b. The local density of states of the edge state decays sharply as we go from the carbon atoms of a zigzag edge to the interior of the graphene sheet, the edge state being well localized at the zigzag edge. These findings in armchair and zigzag edges confirm the theoretical results shown in Fig. 10.7 of Sect. 10.2.

STM observations interestingly prove that the electronic structure varies depending on how the edge carbon atoms are terminated with foreign chemical species. Figure 10.9c gives the result of a zigzag edge in which every three edge carbon atom is dihydrogenated with others remaining monohydrogenated. Bright spots assigned to edge states disappear at the edge, instead a $\sqrt{3}\times\sqrt{3}$ superlattice is observed, completely similar to what happens in an armchair edge. This change can be understood using LDA calculations and also Clar's aromatic sextet rule as we can see in Fig. 10.9c and Fig. 10.10a respectively. The spatial distribution mapping of the local density of states in the vicinity of the Fermi level in Fig. 10.9c confirms the absence of edge states around the zigzag edge, instead the formation of a $\sqrt{3}\times\sqrt{3}$ superlattice is in good agreement with the experimental result. The formation of the superlattice together with the absence of edge states can be understood from the Clar's representation as we can see in Fig. 10.10a. A combination of two Clar's representations suggests sextet localization, which results in the formation of a $\sqrt{3}\times\sqrt{3}$ superlattice. When we add more hydrogen to the zigzag edge to form a completely dihydrogenated zigzag edge, the creation of an edge state and the disappearance of the superlattice are observed again in the STM image as shown in Fig. 10.9d, similar to those in monohydrogenated zigzag edges. This is confirmed with the spatial distribution mapping of the local density of states. The revival of the

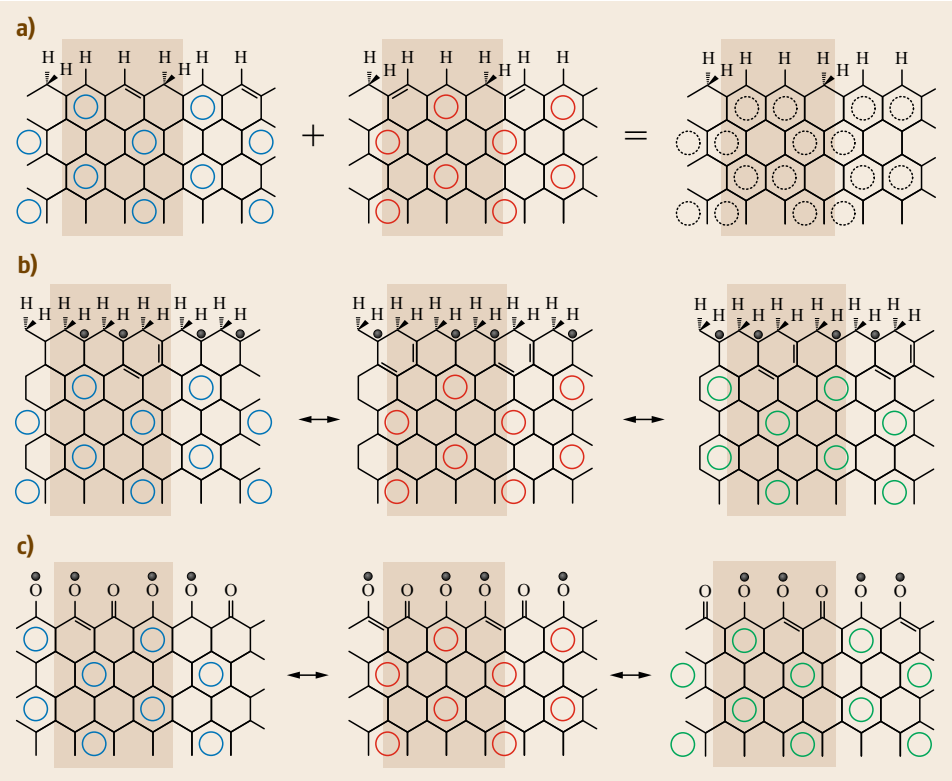

Fig. 10.10a–c Clar's representations of **(a)** zigzag edge, in which every three edge carbon atom is dihydrogenated with others remaining monohydrogenated, **(b)** dihydrogenated zigzag edge and **(c)** carbonylated zigzag edge. The *dots* denote an unpaired electron occupying the nonbonding edge state. In **(a)**, the combination of two Clar's representations (*left* and *center*) gives rise to the formation of a standing wave of $\sqrt{3}\times\sqrt{3}$ superlattice (the representation on the *right*) as a result of sextet localization, whereas the degeneracy of three Clar's representations results in sextet migration for **(b,c)**

electronic feature when we go from the partially dihydrogenated zigzag edge to fully dihydrogenated zigzag edge can be understood in terms of the migration of sextets in the triply degenerate Clar's representations in the fully dihydrogenated zigzag edge in Fig. 10.10b. The presence of unpaired electrons (edge state) in the zigzag edge is confirmed in the Clar's representations. Here it should be noted that the local density of states is distributed also on the two hydrogen sites terminating the edge carbon atoms as can be seen in the STM image and the local density of states distribution. This is the consequence of hyperconjugation; the direction connecting the two hydrogen atoms in the dihydrogenated site is in parallel to the direction of the carbon $2p_z$ orbital, which is perpendicular to the graphene sheet, resulting in the hybridization of hydrogen 1s and carbon $2p_z$ orbitals. Accordingly, the edge state can be extended to the two hydrogen sites terminating the edge carbon atom. It is also interesting that the spatial distribution of the edge state is extended to the interior of the nanoribbon. In the triply degenerate Clar's representations, two edge carbon atoms have an unpaired electron, which migrates between three representations. The magnetic moment of the edge state is estimated as $2/3\,\mu_B$/C atom, which is twice that in the monohydrogenated zigzag edge.

Oxygen-containing functional groups, which terminate edge carbon atoms, give electronic features different from hydrogen atoms. Edges terminated by oxygen-containing functional groups are more realistic for electronics device applications as most devices are handled in ambient atmosphere. Therefore investigation of nanoribbons whose edge carbon atoms are terminated by oxygen-containing functional groups is important. Figure 10.9e shows the STM image of a carbonylated zigzag edge together with the calculated spatial distribution of the local density of states around the Fermi level. Here the presence of an edge state is confirmed as a signature of a zigzag edge. Note that we can see the edge state around the edge and the absence of the superlattice in the STM image and also in the spatial distribution mapping of the density of states in the LDA calculation. The migration of sextets and unpaired electrons in the triply degenerate Clar's representations supports the STM observation and LDA calculation result. The magnetic moment is estimated as $2/3\,\mu_B$/C atom, the same as that in a fully dihydrogenated zigzag edge. What is interesting here is the extension of the edge states into the oxygen atom site in the carbonyl group as can be seen in Fig. 10.9e. In addition the local density of states in the edge state penetrates deeply into the interior of the graphene with a long decay length. Indeed, the decay length of the edge state is estimated as 2 nm from the experiment. The reason the feature different from a conventional monohydrogenated zigzag edge originates from the participation of oxygen $2p_z$ orbitals in the edge state. The oxygen $2p_z$ orbital is in parallel to the carbon $2p_z$ orbital, resulting in the hybridization of these two orbitals. The charge transfer from the edge carbon atom to the electronegative oxygen atom causes the population of the edge state in the oxygen atom and also the extended feature of the edge state.

STM/STS can provide information on the formation of an energy gap in armchair-edged nanoribbons [10.19, 20]. Figure 10.11 shows the STM image and STS spectrum of an armchair-edged graphene nanoribbon (ribbon width: $n = 13$) prepared using the bottom-up method. The armchair-edged graphene nanoribbon obtained through the bottom-up method is confirmed to have atomically precise edges as can be seen in Fig. 10.11a. In the STS spectrum ($\mathrm{d}I/\mathrm{d}V$ versus V plot), the presence of an energy gap is observed between the valence and conduction bands as shown in Fig. 10.11b, in which the energy gap is estimated as $E_g^{n=13} = 1.4 \pm 0.1$ eV for a nanoribbon having a width of $n = 13$. STS observations indicate that narrower nanoribbons have larger energy gap, consistent with theoretical prediction [10.17]; for example, $E_g^{n=7} = 2.5$ eV for $n = 7$. Nanoribbons with widths of $n = 7$ and 13 belong to the same subfamily of $n = 3p + 1$ with $p = 2$ and 4 respectively (Sect. 10.2). The gaps experimentally observed are systematically narrower than those predicted theoretically (3.8 and 2.4 eV for $n = 7$ and 13 respectively) with GW approximation, in which electron correlation is taken into consideration. But they are wider than those predicted by LDA calculation (1.6 eV for $n = 7$). This indicates that the electron correlation effect plays an important role in the gap formation. The discrepancy in the observed gap from the LDA value likely arises from image charge screening due to the gold substrate, on which the nanoribbons are placed. It should be noted that states of the valence and conduction band edges have higher intensity near the edges of the graphene nanoribbon, while the nanoribbon appears relatively featureless for energies within the gap as evidenced in Fig. 10.11b (B-D).

Raman spectroscopy is a powerful tool in characterizing the electronic and lattice vibrational structures of graphene nanoribbons and their edge geometry effect [10.21], where resonance Raman spectra specific to the electronic feature of zero-gap semiconductors in graphene is sensitive enough to get information on individual nanoribbons even though they are in the nanodimension. In principle there are important Raman bands called G-band, D-band and G′ (or 2D) at 1580, 1350 and 2700 cm^{-1} respectively, which can be utilized for characterizations of nanoribbons. The former one originates from the first-order Raman process asso-

ciated with intravalley scattering with the participation of a zone center phonon, while the latter two are owing to the double resonant Raman process related to the intervalley transition. In particular the intervalley scattering process in the D-band takes place together with the participation of elastic defect scattering. The G- and D-bands are sensitive to the edge geometry in graphene nanoribbons. We have learned how the electron scattering process takes place in armchair and zigzag edges in Sect. 10.2; that is, the K-K′ intervalley transition is responsible for the elastic scattering at the armchair edge, giving rise to the electron wave interference. Therefore, the D-band, which is owing to the elastic edge scattering, appears only in armchair-edge nanoribbons, whereas it does not in zigzag-edged ones. This can be seen in observations of Raman spectra as shown in Fig. 10.12a [10.22]. In the observed Raman spectra, the D-band appears in the armchair edge despite being weak in the zigzag edge and not observed in the interior of the graphene sheet, in good agreement with theoretical suggestion. The G-band can be observed both in armchair and zigzag edges as confirmed in Fig. 10.12a. Figure 10.12b shows the details of a G-band observed in armchair-edged graphene nanoribbon exhibited in the AFM image [10.23]. The experiment is carried out using a polarized laser beam. The G-band has large polarization angle dependence, whose intensity is expressed as $\cos^2\theta$ with polarization angle θ. This angular dependence is reproduced theoretically in terms of the K-K′ intervalley scattering coupled with longitudinal optical phonon mode as given in Fig. 10.12f [10.24]. The G-band shows angular dependence different in zigzag-edged nanoribbons compared to armchair-edge ones, as can be seen in theoretical predictions in Fig. 10.12f. It is given as $\cos^2\theta$ in armchair-edged nanoribbons. These findings in the experimental and theoretical works allow us to utilize Raman G- and D-bands as a powerful tool for characterizing the electronic and structural features in graphene nanoribbons.

Near-edge x-ray absorption fine structure (NEXAFS) in x-ray absorption spectroscopy [10.25, 26] and electron energy loss near edge structure (ELNES) in electron microscopy [10.27] also give important information about graphene nanoribbons. These are element-specific for investigating the electronic structure of states above the Fermi level E_F, near which the edge state is located for zigzag-edged nanoribbons. Therefore, we can extract information on the electronic structure of the edge state that is populated around the edge carbon atoms. In particular, ELNES together with microscope images can offer details on the electronic structure in atomic resolution in graphene nanostructures. Figure 10.13 shows the experimentally observed NEXAFS for nanographene, compared with that for HOPG [10.25]. The NEXAFS spectra of nanographene

and graphite (HOPG) have typically two peaks, at 285.5 and 291.9 eV, which correspond to the C1s to π^* and σ^* transitions respectively, as shown in Fig. 10.13a. In the nanographene spectrum, an extra small peak around E_F (284.36 eV) is observed at 284.5 eV, which is assigned to the edge state.

The position of the edge state in energy is sensitive to the detailed structure of the graphene edge [10.26] arising from the detailed shape of the edges and any chemical modifications. The chemical shift $\Delta E_b(1s)$, which is defined as the peak position with respect to the 1s core-level binding energy $E_b(1s)$ of interior C, in the NEXAFS spectra of graphene nanoribbons calculated by density functional theory (DFT) theory, show a systematic trend depending on the edge shape and chemical modifications, as shown in Fig. 10.13c,d [10.26], where monohydrogenated or dihydrogenated carbons appear at the zigzag edges. Monohydrogenated edges, dihydrogenated edges, and zigzag edges with a mixture of monohydrogenated and dihydrogenated edge carbon atoms are investigated. Here, $z1_m2_n$ denotes a zigzag edge in which the unit cell consists of a monohydrogenated region with m edge carbon atoms and a dihydrogenated region with n edge carbon atoms. In the edge carbon atom of a pure monohydrogenated zigzag edge or the monohydrogenated edge carbon atom, which is neighbored by monohydrogenated sites on both side, in a zigzag edge having a mixture of monohydrogenated and dehydrogenated sites, the chemical shift shows a large negative value of $\approx -1.0\,\text{eV}$, suggesting the presence of an edge state well localized at the edge carbon atom. Note the region encircled with B_1' in Fig. 10.13c. The edge carbon atom at a site surrounded by dihydrogenated edge carbon site(s) has a less negative chemical shift of ≈ -0.2 to $-0.5\,\text{eV}$ (regions B_2, B_3), which is in good agreement with the STM observations of a dihydrogenated zigzag edge discussed above [10.5]. The edge carbon atom having a larger number of dihydrogenated neighboring sites has less a negative chemical shift. In contrast, the dihydrogenated edge carbon atom (region A) has a positive chemical shift of ≈ 0.6–$0.8\,\text{eV}$, and the edge state is absent at the carbon site.

Photoemission spectroscopy (PES) is available for characterizations of nanoribbons, in particular their electronic structures of the valence states below the Fermi level [10.20, 28]. The formation of a gap is observed in angle-resolved photoemission spectroscopy (ARPES) spectra for armchair-edged graphene nanoribbon ($n = 7$) 7-AGNR grown on narrow terraces of (111) structure (3.83 nm in width) periodically created on a stepped Au(788) surface. The grown nanoribbons are unidirectionally aligned along the terrace. Figure 10.14a shows the ARPES spectrum of the nanoribbons. The spectrum proves that the valence band

top, which is parabolic shaped, is located 0.7 eV below the Fermi level, as a consequence of the gap formation. The valence band top position is in quantitative agreement with the STS result, suggesting that the bandgap (2.3 eV) is not positioned symmetrically with respect to the substrate Fermi level. This is explained on the basis of the difference in the work function between the graphene and Au substrate. The effective mass is estimated as $m^* = 0.21 m_e$.

The formation of edge state located around the Fermi level is confirmed in zigzag edges also using ARPES. Figure 10.14b,c shows the results of ARPES experiments. The graphite π valence bands, whose top touches the Fermi energy at the K point, are clearly visible, in addition to the σ bands well below E_F, in excellent agreement with a first-principles band structure calculation. In Fig. 10.14c, an anomalous feature of the edge state, denoted by a solid line, appears just at the top of the π valence band below E_F. This state is almost flat at wave numbers from $k_x \approx 0.0$ to -0.05 Å^{-1}, and it shows a slight upward dispersion toward E_F at $k_x \approx 0.05$ to -0.10 Å^{-1}.

10.4 Syntheses: Top-Down Methods and Bottom-Up Methods

10.4.1 Graphene Nanoribbon Formation by Top-Down Approaches

GNRs have been fabricated by top-down approaches and bottom-up approaches. A typical top-down method makes use of electron beam lithography. In fact, *Han* et al. fabricated GNRs with widths down to 14 nm and demonstrated that the energy gap, E_g, for which quantum-size effect and aromatic stability are responsible (Sects. 10.2 and 10.3), is expressed as a function of the ribbon width as

$$E_g = \frac{\alpha}{W - W^*}, \qquad (10.5)$$

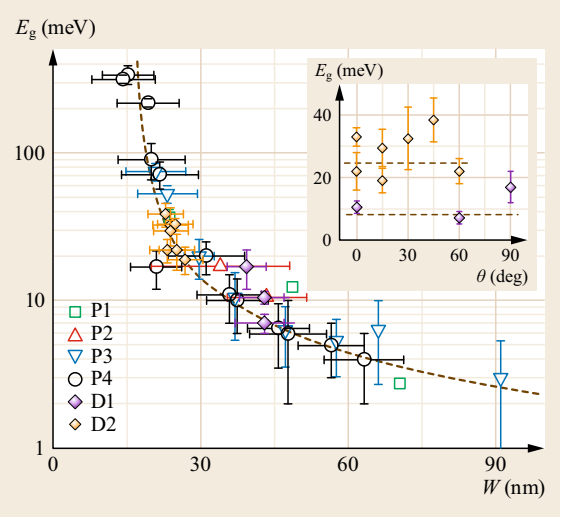

Fig. 10.15 Dependence of energy gap (E_g) on ribbon width (W) for six nanoribbon samples (P1, P2, P3, P4, D1, D2). The *insert* shows that the dependence of E_g on the crystallographic direction of GNRs. The angle (θ) of GNR was taken from an arbitrarily determined direction. No angle dependence was observed (after [10.29])

where $\alpha = 2$ eV and $W^* = 16$ nm (Fig. 10.15) [10.29]. W^* is considered to be the inactive edge width and is interpreted as the difference between the apparent ribbon width and the actual ribbon width or the decrease in the effective ribbon width as a result of edge defects. Electron beam lithography systems keep improving, and now it can pattern GNRs with widths below 10 nm [10.30]. Studies on the electron transport in GNRs fabricated by electron beam lithography have been performed further, and the energy gap above is now interpreted as a transport gap, which is generally larger than the theoretically calculated bandgap [10.31, 32]. The transport gap has been interpreted using various models including Anderson localization, variable-range hopping, and the Coulomb blockade model. In all the models, the existence of defects at the edges is considered to cause the transport gap.

Graphene nanoribbons were also made by using other top-down approaches. In fact, an array of GNRs with widths down to 8 nm have been fabricated by using directed self-assembly (DSA) of a cylindrical poly(styrene-b-dimethylsiloxane) (PS-b-PDMS) block copolymer as shown in Fig. 10.16 [10.33]. The DSA

Scale bar: 100 nm **(e,i)** (after [10.34])

technique is one of the promising techniques for patterning sub-10 nm features in the aggressively scaled semiconductor devices. The variations in width of fabricated GNRs were still process dependent. The variations in width in each single GNR, and those in width of multiple GNRs were both at least around 3 nm. These variations actually caused poor transistor characteristics, as described in the next section.

Direct patterning of GNRs by focused helium ion beams in a helium ion microscope has also been performed [10.35, 36], fabricating a 5 nm-wide GNR array [10.36]. However, the G-band and 2D band (at 2700 cm^{-1}) in Raman spectra for such GNRs broaden as the GNR width decreases from 15 to 5 nm. In fact, the 2D band is almost indistinguishable for GNRs narrower than 8 nm [10.36]. These Raman spectra can be explained by softening of the phonons due to the dominance of defects in the GNR lattice especially around the edges. The defects may have been due to imperfect etching by helium ions. It is also possible that helium ions backscattered from the substrate damaged the GNRs.

Scanning tunneling microscopy (STM) lithography, where high bias potential is applied to the STM tip in order to etch graphene, was demonstrated to form GNRs [10.12]. The constant-current STM im-

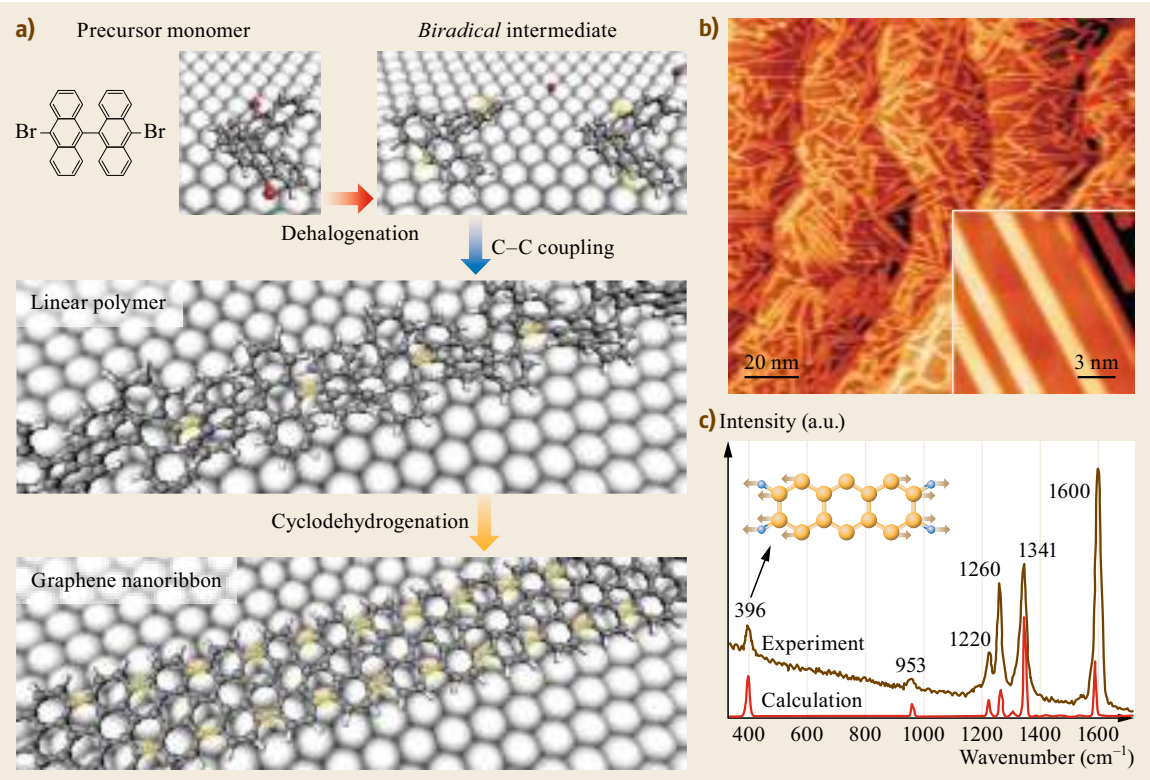

Fig. 10.19 **(a)** Fabrication process of atomically precise bottom-up 7-AGNRs. **(b)** Typical STM images of 7-AGNRs. **(c)** Typical Raman spectrum of the 7-AGNR. The peak at 396 cm^{-1} is characteristic for the 0.74 nm width of 7-AGNR, assigned to the radial-breathing like mode with the atomic displacements (see the *inset*) (after [10.37])

age of a 10 nm-wide armchair GNR (AGNR) exhibited confinement-induced standing wave patterns. An AGNR with a width down to 2.5 nm was formed by this technique. The energy gap obtained by scanning tunneling spectroscopy (STS) for the 2.5 nm-wide AGNR was about 0.5 eV, agreeing with first-principles calculations using local density approximations (LDA). Another interesting approach to fabricating arrays of suspended GNRs were recently reported (Fig. 10.17), where GNRs, which mainly consisted of multilayer graphene, were grown by plasma-enhanced chemical vapor deposition (PECVD) on arrays of nickel nanobars with widths from 20 to 100 nm [10.34]. The fabrication process is illustrated in Fig. 10.18. The GNRs with widths down to 6.9 nm were obtained using this approach. From polarized Raman spectra, it was concluded that the GNRs had near-zigzag edges, although the mechanism for having preferential edge orientation is not yet clear.

As described above, several top-down approaches to form GNRs have been reported. It is now even possible to fabricate arrays of GNRs. However, their Raman spectra and electrical properties, which are explained later, are not as good as expected. This is, as mentioned above, due to rough edges of GNRs caused by limitations in the current top-down methods. However, these kinds of difficulties may be solved in the near future, considering the history of semiconductor technologies.

10.4.2 Graphene Nanoribbon Formation by Bottom-Up Approaches

As a bottom-up approach, a method of fabricating atomically precise armchair-edged GNRs from 10,10-dibromo-9,9-bianthryl (DBBA) as a precursor was reported in 2010 [10.37]. Figure 10.19 illustrates the fabrication method. First, DBBA molecules are evaporated onto Au(111) substrate under ultrahigh vacuum (UHV). When the substrate temperature is increased to around 200 °C, halogen atoms (Br) are removed from the precursors and the radical intermediates diffuse and meet on the surface. The intermediates are then bonded with each other via aryl-aryl coupling, forming linear chains, which is basically the Ullmann reaction on a surface. When the temperature is further increased to 400 °C, cyclodehydrogenation occurs

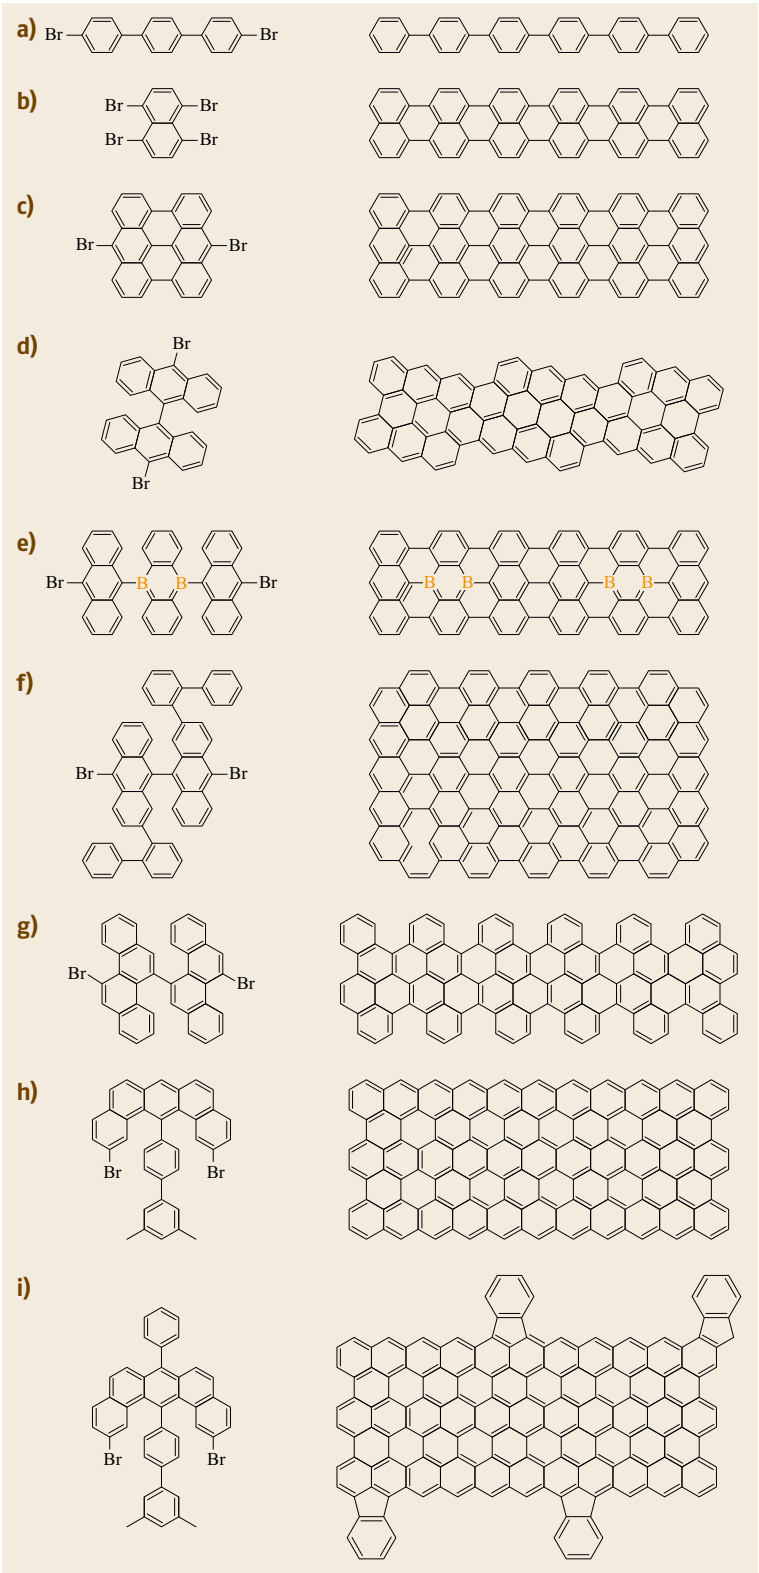

Fig. 10.20a–i Precursors (*left*) and GNRs (*right*) formed from the corresponding precursors (after [10.19, 38, 39])

to transform polymers into atomically precise armchair GNRs. As shown in Fig. 10.19, the ribbon width is well controlled and a Raman vibrational mode that depends on the ribbon width is observed. The fabricated GNRs are those with armchair-shaped edges with seven dimer lines (7-AGNR) and the bandgap is theoretically predicted to be about 3.7 eV [10.17]. *Ruffieux* et al. estimated the bandgap by STS to be approximately 2.3 eV [10.20], in reasonable agreement with the theoretical bandgap [10.17] considering the mirror charge effects of the Au substrate. The electrical conductance of such GNRs was first measured by picking up a 7-AGNR with an STM tip and measuring the conductance between the tip and the substrate. The GNR exhibited nearly insulating behavior due to the large bandgap [10.40].

The formation mechanism of GNR above has been studied further theoretically and experimentally [10.41–44]. Since GNRs are formed by the on-surface Ullmann reaction, the choice of substrate greatly affects the reaction. The reaction may be divided into three main steps: namely, dehalogenation, polymerization, and cyclodehydrogenation. *Simonov* et al. experimentally showed that the onset temperature of each step depends on the substrate type [10.43]. For instance, at room temperature, the DBBA precursor molecules on Au(111) remain intact, while on Cu(111) a complete surface-assisted dehalogenation occurs. On Cu(111), tilted polymer chains are formed even at room temperature or slightly elevated temperatures. Intramolecular cyclodehydrogenation begins at the annealing temperature above 100 °C on Cu(111) and flat AGNRs are formed at 200 °C, in contrast to the case of Au(111) described above. Theoretical simulations have also revealed that energy barriers for each reaction step are greatly reduced by the existence of metal surfaces, and that the degree of barrier lowering depends on the choice of metals [10.41, 42]. The choice of halogen atoms introduced to precursors can also play a role in GNR formation [10.42, 44]. For example, iodine atoms desorb more easily from precursors than bromine atoms. The desorbed halogens seem to remain on the surface until the polymerization process is completed and may poison the substrate, hindering long-range ordering of the self-assembled structures [10.42]. However, the role of halogens on the surface still remains unclear, and further studies are needed.

The bandgap of 3.7 eV in 7-AGNR may be too large for the application of GNRs to electronic devices. However, different types of atomically precise bottom-up graphene nanoribbons have been synthesized since 2010 (Fig. 10.20) [10.19, 38, 39, 45–49]. Such GNRs have been realized by carefully designing appropriate precursor molecules, as also illustrated in Fig. 10.20. As for AGNRs, it is now claimed that 3-, 5-, 7-, and 13-AGNRs have successfully been formed. The bandgaps observed by STS agree reasonably well with theoretical predictions [10.17], by taking into account the influences of metal surface. The typical length of 7-AGNRs was a few tens of nanometers. On the other hand, newer AGNRs, say, 5- and 13-AGNRs appeared to be shorter, typically less than 10 nm. This is not good considering real-world applications. This might be related to the lifetime of radicals for each precursor and further studies are needed. 13-AGNRs above were actually formed in attempt to obtain AGNRs with a smaller bandgap. In order to lower the bandgap further, wider AGNRs would be required in general. It is imagined that formation of wider AGNRs requires relatively large precursor molecules, which can be difficult to evaporate. Therefore, a different strategy may be needed to obtain wider AGNRs.

A zigzag-edged GNR (ZGNR) has recently been formed on Au(111) surface by employing precursors shown in Fig. 10.20h [10.38]. A noncontact AFM image of the 6-ZGNR obtained with a CO-functionalized tip, as well as STM images, are shown in Fig. 10.21. Anticipated edge states of 6-ZGNR were not observed for 6-ZGNR on Au(111) due to the surface state of the underlying Au(111) substrate; however, the edge states were obtained for 6-ZGNRs on insulating NaCl islands, where they are electronically decoupled from the metal substrate. The edge states were observed to have a bandgap, in good agreement with theoretical calculations using the GW approximation, in which the electron correlation effect is involved [10.17]. The successful formation of ZGNRs may open up possibilities for ZGNR-based spintronics devices, as discussed later.

Boron-doped AGNRs have also been formed as shown in Fig. 10.22 [10.46, 47]. However, the ratio of boron atoms to carbon atoms is too high to refer this case to doping, completely changing the original band structure. Therefore, replacing carbon atoms in the GNR body may not be a good idea for doping GNRs. However, this kind of technique can produce GNR families with similar dimensions, but having various electronic states, and can provide another set of building blocks for carbon-based nanoelectronics.

10.4.3 Graphene Nanoribbon Formation by Other Approaches

Other methods have also been used in attempts to form GNRs. For example, *Li* et al. formed GNRs by heating exfoliated expandable graphite to 1000 °C in a forming gas, dispersing the resulting graphite in a 1,2-dichloroethane (DCE) solution of poly[(*m*-phenylenevinylene-*co*)-2,5-(dioctoxy-p-phenylenevin-

ylene)] (PmPV) and ultrasonicating it [10.13]. GNRs with widths narrower than 10 nm were obtained. TEM revealed that these GNRs had ultrasmooth edges. As explained later, electrical properties of these GNRs are probably better than those of GNRs obtained by any other approaches so far. The bandgap was also in reasonable agreement with that obtained by first-principles calculations (without consideration of the

electron correlation). With this method, relatively high-quality GNRs can be obtained; however, the control of the ribbon width and length is difficult.

Methods of fabricating GNRs from carbon nanotubes (CNTs) have also been proposed [10.51, 52]. In one method, GNRs were fabricated by cutting the side walls of multiwalled CNTs in the lengthwise direction with the treatment of multiwalled CNTs (MWCNTs) with a strong oxidant [10.52]. Here, the obtained GNRs consisted of graphene oxide; they were basically an insulator and required reduction treatment for use as graphene. Somewhat later, another method of fabricating GNRs by mildly oxidizing MWCNTs in a gas phase and dispersing the resulting MWCNTs in a DCE solution of PmPV was reported (Fig. 10.23) [10.50]. The obtained GNRs had smooth edges. A mobility of 1500 cm^2/Vs was obtained for the GNRs with a width of 14 nm. At low temperature, the GNRs exhibited coherent transport and Fabry–Perot interference. The methods of fabricating GNRs from CNTs were originally successful only with relatively thick multiwalled CNTs, leading to the formation of relatively wide GNRs. However, recently narrower GNRs with widths of 2–3 nm were also obtained from single-walled CNTs [10.53].

It was also reported that graphene can be preferentially formed on narrow twin crystal regions of Cu films by carefully tuning the CVD conditions [10.54]. Such twin crystal regions are often obtained when a Cu film is annealed at high temperature. Figure 10.24 shows SEM images of graphene ribbons formed on the twin crystal regions. Such regions have Cu(001) or high index surfaces, in contrast to the other area having a Cu(111) surface. In fact, simulations revealed that graphene nucleation is more likely to occur on Cu(001) than Cu(111). Although GNRs obtained by this approach are still about 100 nm wide, it was reported that much narrower and denser twin crystal regions can be obtained [10.55]. So, it seems possible to obtain narrower GNRs by this approach. Furthermore, *Jacobberger* et al. [10.56] has recently demonstrated that GNRs can be formed on Ge(001) by CVD. The GNRs were self-aligning 3° from the Ge(110) directions, and predominantly had armchair edges. The widths of GNRs were as narrow as 10 nm and the aspect ratio was as high as 70. The mechanism of the preferential growth was discussed in the manuscript, but does not seem to be conclusive yet. Further studies would be necessary for understanding such interesting growth manner.

Graphene nanoribbons can also be formed on SiC surface, as shown in Fig. 10.25 [10.57]. In this technique, controlled facets are achieved by patterning

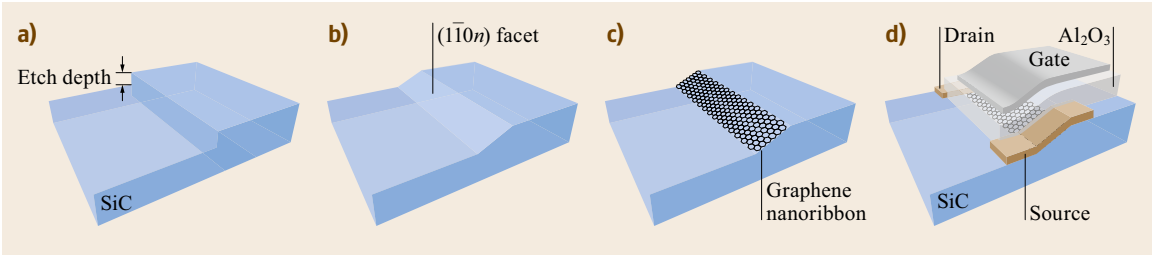

Fig. 10.25a–d Process for selective graphene nanoribbon growth. **(a)** A nanometer-scale step is etched into SiC by fluorine-based reactive ion etching. **(b)** The SiC is heated to 1200–1300 °C (at low vacuum), inducing step flow and relaxation to the (1–10n) facet. **(c)** Upon further heating to 1450 °C, graphene nanoribbon forms on the facet in a self-organized manner. **(d)** Device structure with source and drain contacts, GNR channel, Al_2O_3 gate dielectric and top gate (after [10.57])

nickel lines on a SiC substrate perpendicular to the $< 1{-}100 >$ direction; these lines are transferred into the SiC by fluorine-based reactive ion etching (RIE), controlling the etch depth in nanometer precision. As shown in Fig. 10.25, the etch depth ultimately defines the width of the GNRs. Etch depths of 20 nm were easily achieved, resulting in a ribbon width (40 nm) sufficiently narrow to give a sizable bandgap at room temperature. After removal of the nickel mask and cleaning, the crystal is heated to temperatures of 1200–1300 °C at 10^{-4} torr for 30 min, inducing SiC step flow. The abrupt step relaxes to a (110 n) facet, and the temperature is then elevated to 1450 °C within 1.5 min, maintained for 10 min for graphene growth, then allowed to cool naturally, falling below 1300 °C within 15 s. With this technique, GNRs can be obtained all over a large substrate. Forming narrower GNRs is, however, required for application to transistor channels.

10.5 Potential Applications

10.5.1 Application to Transistors

Graphene nanoribbons have intrinsically excellent and interesting properties, and thus there are many potential applications. One of the promising applications is transistors. As described in the previous sections, the band structure varies with the ribbon width and edge structure. According to theoretical calculations, the bandgap changes from ≈ 5 eV down to ≈ 0 eV by controlling the structure, which is amazing and almost impossible with materials other than carbon. Not only logic circuit applications with small-bandgap GNRs but also high-power applications with large-bandgap GNRs may be possible. In fact, large-scale integrated circuits (LSIs), whose performance has continuously been improved by scaling (miniaturization), is now facing the physical limitation of scaling. Therefore, the semiconductor devices will have to be improved by methods other than scaling in the near future. Employing new channel materials with high mobility, such as graphene and CNTs, is one of the promising candidates. Like carbon nanotubes (CNTs), long ballistic lengths in GNRs can make a ballistic transistor with excellent transport properties realistic. It should be noted here that, although it is generally understood that there is a trade-off between the mobility and the bandgap for nonballistic transport, this understanding does not simply apply to the ballistic regime: transport properties should be understood based on the first-principles calculations [10.58].

As for characteristics of GNR transistors, several theoretical studies have been performed [10.59–62], typically based on the nonequilibrium Green's function formalism. Overall understanding is that the performance of GNR transistors is comparable with that of CNT transistors, and better than that of silicon complementary metal–oxide–semiconductors (CMOSs) or nanowire transistors. A typical transistor structure is illustrated in Fig. 10.26. A top-gate structure is normally used in real-world applications, where the electronic band in the channel is electrostatically modulated by the top-gate bias in order to turn on the channel current from the source to drain electrodes. Experimentally, however, a bottom-gate structure is often employed for simplicity. Simulation results by *Fiori* and *Iannaccone* [10.61] are shown in Fig. 10.27. In this figure, transfer characteristics of both GNR and CNT transistors are shown. As for the GNR transistor, an array of GNRs is assumed. The width (W) of each GNR is assumed to be 1.37 nm, and the length (L), 15 nm. The space between the GNRs is 4 nm. The gate-oxide thickness is assumed to be 1 nm. In this case, the bandgap was calculated to be 0.6 eV using the tight-

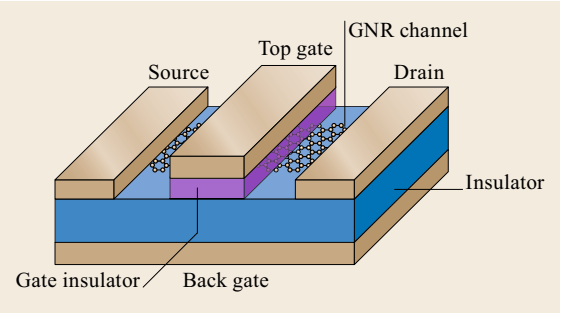

Fig. 10.26 Typical transistor structure with a GNR as a channel

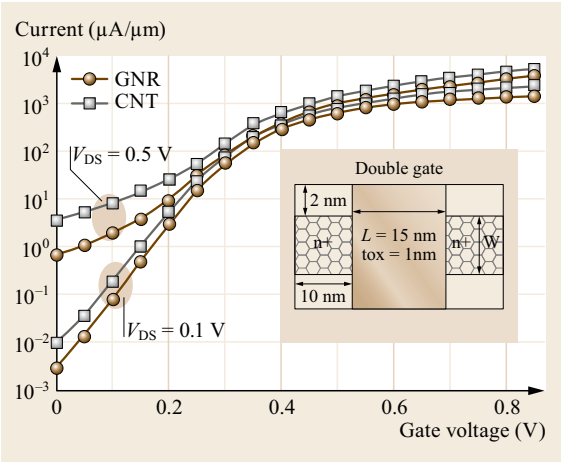

Fig. 10.27 Transfer characteristics of double-gated CNT and GNR field-effect transistors (FETs), with channel length of 15 nm, gate-oxide thickness (tox) of 1 nm, and channel of 1.37 nm. *Inset*: Illustration of the GNR-FET. The source and drain extensions are 10 nm long. The spacing between parallel GNRs is 4 nm, the double of 2 nm shown in the illustration (after [10.61])

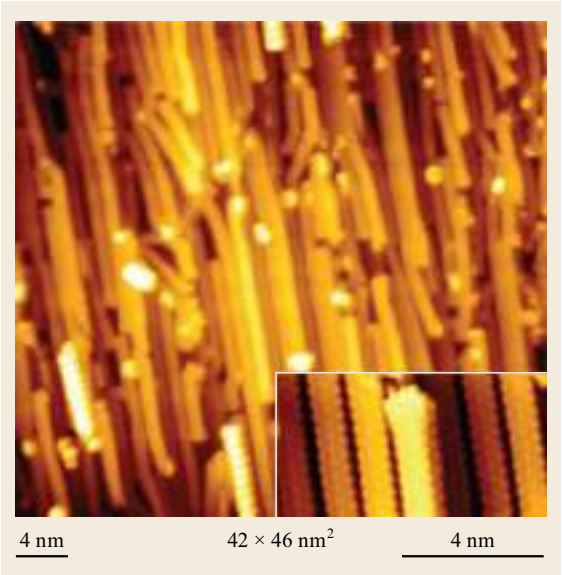

Fig. 10.28 STM images of aligned 7-AGNRs on Au(788) surfaces. Scale bars: 4 nm. (Reprinted with permission from [10.63], copyright 2012 American Physical Society)

binding approach, which was smaller than that obtained by calculations using a first-principles many-electron Green's function approach within the GW approximation [10.17]. Because of this small bandgap, the off-current is relatively large when the drain voltage, V_{DS}, is 0.5 V. This is caused by band-to-band tunneling. However, the off-current is suppressed when the drain voltage is 0.1 V. Surprisingly, even when the drain voltage is 0.1 V, an on-current larger than 1 mA/μm is obtained, which is a requirement for high-performance transistors. Since the power consumption of a transistor during operation is proportional to the square of the supply voltage, this implies that GNR transistors can greatly reduce the power consumption of electronics devices, such as large-scale integrated circuits. Of course, if the edge roughness exists, the transistor performance is degraded, as also shown by *Fiori* and *Iannaccone* [10.61]. However, atomically precise bottom-up GNRs explained in the former section can be a solution to this problem. Moreover, *Linden* et al. demonstrated densely aligned growth of AGNRs on vicinal Au(778) surface as shown in Fig. 10.28 [10.63], which indicates an array of GNRs can actually be available as transistor channels.

It may be noticed that, in Fig. 10.27, the gate voltage required to obtain a large drain current (> 1 mA/μm) is still as large as 0.5 V or so. This means that, even if the drain voltage is lowered to 0.1 V, the supply voltage should remain high. This is mainly caused by the operation principles of the transistors described above. In fact, for MOSFETs (metal-oxide-semiconductor field-effect transistor), subthreshold swing (voltage required to increase the drain current by one decade in the subthreshold region) has to be equal to or larger than 60 meV/decade at room temperature. Therefore, for example, in order to obtain the current on-off ratio larger than 10^5, the gate voltage of 0.3 V or larger would be required. This is also a problem for the conventional MOSFETs using silicon. As a solution to this problem, a new-principle transistor, tunnel FET (TFET), is actively studied, which makes use of band-to-band tunneling to turn on the current [10.65]. GNRs can also be applied to TFETs and theoretical simulations show that the on-current of GNR TFETs can be more than two orders of magnitude higher than that of Si TFETs [10.66, 67]. In fact, the low on-current of Si TFETs, which is

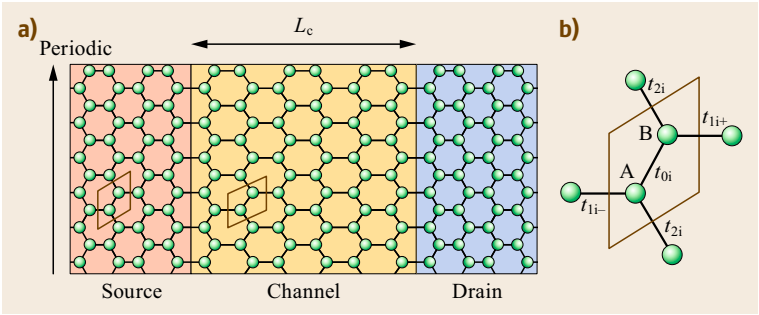

Fig. 10.29 **(a)** A schematic illustration of the model structure, where the graphene is stretched along the armchair direction over the gated channel region. The *left* and the *right* unstrained graphene regions act as the source and drain electrodes. **(b)** shows the graphene unit cell consisting of two independent sublattice sites A and B interacting through transfer integrals t. Stretching makes t_{1i+} and t_{1i-} along the stretching direction weakened (after [10.64])

caused by the indirect bandgap of Si, is a serious obstacle for practical realization [10.65] and GNR TFETs can be a solution.

Another interesting new-principle transistor using graphene is illustrated in Fig. 10.29 [10.64]. In this transistor, an axially strained graphene is used as a channel, and unstrained graphene is used for the source and drain. The strained graphene has the Dirac point in a different k-space position. When the gate voltage is applied, the conduction bands of the strained graphene and unstrained graphene can overlap in the k space, thus turning on the transistor. This transistor behavior is similar to TFETs described above, and subthreshold swing less than 60 meV/decade can be achieved. Although this transistor is designed for gapless graphene, this concept can also work for relatively wide GNRs.

Experimental studies on GNR transistors have also been performed. So far, the best performance was obtained with GNRs described in the beginning of Sect. 10.4.3 [10.13]. In fact, an on-off current ratio of 10^5–10^7 was obtained for the GNR channels with a width < 10 nm at room temperature. Typical mobility for such GNRs was 100–200 cm^2/Vs. This combination of the on-off current ratio (10^5–10^7) and mobility (100–200 cm^2/Vs) is possibly the best reported combination for GNRs, although the mobility is not yet as good as expected. Although GNRs with widths narrower than 10 nm have been obtained by top-down approaches as described in Sect. 10.4.1, the typical on-off current ratio of the transistors with such GNRs was only 10–100. The drain current per channel width is also greatly degraded by the etching process, resulting in poor mobility. This poor performance is probably caused by the rough edges of such GNRs. Possible residues from the top-down processes can also be a reason. On the other hand, the GNR array demonstrated excellent gas sensing properties [10.36], detecting NO_2 with concentrations down to ppb levels, which is much better than graphene-based gas sensors [10.68].

Transistors using atomically precise bottom-up GNRs have also been fabricated recently [10.69, 70]. Transistors using 7-AGNR show an on-current of ≈ 1 nA/GNR and an on-off current ratio of $\approx 10^3$ [10.69]. These results are again poorer than expected, which may be caused by high Schottky barriers at the source and drain contacts and/or possible contamination on the channel. Transistors using 9-AGNRs and 13-AGNRs as channels have also been fabricated. These transistors exhibited on-currents as high as 100 nA at a drain bias of 1 V and on-off ratios of 10^2–10^5 [10.70]. The improvement in on-current is probably due to lower Schottky barriers originated from the smaller bandgaps of 9-AGNRs and 13-AGNRs. Further improvement is expected by improving the device fabrication processes, which is still ongoing.

10.5.2 Interconnect Application

GNR is also a good candidate for interconnects for scaled LSI and molecular devices. In fact, along with the miniaturization of devices, LSI interconnects are facing two problems: decreased reliability and increased effective resistivity of Cu interconnects. According to the International Technology Roadmap for Semiconductors 2013, the resistivity of Cu interconnects is estimated to exceed 10 $\mu\Omega$ cm (1.7 $\mu\Omega$ cm for bulk Cu) by about 2020 when the linewidth is predicted to have become narrower than 10 nm. GNRs along with CNTs can be a solution to these problems.

It has been reported that the reliability of graphene interconnects, as well as CNT interconnects, is superior to that of Cu interconnects. The breakdown current densities of both exfoliated graphene and CVD graphene are of the order of 10^8–10^9 A/cm^2 [10.30, 71, 72]. In the study of *Murali* et al. [10.71], GNRs with widths

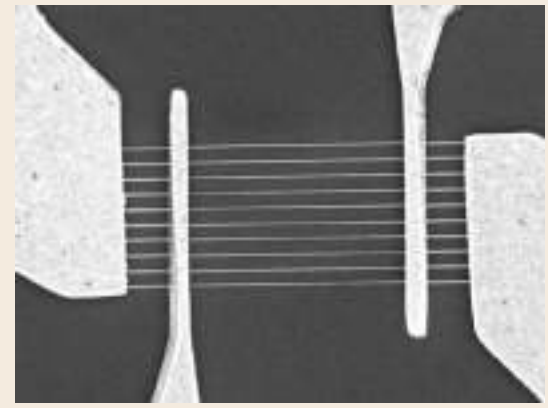

Fig. 10.30 SEM image of ten GNRs with electrodes. The GNRs below hydrogen silsesquioxane (HSQ) lines are 21 nm-wide between the middle electrode pair. (Reprinted with permission from [10.71], copyright 2009 AIP Publishing)

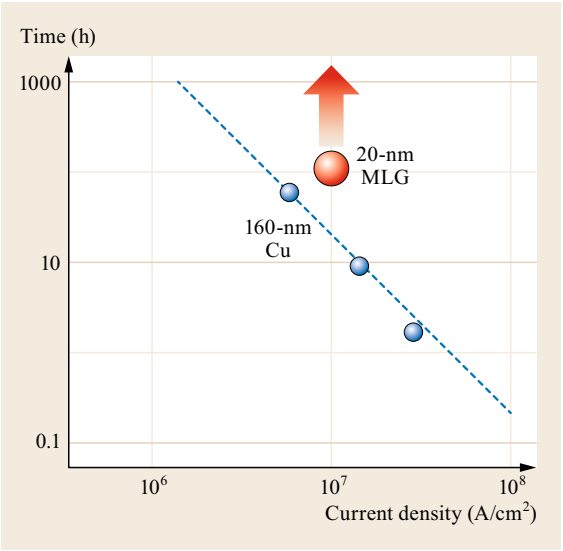

Fig. 10.31 Results for reliability tests. The *vertical axis* shows the time to failure. The *horizontal axis* shows the current density applied. The *dotted line* is a fitting line for Cu interconnects. The 20 nm-wide multilayer graphene (MLG) interconnect did not break after 100 h under a current density of 10^7 A/cm^2 (after [10.30, 73])

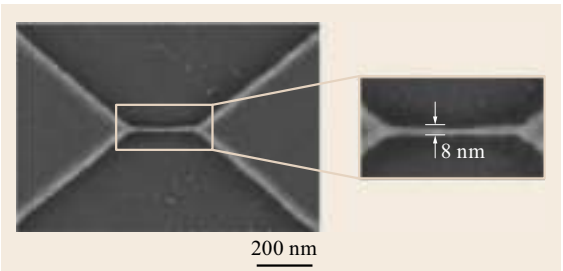

Fig. 10.32 Multilayer (ten-layer) graphene interconnect patterned by electron beam lithography. Resist for electron beam lithography, HSQ, is left on the graphene interconnects (after [10.30])

as narrow as 16 nm were fabricated by electron beam lithography and exhibited a high breakdown current (Fig. 10.30). Figure 10.31 shows the results of a reliability test conducted for 20 nm-wide GNR interconnects made of CVD graphene [10.30, 73]. The current density durability of the CVD graphene was superior to that of Cu. Although the results explained here are for relatively wide GNRs, the reliability of narrower GNRs is also expected to be good.

The transport properties of GNR interconnects have theoretically been predicted [10.74, 75]. Results are somewhat different from each other possibly due to the differences in assumption. The general understanding is that the resistivity of GNRs can be better than that of scaled Cu interconnects if the ballistic transport is realized. Doping to graphene can improve the resistivity further. However, in fact, the fabrication of graphene interconnects having resistance lower than Cu interconnects is not an easy task. Interconnects with a low resistivity were not obtained simply by patterning graphene by lithography. In such cases, electron transport tends to be diffusive, and the resistance becomes comparable with that of bulk graphite, which is about 40 $\mu\Omega$ cm, one order of magnitude higher than that of Cu (1.7 $\mu\Omega$ cm).

Doping by intercalation is an option to reduce the resistivity of GNRs, as mentioned above. Lowering the resistivity of graphite by intercalation was first reported many years ago [10.77]. Several materials have been reported to achieve resistivity lower than that of Cu by intercalation to graphite. *Xu* et al. theoretically demonstrated that AsF_5-doped multilayer GNRs can have resistivity lower than that of Cu [10.74]. Murali experimentally demonstrated that an electrostatically doped exfoliated GNR can have a resistivity comparable to that of Cu. *Kondo* et al. patterned CVD-grown graphene by electron beam lithography to fabricate GNRs as narrow as 8 nm, as shown in Fig. 10.32 and obtained a resistivity of 3.2 $\mu\Omega$ cm by the intercalation of $FeCl_3$ [10.30, 72, 73]. This value is actually better than the predicted resistivity of Cu interconnects with similar dimensions.

As mentioned above, obtaining GNRs exhibiting ballistic transport has been awaited, but is not an easy task. Use of atomically precise bottom-up

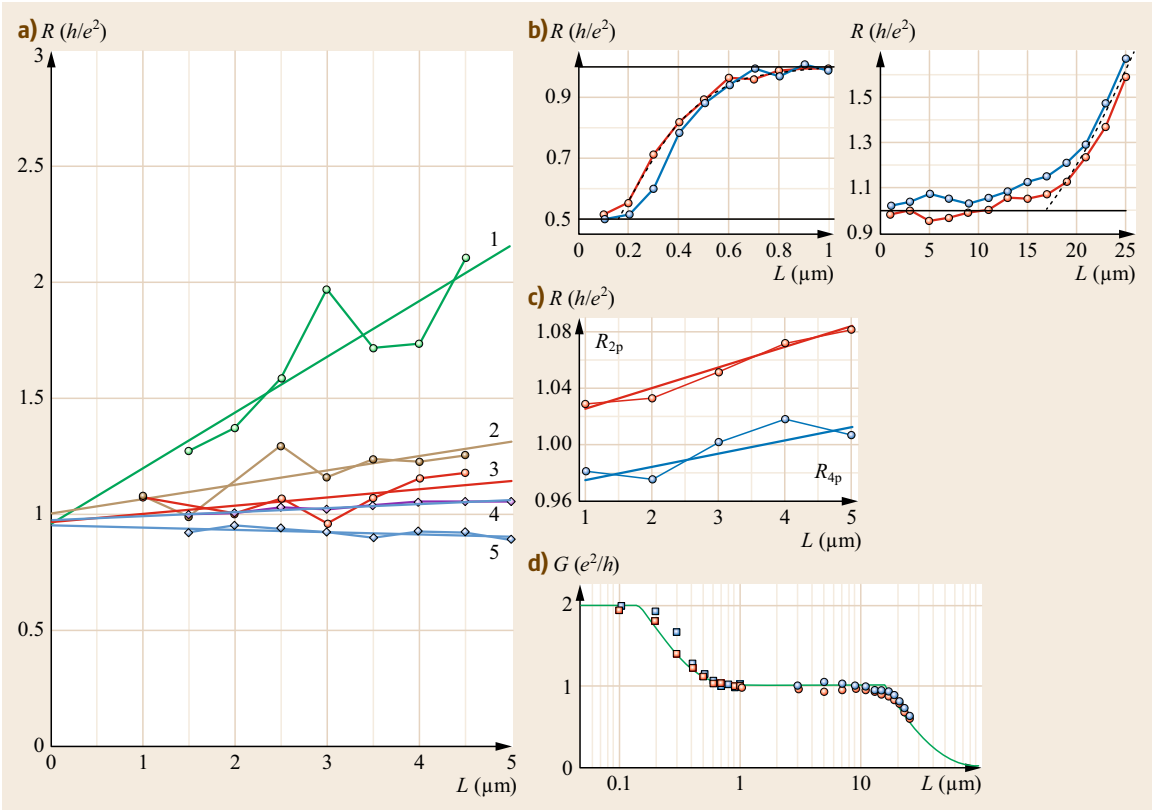

Fig. 10.33 **(a)** Multiprobe in situ transport measurements of graphene nanoribbons, showing resistance versus probe spacing, L. Linear fits, shown as five straight lines, extrapolate to $R_0 = h/e^2$. The slopes of the fitting lines 1–4 correspond to $R' = 6.2,\ 1.6,\ 0.92,\ 0.44\,\mathrm{k}\Omega/\mu\mathrm{m}$, corresponding to the mean free path, $\lambda_0 = 4.2, 28, 16, 58\,\mu\mathrm{m}$ (estimated by the following relationship: transmission, $\mathrm{Tr} \approx (1 + L/\lambda_0)^{-1}$). Fitting line 5 is consistent with zero slope. Numbered traces are as follows: 1, UHV annealed at 1100 °C for 15 min; 2, UHV annealed at 1150 °C for 15 min; 3–5, re-annealed at 1150 °C for 15 min. **(c)** Comparison of two-probe (2p) and four-probe (4p) measurements. **(b)** Nonlinear resistance increases observed at $L = 160\,\mu\mathrm{m}$ and at $L = 16\,\mu\mathrm{m}$ in two different ribbons measured at room temperature, presented as conductance, $G(L)$ **(d)** (after [10.76])

GNRs is one of the most promising options, and it is actually on the way. However, recently, ballistic transport at room temperature has been observed for GNRs formed on SiC [10.76]. The GNR structures were grown selectively by sublimation epitaxy on mesastructured 6H-SiC(0001) surfaces, as illustrated in Fig. 10.25 [10.57]. GNRs with a width of 40 nm exhibited a ballistic length greater than 10 μm (Fig. 10.33), which was equivalent to sheet resistances below 1 Ω/square. This is really a surprising, but promising, result for future nanoelectronics using GNRs.

10.5.3 Other Potential Applications

Graphene nanoribbons have other promising applications. One of them is application to spintronics. As described in the previous sections, ZGNRs have spin-polarized edge states. The orientations of the spins localized at the two edges are opposite to each other as shown in Fig. 10.34 and ZGNRs have antiferromagnetic properties overall. *Son* et al. [10.78] showed theoretically that ZGNRs can be half-metallic by applying an in-plane electric field perpendicular to the edge directions. Later, it was also predicted that the half metallicity can be obtained by modifying each edge with different chemical functional groups, such as NO_2 and CH_3 [10.79]. If GNRs are half-metallic, they can be used to inject spin-polarized electrons for spintronics. Furthermore, *Magada* et al. experimentally showed that ZGNR exhibited transition from antiferromagnetic to ferromagnetic configurations when they became wider than about 7 nm [10.80]. This implies that ZGNRs along with AGNRs can be used as the main

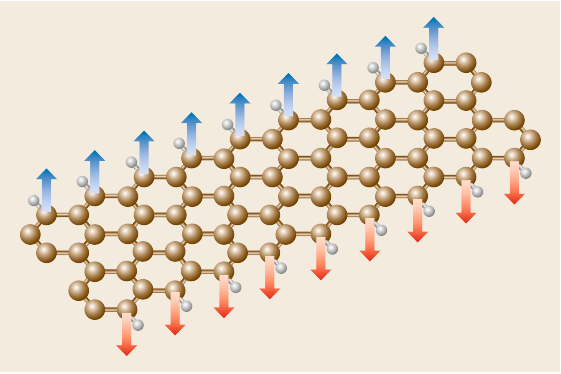

Fig. 10.34 ZGNR with edge-localized spins. The polarized spins at the two edges are opposite to each other

building blocks for spintronic devices, including magnetroresistive random access memory (MRAM), spin FETs and spin MOSFETs.

Graphene nanoribbons are also a candidate for future computing devices. In fact, *Trauzettel* et al. proposed to form spin qubits in graphene quantum dots [10.81]. In their proposal, the quantum dots are made of a gated AGNR. Because the spin-orbit coupling is weak and the hyperfine interaction is small in graphene, the spin coherence time can be large. Moreover, spin qubits in graphene cannot only be coupled between nearest-neighbor quantum dots but also over long distances, according to their explanation. A schematic diagram of the proposed graphene quantum dots is shown in Fig. 10.35. Such quantum dots need AGNRs with perfect edges, which can be formed using the bottom-up technique described in the former section. Quantum computers using AGNRs may be realized in the future.

Graphene nanoribbons can also be used for photovoltaic devices. *Konabe* and *Okada* theoretically predicted that multiple-exciton generation occurs in AGNRs wherein the efficiency of photoelectric conversion exceeds 100% [10.82, 83]. This suggests that high-efficiency and flexible solar cells can be realized with AGNRs. For this purpose, mass production of AGNRs in liquid chemicals may be necessary. Another application might be as additives to electrodes of secondary batteries and fuel cells. Functionalized GNRs could also be used as catalysts. If the technology to form GNRs with arbitrary structures is established in the future, many more applications are expected to be realized.

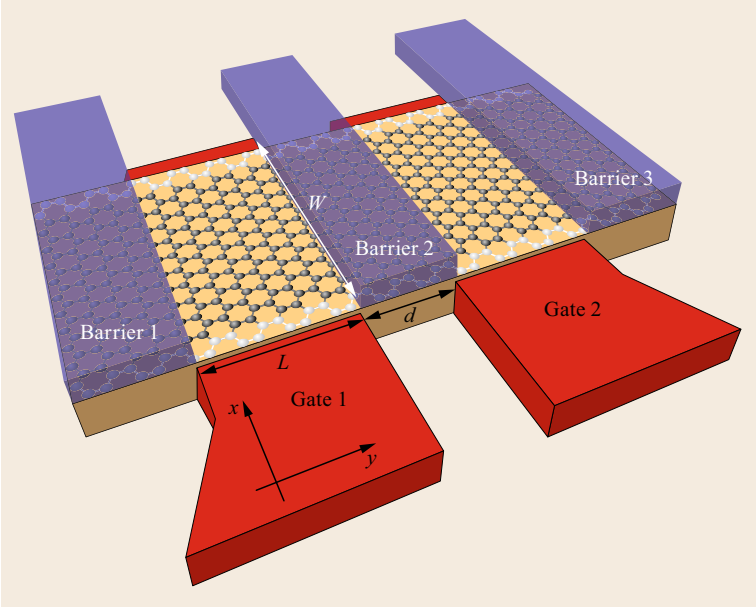

Fig. 10.35 Schematic diagram of graphene quantum dots (after [10.81])

10.6 Conclusions

Graphene is a one-atom-thick 2-D sheet, in which carbon atoms are arranged in a hexagonal honeycomb lattice. When an infinite graphene sheet is cut into nanofragments, graphene nanostructures are created. Among graphene nanostructures created by cutting, we have ribbon-shaped nanostructures called graphene nanoribbons. What makes graphene nanostructures different from infinite graphene and also from carbon nanotubes and fullerenes is the presence of open edges in the former. Owing to the presence of open edges, these graphene nanostructures have electronic structures strongly modified from an infinite graphene having features of a zero-gap semiconductor. There are two fundamental edge geometries; that is, armchair edge and zigzag edge, and how the electronic structure is modified depends crucially on the edge geometry. The modifications can be understood on the basis of the boundary condition, which is given by the open edges, for the electrons having the features of massless Dirac fermion in graphene. In the armchair edge, electron wave interference takes place, resulting in energetic stabilization, whereas the broken symmetry of the pseudospin of the Dirac fermion is responsible for the creation of a nonbonding edge state in the zigzag edge. This can also be interpreted in terms of aromatic stability and creation of unpaired electrons for armchair and zigzag edges respectively, in chemistry, taking into account that graphene nanofragments are considered as nanosized polycyclic aromatic hydrocarbon molecules.

Accordingly the electronic structures of graphene nanoribbons having armchair and zigzag edges are owing to these geometry-dependent modifications. Namely, armchair-edged graphene nanoribbons, which are energetically stable, have energy gaps, which depend on the ribbon widths, while zigzag-edged nanoribbons have nonbonding edge states, which are spin polarized and localized in the vicinity of the zigzag edges. The zigzag-edged nanoribbons become electronically, magnetically and chemically active at the expense of aromatic stability. It should be noted that how edge carbon atoms are terminated with functional groups also modifies the electronic structures in addition to the edge-geometry-originating modifications. Therefore the combination of chemistry details and edge geometry gives rise to a large variety of electronic properties.

The properties of graphene nanoribbons and also the structures of graphene edges can be characterized using various experimental techniques and also first-principle theoretical calculations. Microprobe experiments such as STM/STS and AFM together with DFT calculations give important local information on the electronic structures and also the atomic arrangements in atomic scale precision. The transmission electron microscope is also a useful tool in getting information not only of atomic arrangements but also of local electronic structures. Raman spectroscopy is particularly important in characterizing the edge geometry, as the resonant Raman signals, which are sensitive even for a single graphene nanostructure, have distinct edge geometry dependence. Electron transport measurements are indispensable for electronic structure characterizations.

Synthesis of graphene nanoribbons can be carried out basically using top-down and bottom-up methods. In the top-down methods, electron beam lithography is most important, though future improvement is required for fabricating sub-10 nm-width nanoribbons. Direct patterning of graphene nanoribbons by focused helium ion beams in a helium ion microscope can reach a 5 nm-wide graphene nanoribbon array. STM lithography can go to a width of 2.5 nm. The drawback in the top-down technique is difficulty in obtaining atomically precise edges, which theoretical predictions on the geometry-dependent electronic structures require. Bottom-up methods are important in fabricating graphene nanoribbons that have atomically precise edges. Polymerization of precursor monomer molecules with the aid of the catalytic activity of metal substrates gives a variety of armchair- and zigzag-edged graphene nanoribbons and also graphene nanoribbons having wiggled edges and chiral edges. We can create also nanoribbons in which heteroatoms are doped.

The presence of bandgap in graphene nanoribbons, armchair-edged graphene nanoribbons in particular, is important in transistor device applications. The bandgap, which varies depending on the ribbon width, is advantageous in fabricating electronics devices. Graphene nanoribbons are a good candidate for interconnects for scaled LSI and molecular devices. Zigzag-edged graphene nanoribbons, which have spin-polarized edge states in the vicinity of the edges, are expected to be useful in spintronics applications.

11. Nanoparticles and Their Applications

Seyedsina Moeinzadeh, Esmaiel Jabbari

Nanoparticles (NPs) are synthesized from several classes of materials including inorganic, organic, hybrid and biological materials. Inorganic NPs are synthesized by ball milling, vapor deposition, electrospraying, reduction of metal salts, sol–gel, coprecipitation and thermal decomposition. Organic NPs are synthesized by microemulsion, nanoprecipitation, dialysis and rapid expansion of supercritical solutions. Hybrid NPs are synthesized from both organic and inorganic materials. There are a number of naturally occurring biological NPs including lipoproteins, exosomes, ferritin, and viruses. Further, NPs can be synthesized from biomolecules including proteins, peptides and polysaccharides. The surface to volume ratio, superparamagnetism, hardness, Coulomb energy and catalytic activity of NPs are generally higher than those of bulk materials. Due to their unique structural, magnetic, mechanical and electrical properties, NPs are used in a wide range of applications including biosensing, drug delivery, bioimaging, catalysis, nanomanufacturing, lubrication, electronics, textile manufacturing, and water treatment systems. This chapter covers the classification, synthesis, properties and applications of NPs.

11.1 Overview

Nanoparticles (NPs) are solid colloidal particles with dimensions in the range of a few nanometers to a few hundred nanometers [11.1]. Due to their small size, NPs have significantly higher surface to volume ratios, hence different physicochemical properties compared with bulk materials. NPs have applications in a wide range of areas including [11.2]:

- Biosensing
- Drug delivery
- Bioimaging
- Catalysis
- Nanomanufacturing
- Lubrication
- Electronics
- Textile industry
- Water treatment.

In the first part of this chapter, various methods for the synthesis of inorganic, organic, hybrid, and biological NPs are described. The properties of NPs including size and morphology as well as their unique magnetic, mechanical and electrical properties are discussed next. The major applications of NPs are discussed in the last part of this chapter.

11.2 NPs Classification and Synthesis

11.2.1 NPs Classification

Multiple approaches are used to classify nanoparticles into the following: two-dimensional (e.g., nanotubes) and three-dimensional (e.g., spherical NPs, dendrimers). NPs can be synthesized from several classes of materials including inorganic (e.g., metal oxide NPs), organic (e.g., polymeric NPs), hybrid and biological materials [11.3]. Hybrid NPs are comprised of an inorganic core with organic shell or an organic core with inorganic shell. NP synthesis falls into two major categories namely top-down and bottom-up synthetic approaches. In the top-down approach, NPs are synthesized from bulk materials using traditional solid-state techniques (e.g., milling, machining) or lithographic techniques. In the bottom-up approach, NPs are synthesized from single molecules via chemical reactions, self-assembly, aggregation or chemical vapor deposition [11.1].

11.2.2 NPs Synthesis

Inorganic NPs

Depending on the type of material and the desired NP size, different physical or chemical strategies can be used to synthesize inorganic NPs [11.1]. Here, a number of physical techniques (ball milling, vapor deposition and electrospraying) and chemical methods (reduction of metal salts, sol-gel, coprecipitation and thermal decomposition) are described for the synthesis of inorganic NPs. The microemulsion technique that is extensively used for the synthesis of both organic and inorganic NPs is described in the section on organic NPs.

The ball milling method is a physical top-down synthesis approach based on breaking of solid particulate materials into smaller particles using high-energy balls rotating within a closed chamber [11.1]. Metal and metal oxide NPs have been synthesized using the ball milling method [11.4, 5]. The size and physicochemical characteristics of NPs synthesized via ball milling depend on milling time, rotation speed, ball to powder weight ratio as well as temperature and pressure [11.1]. For example, magnetite (Fe_3O_4) NPs with sizes ranging from 12 to 20 nm were synthesized via ball milling of iron powder in the presence of distilled water [11.5]. The size of Fe_3O_4 NPs decreased and the purity of NPs increased with increasing milling time from 10 to 96 h [11.5].

Vapor deposition is a physical approach for the synthesis of NPs based on vaporization of the material from a solid source using an ion (sputtering), electron (electron beam evaporation) or laser (laser ablation) beam followed by nucleation and growth of the vaporized material on a substrate (Fig. 11.1) [11.1]. Metal and metal oxide NPs have been synthesized via the vapor deposition method. For example, pure metallic (Fe, Ag, Au, Y, Co), nonmetallic (C) and metal oxide (TiO_2) NPs were synthesized via sputtering-based vapor deposition on a direct current (DC) magnetron cathode [11.6]. The size and physicochemical characteristics of NPs synthesized by vapor deposition are affected by [11.6]:

- Target to substrate distance
- Type of substrate
- Substrate temperature
- Deposition time
- Chamber pressure
- Electrical power.

In the laser-based vapor deposition method, the number of pulses, deposition time, gas pressure and substrate temperature significantly affects the size and morphology of NPs [11.7, 8]. For instance, the average size of FeCo NPs synthesized by pulsed laser vapor deposition increased from 4.8 to 8.6 nm as the argon

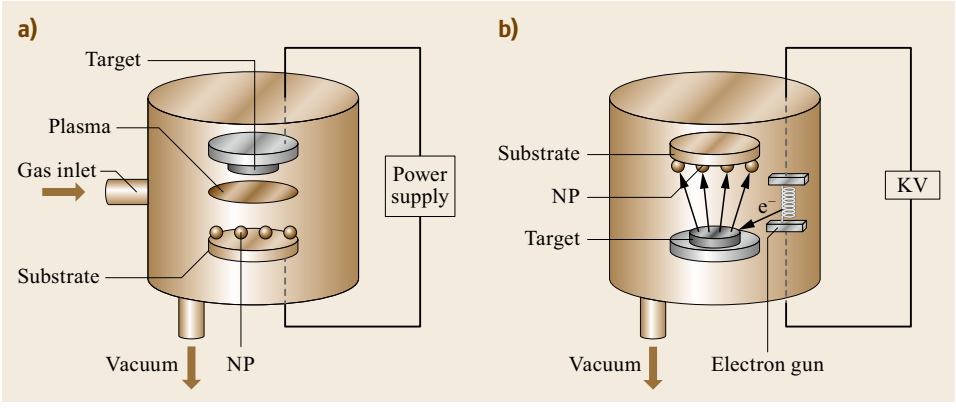

Fig. 11.1a,b Schematic representation of the physical vapor deposition method using **(a)** ion and **(b)** electron beams

gas pressure inside the chamber increased from 10 to 90 kPa [11.7]. Further, agglomeration of the FeCo NPs was reduced by increasing the temperature gradient [11.7].

In the electrospraying method, nanodroplets of a solution of the selected material are sprayed from a syringe to a collector within a high electric field (Fig. 11.2) [11.9]. Metal, metal oxide and polymer NPs have been synthesized via electrospraying [11.9–11]. A number of solvents including toluene, ethanol, methanol and isopropyl alcohol have been used for electrospraying of inorganic NPs [11.1]. For example, Sn NPs with an average size of 3 nm were synthesized by electrospraying a solution of $SnCl_2 \cdot 2H_2O$ in isopropyl alcohol into a reductive bath [11.10]. Monodisperse gold NPs with 5.7 nm diameter were synthesized by electrospraying $HAuCl_4 \cdot H_2O$ solution in isopropanol into a bath containing the reducing agent octadecylaminomethanol and the nonpolar solvent cyclohexane [11.11].

The most common chemical method for the synthesis of metallic NPs is reduction of metal ions in a metal salt solution using a reducing agent. Sodium borohydride ($NaBH_4$) and hydrazine (N_2H_4) are commonly used as reducing agents for the reduction of metal ions [11.12]. For example, the ferric ions in the solution of $FeCl_3 \cdot 6H_2O$ salt were reduced using sodium borohydride to synthesize iron NPs [11.13]. The size and morphology of NPs synthesized by the reduction method depends on temperature and pH of the reaction medium as well as the reactant concentration [11.14, 15].

The sol-gel technique has been used extensively for the synthesis of metal oxide NPs. The sol-gel method, can be divided into three major steps [11.12, 16]. In the first step (sol formation), the metal alkoxide or the metal salt is hydrolyzed in water/ethanol solution to form metal hydroxide (11.1). The metal hydroxide then undergoes condensation to create metal–O–metal bridges (11.2). For example, the hydrolysis and condensation reactions of tetraethylorthosilicate ($Si(OC_2H_5)_4$) in the synthesis of silica NPs are as follows

$$Si(OC_2H_5)_4 + 4(H_2O) \xrightarrow{\text{hydrolysis}} Si(OH)_4 + 4C_2H_5OH \quad (11.1)$$

$$Si(OH)_4 + Si(OH)_4 \xrightarrow{\text{condensation}} (OH)_3Si{-}O{-}Si(OH)_3 + H_2O \quad (11.2)$$

Colloidal particles or sol is formed when sufficient metal–O–metal bridges are created locally. Usually a mineral base (e.g., NH_3) or a mineral acid (e.g., HCl) is used as a catalyst. In the second step, colloidal particles link together with time to create a three-dimensional network at the nanoscale. In the third step, the nanoparticles are dried by heating, freeze drying or supercritical drying [11.16]. After drying and dehydration, NPs are densified by heat treatment at high temperatures [11.16].

Coprecipitation is another approach for the synthesis of inorganic and hybrid NPs [11.12, 17]. In the coprecipitation method, two or more water soluble salts react in aqueous solution to form a water insoluble salt that precipitates and forms NPs [11.12]. For example, hydrated ferrous chloride ($FeCl_2 \cdot 4H_2O$) and ferric chloride ($FeCl_3 \cdot 6H_2O$) undergo oxidative reaction following deprotonation in aqueous solution in the presence of $NH_3 \cdot H_2O$ as the precipitating agent [11.12]. The overall reaction can be written as

$$2Fe^{3+} + Fe^{2+} + 8OH^- \rightarrow Fe_3O_4 + 4H_2O\,. \quad (11.3)$$

When the concentration of Fe_3O_4 product in the solution increases above the solubility limit, the product precipitates by nucleation in the liquid phase. The growth of Fe_3O_4 crystals continues with precipitation reaction on the nucleating surfaces. Finally, the small particles undergo agglomeration via Ostwald ripening and form Fe_3O_4 NPs [11.12].

The thermal decomposition technique is used to synthesize metal oxide NPs from metal salts [11.12, 17]. In this method, a transition metal (e.g., Fe, Zn, Zr, and Co) salt is stabilized in an organic solvent/surfactant solution and mixed with an organic compound to form an organometallic complex. The organometallic complex is decomposed at high temperatures to create metal oxide NPs. A wide range of surfactants including oleylamine [11.18], oleic acid [11.19], benzylamine [11.20], and pentanedione [11.21] have been used to stabilize metal salts in the thermal decomposition process.

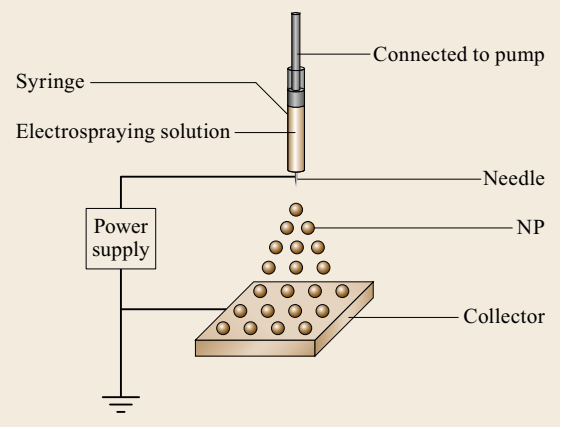

Fig. 11.2 Schematic representation of electrospraying method for the synthesis of NPs

Organic NPs

Several synthetic approaches for the synthesis of organic NPs are used. These include microemulsion, nanoprecipitation, dialysis and rapid expansion of a supercritical solution. The microemulsion method, used extensively for the synthesis of organic NPs, involves two major steps [11.22]. In the first step (emulsification), the organic compound (e.g., the polymer) is dissolved in a selective solvent and the polymer solution (dispersed phase) is emulsified in a second solvent (continuous phase) that is fully or partially immiscible in the dispersed phase solvent (Fig. 11.3). Nanodroplets of the disperse phase with diameters ranging from 10–500 nm are formed in the emulsification step [11.22]. There are two methods for the emulsification of the dispersed phase namely high-energy and low-energy methods. High-energy methods usually involve sonication or high-shear mixing [11.23]. The low-energy methods are divided into two groups: microemulsification based on spontaneous diffusion and microemulsification based on phase inversion stimulated by a change in temperature or composition [11.23, 24]. In the spontaneous emulsification of oil nanodroplets in water, the oily phase is composed of a partially immiscible solvent and a water soluble solvent, usually acetone or ethanol. When the oily and aqueous solutions are mixed, the water soluble solvent rapidly diffuses from the oily phase to the aqueous phase. This rapid diffusion between the two phases produces surface tension gradients that lead to the formation of a microemulsion [11.25].

The phase inversion techniques for microemulsification are classified into two groups: The so-called phase inversion temperature (PIT) method is centered on the hydrophilic-lipophilic transition of polyethylene glycol (PEG)-based surfactants at high temperatures as a result of disruption of the hydrogen bonding [11.24]. As shown in Fig. 11.4, an oil (dispersed phase)/water (continuous phase) emulsion at constant composition inverts to a water/oil emulsion when temperature rises above the inversion temperature [11.26]. The affinity of surfactants for oil and water phase is similar at the inversion temperature leading to a minimal interfacial tension and bicontinuous microemulsion in the transition region. Therefore, kinetically stable nanodroplets can be formed by rapid cooling or dilution of the aforementioned emulsion systems at invasion temperature [11.24] (Fig. 11.4). The second phase inversion technique for microemulsification, the so-called emulsion inversion point (EIP) method, employs emulsion composition change for phase transition. The water/oil emulsion is formed by successive addition of water to an oil solution. The emulsion undergoes phase transition from water/oil to oil/water with increasing volume fraction of water. A bicontinuous microemulsion with minimal interfacial tension and nanosized droplets is formed at the phase inversion point [11.26].

Following emulsification, the NPs are formed in the second step of the microemulsion technique from the emulsified nanodroplets via solvent removal, gelation, or emulsion polymerization (Fig. 11.3a). Different approaches including solvent evaporation and solvent displacement methods have been employed for solvent removal and precipitation of the NPs in

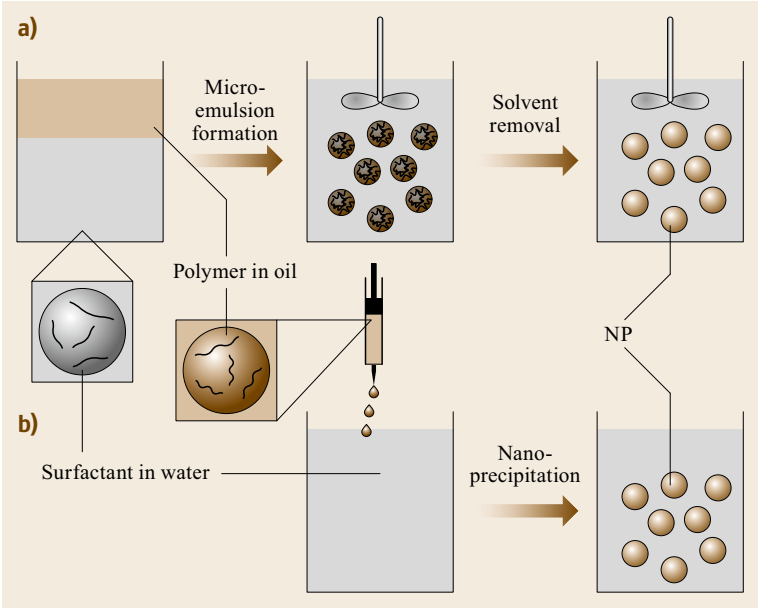

Fig. 11.3a,b Schematic representation of **(a)** microemulsion and **(b)** nanoprecipitation techniques for the synthesis of organic NPs

microemulsion systems [11.24]. In the solvent evaporation method, a volatile solvent (e.g., chloroform or dichloromethane) is used as the solvent in the disperse phase. The volatile solvent is evaporated under vacuum leaving the polymer in the nanodroplets. During solvent evaporation, the size of the nanodroplets initially decreases dramatically due to solvent loss and then increases significantly due to droplet coalescence [11.24]. Organic NPs from numerous polymers and copolymers including poly(lactide) (PLA), poly(lactide-co-glycolide) (PLGA), poly(ε-caprolactone) (PCL), and PEG-co-PLA were synthesized via the solvent evaporation method [11.27–29]. In the solvent displacement method, a solvent with partial miscibility in water is used in the disperse phase. NPs are formed by solvent displacement from the dispersed phase to the continuous aqueous phase upon successive addition of water or dialysis [11.24].

The gelation of macromolecules in the nanodroplets is another approach for the synthesis of NPs in microemulsion systems. Several gelation mechanisms depending on physicochemical properties of the macromolecules within the nanodroplets are employed for NP formation. These include temperature-sensitive physical gelation, pH-sensitive gelation and chemical crosslinking [11.30, 31]. For example, nanogels based on polyethylene glycol (PEG) macromers chain-extended with short lactide (L) and glycolide (G) segments were synthesized via dialysis method and they were used for grafting proteins (Fig. 11.5a) [11.32]. The size of synthesized nanogels ranged from 118 to 190 nm depending on the molecular weight of PEG and L/G molar ratio [11.32]. Further, the rate of BSA protein release from the nanogels was between 51% release after 24 days and complete release in 11 days depending on the molecular weight of PEG and L/G molar ratio (Fig. 11.5b) [11.32].

Polymerization of monomers in nanodroplets is used extensively for the synthesis of NPs from microemulsions. In the first step, nanodroplets of monomers with low water solubility are formed in the aqueous solution containing a surfactant and a water soluble initiator (Fig. 11.6). Free radical or ionic initiators are used depending on the type of polymerization reaction. The collision of initiator molecules and monomer molecules starts the polymerization reaction within the nanodroplets. Solid NPs are formed with the progress of polymerization reaction and increase in the molecular weight of the polymer molecules in the nanodroplets. NPs of different polymers including polystyrene (PS), poly(methyl methacrylate) (PMMA) and poly(vinylcarbazole) were synthesized using emulsion polymerization [11.2, 33, 34]. Further, surfactant-free emulsion polymerization has been employed for the synthesis of NPs based on acrylic or vinyl monomers [11.24]. For example, PMMA, PS and poly(vinyl acetate) (PVA)-based NPs with diameter ranging from 155 to 345 nm were synthesized using surfactant-free emulsion polymerization and sodium persulfate as the initiator [11.35]. The surfactant removal, an indisputable step in conventional emulsion polymerization, is absent in the surfactant-free emulsion polymerization technique, which is a significant advantage in large-scale manufacturing of organic NPs.

In addition to the conventional and surfactant-free emulsion polymerization, interfacial polymerization has been used for the synthesis of polymeric nanocap-

sules (Fig. 11.6) [11.36]. In interfacial polymerization, a monomer is dissolved in the emulsified nanodroplets and a second monomer (comonomer) is dissolved in the continuous phase. The two monomers undergo polymerization at the oil/water interface on the surface of the nanodroplets to form nanocapsules [11.36]. For example, poly(alkylcyanoacrylate)-based nanocapsules are synthesized using the interfacial polymerization method [11.37]. The alkylcyanoacrylate monomer dissolved in the oil nanodroplets reacts with hydroxyl ions in water and undergo interfacial polymerization at the oil/water interface [11.37]. Polybutylcyanoacrylate nanocapsules prepared via the method of interfacial polymerization had diameters of less than 150 nm, and the nanocapsules were used for encapsulation of the D-cycloserine drug [11.38]. Poly(ethyl 2-cyanoacrylate) nanocapsules synthesized using interfacial polymerization had ≈ 150 nm size and the nanocapsules were used for encapsulation of insulin [11.39]. Nanocapsules encapsulating hydrophilic drugs were synthesized by inverse emulsion (water/oil) using a thiol-isocyanate interfacial polymerization [11.40].

Conventional radical polymerization suffers from poor control over the molecular weight and polydispersity of the polymer chains which significantly influences the uniformity of polymeric NPs synthesized using radical polymerization [11.36]. Therefore, living radical polymerization has recently been employed to synthesize NPs with narrow size distributions [11.41]. For example, styrene monomer underwent reversible addition and fragmentation transfer (RAFT) polymerization in poly(*N*-isopropylacrylamide-*b*-dimethylacrylamide) based emulsions to form polystyrene NPs [11.42]. The resulting polystyrene NPs had 38–110 nm diameter and < 0.13 polydispersity index (derived from the standard deviation

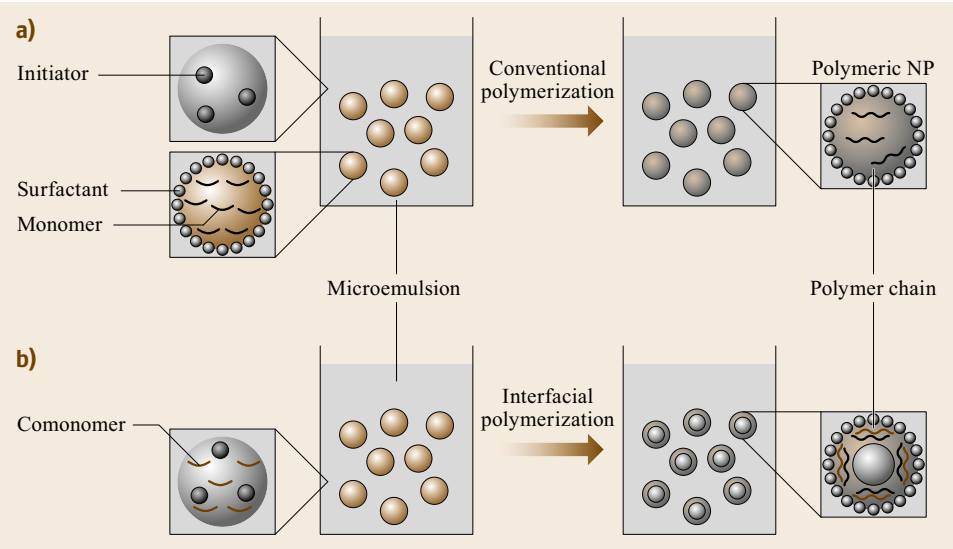

Fig. 11.6a,b Schematic representation of **(a)** conventional and **(b)** interfacial microemulsion polymerization

of the hypothetical Gaussian distribution) [11.42]. Nitroxide mediated polymerization (NMP), a well-known living polymerization technique, was employed to synthesize polystyrene, poly(*n*-butyl acrylate) or poly(methyl methacrylate) NPs with narrow size distributions [11.43–45]. Further, NPs based on poly(methyl methacrylate), poly(*n*-butyl methacrylate) and poly(ethylene oxide) were synthesized using the method of atom transfer radical polymerization (ATRP) [11.46–48].

In the nanoprecipitation method, the polymer is first dissolved in a water-miscible organic solvent. The polymer solution is then injected into a stirred aqueous solution containing a stabilizer (Fig. 11.3b). The spontaneous nanodrop formation followed by rapid diffusion of the organic solvent to the aqueous phase leads to polymer precipitation at the nanoscale and the formation of NPs stabilized by the stabilizer [11.36] (Fig. 11.3b). After NP formation, the organic solvent is removed by evaporation and the NPs are collected via centrifugation. The organic solvent in the nanoprecipitation technique should dissolve the polymer, be soluble in water, and have a low boiling point to facilitate its removal by evaporation. To satisfy the aforementioned criteria, acetone and tetrahydrofuran (THF) are widely used as solvents for nanoprecipitation [11.49, 50]. NPs of different polymers including PLA [11.50, 51], PLGA [11.49, 52], PCL [11.53, 54] and gelatin [11.55] were synthesized using the nanoprecipitation technique.

The dialysis method for the synthesis of NPs is based on solvent displacement similar to the nanoprecipitation method with the difference that there is a membrane barrier between the two phases in the dialysis method. In a typical procedure for the dialysis method, the polymer is dissolved in a water-miscible organic solvent, the organic solution is placed in a dialysis tube and dialyzed against distilled water [11.32]. The molecular weight cut off of the dialysis tube is usually smaller than the molecular weight of the polymer molecules but significantly larger than the solvents molecular weight. Therefore, the solvent diffuses out and water diffuses inside the dialysis tube while polymer molecules stay in the tube during dialysis. The solvent quality for the polymer in the dialysis tube decreases with time which causes polymer aggregation and precipitation at the nanoscale [11.24]. The formed NPs are stabilized by either a stabilizer or a hydrophilic block on the polymer molecule.

In the method of rapid expansion of a supercritical solution, the polymer is dissolved in a supercritical fluid (e.g., carbon dioxide) at high pressure and then the solution is expanded through an orifice or a nozzle into ambient air or a liquid. NPs are formed in the expansion jet due to a rapid pressure reduction [11.36]. The expansion of the supercritical solution into a liquid leads to the formation of uniform nanosized particles as opposed to expansion into air wherein both nanosized and microsized particles form [11.36]. For example, tetrahydrocurcumin (THC) loaded PLA NPs with 80–110 nm size and spherical morphology were synthesized by rapid expansion of supercritical solution of PLA and THC into water [11.56]. Further, NPs made of pure hydrophobic drugs including Naproxen and Ibuprofen have been synthesized using the rapid expansion of the supercritical solution technique [11.57, 58].

Organic–Inorganic Hybrid NPs

Hybrid NPs are composed of both organic and inorganic materials. The inorganic part may form the core or the shell of the hybrid NPs. Here, the methods for synthesis of hybrid NPs with inorganic core are discussed first followed by the discussion for the synthesis of hybrid NPs with organic core.

Hybrid NPs with Inorganic Core. Polymers can be grafted to the surface of inorganic NPs through covalent or noncovalent bonds (Fig. 11.7). Non-covalent attachment usually employs the electrostatic interaction between a charged polymer and an oppositely charged inorganic NP (Fig. 11.7a) [11.59]. For example, positively charged poly(allylamine hydrochloride) polymer was deposited on the negatively charged citrate-coated gold NPs using a layer-by-layer approach [11.60]. In another example, positively charged Fe_3O_4 NPs with 5 nm diameter were coated with negatively charged poly(acrylic acid)-*b*-poly(ethylene oxide) polymer. The coated NPs interacted with oppositely charged pristine NPs and formed aggregates with hydrodynamic diameter ranging from 50 to 100 nm [11.61].

The functional groups present on the surface of inorganic NPs (e.g., hydroxyl groups on the surface of metal oxide NPs) can be used to conjugate polymer chains to NPs (Fig. 11.7b) [11.62]. For example, polymethacrylic acid (PMAA) was conjugated to the surface of ZnO NPs through the reaction of −OH groups on the NP surface with carboxyl groups of PMAA [11.63]. In order to improve dispersion properties of silica NPs, poly(ethylene glycol) methacrylate (PEGMA) or poly(propylene glycol) methacrylate (PPGMA) were conjugated on the surface of vinyl-functionalized silica NPs via UV photo-polymerization [11.63]. Polystyrene was conjugated to TiO_2 NPs via a three-step process [11.64]. First, the surface of TiO_2 NPs was functionalized with phosphonic acid. Next, the surface of phosphonic acid modified NPs was functionalized with azide groups. Then, polystyrene was conjugated to azide functionalized NPs via the click reaction [11.64]. In another study, amine-terminated silica-coated Fe_3O_4 NPs were synthesized via sol-gel method and functionalized with alkyne groups using Michael addition of propargyl acrylate [11.65]. Then, poly(ester amine) was grafted to the alkyne-functionalized NPs using the click reaction [11.65].

In addition to grafting of preformed polymers to inorganic NPs, in situ polymerization of monomers on the surface of NPs (grafting from the surface) has been used extensively for the synthesis of organic–inorganic hybrid NPs (Fig. 11.7c) [11.66]. For example, densely grafted polystyrene and PMMA chains were grown on the surface of silica NPs by incorporation of atom transfer radical polymerization (ATRP) initiator on the surface of NPs [11.67]. A technique similar to ATRP was

recently applied for the synthesis of PMMA-Al_2O_3 hybrid NPs [11.68]. In an attempt to synthesize thermoresponsive NPs, poly(*N*-isopropylacrylamide) (PNIPAm) chains were grown on the surface of Fe_3O_4 NPs using surface-initiated reversible addition-fragmentation transfer (RAFT) reaction [11.69]. The hydrodynamic diameter of the thermoresponsive hybrid NPs decreased from 37 to 24 nm when temperature increased from 28 to 36 °C [11.69]. PMMA-Fe_3O_4 hybrid NPs were synthesized using a thiol-lactam initiated radical polymerization technique [11.66].

Hybrid NPs can also be synthesized via emulsion polymerization of monomers in the presence of inorganic NPs (Fig. 11.7d). The surface of inorganic NPs is typically modified to increase compatibility with the polymer matrix [11.70]. For example, silica NPs with 20 or 78 nm diameter and hydrophobically-modified with γ-methacryloxypropyl trimethoxysilane (γ-MPS) were encapsulated in poly(methyl methacrylate-co-butyl acrylate) polymer NPs via emulsion polymerization [11.71]. Untreated silica NPs aggregated in the miniemulsion system and did not uniformly distribute in the poly(methyl methacrylate-co-butyl acrylate) NPs [11.71]. Polystyrene-silica hybrid NPs were synthesized via a miniemulsion polymerization technique using octaphenyl polyoxyethylene as a surfactant [11.72]. The hybrid polystyrene-silica NPs had a raspberry-like morphology with 130–370 nm diameter and 17–31% inorganic silica content [11.72]. Hybrid NPs with an inorganic TiO_2 core and organic polyacrylic shell were synthesized via emulsion polymerization of methyl methacrylate-butyl acrylate (inner shell) and dimethylaminoethyl methacrylate-butyl acrylate-acrylic acid (outer shell) in the presence of TiO_2 NPs modified with glycidyl methacrylate [11.73]. The TiO_2-polyacrylic hybrid NPs had 85–125 nm diameter [11.73]. Polystyrene nodules were formed on the surface of silica NPs via emulsion polymerization of styrene in the presence of silica NPs modified with an oxyethylene-based macromonomer [11.74]. The morphology of silica-polystyrene hybrid NPs depended on the ratio between silica seeds and growing polystyrene nodules and changed from snowman-like to daisy-like and raspberry-like morphology when increasing the ratio [11.74].

Hybrid NPs with Organic Core. Preformed inorganic NPs can be positioned on the surface of organic NPs using surface treatment followed by aggregation of inorganic–organic NPs (hetero-coagulation) (Fig. 11.8a) [11.70]. For example, negatively charged inorganic gold or silica NPs were deposited on the surface of polystyrene NPs functionalized with positively charged amine groups [11.75]. The position of inorganic NPs within the polymeric NPs can be adjusted by proper surface treatment. For example, gold NPs modified with mercaptoundecanol and dodecanethiol ligands were positioned in the shell of polystyrene-*b*-poly(acrylic acid) NPs whereas gold NPs modified with only hydrophobic dodecanethiol were distributed

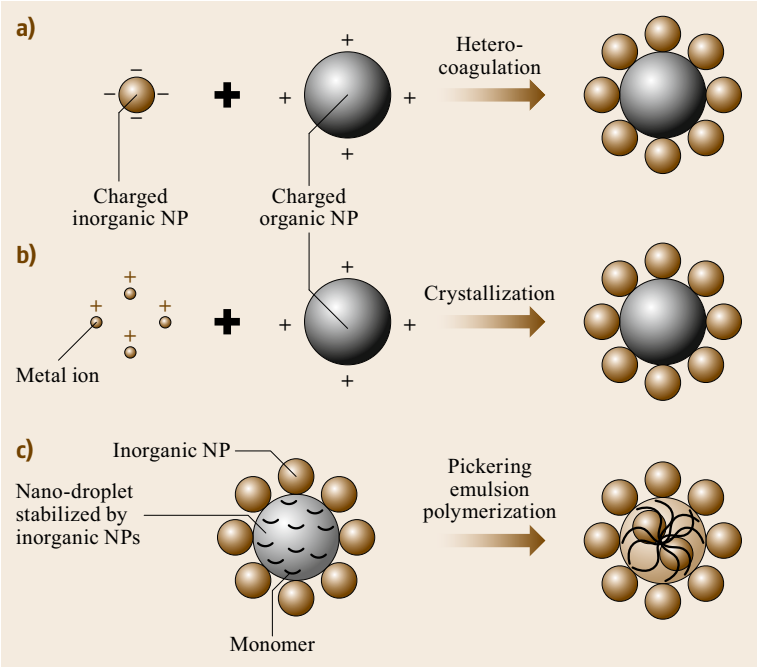

Fig. 11.8a–c Schematic representation of methods for the synthesis of hybrid NPs with organic core. **(a)** Hetero-coagulation of preformed inorganic and organic NPs. **(b)** Crystallization of inorganic NPs on the surface of organic NPs. **(c)** Pickering emulsion polymerization of monomers in the nanodroplets stabilized by inorganic NPs

in the core of the block-copolymer NPs [11.76]. Further, inorganic NPs can be covalently attached to the surface of organic NPs by conjugation. For instance, in an attempt to prepare fluorescent thermosensitive hybrid NPs, organic PNIPAM NPs were covered with inorganic CdTe nanocrystals via an amide coupling agent [11.77]. The photoluminescence (PL) intensity of the hybrid PNIPAM-CdTe NPs was temperature dependent [11.77].

Another approach for the synthesis of hybrid NPs is crystallization of inorganic materials on the surface of polymeric NPs (Fig. 11.8b) [11.70]. In this approach, the surface of polymeric particles should be charged to induce nucleation of the inorganic metals or metal oxides on the polymeric surface.

Several techniques including noncovalent assembly of a polyelectrolyte, covalent conjugation of a polyelectrolyte, and incorporation of a functional comonomer have been used to modify the surface of organic NPs for the synthesis of hybrid NPs [11.70]. For example, gold and platinum NPs (2−3 nm) were formed on the surface of polystyrene NPs (≈ 100 nm) covered with cationic 2-aminoethylmethacrylate polyelectrolytes [11.78]. In another example, styrene and a surface active comonomer (surfmer) with negatively charged phosphate groups underwent miniemulsion polymerization to form polystyrene NPs [11.79]. Negatively charged polystyrene NPs were then used for controlled crystallization of cerium, iron, and zinc oxide nanocrystals in aqueous or alcohol medium [11.79]. In addition, poly(styrene-co-acrylic acid) NPs surface-functionalized with negatively charged carboxyl groups were prepared via the miniemulsion technique and then covered with inorganic hydroxyapatite nanocrystals [11.80]. Calcium phosphate (CaP) NPs were deposited on the surface of PLA and PLGA nanofibers functionalized with negatively charged Glu-Glu-Gly-Gly-Cys peptide in a modified simulated body fluid (mSBF) (Fig. 11.9) [11.81, 82]. The deposition of CaP NPs increased and the size of NPs decreased when a carboxylate-rich organic acid such as citric acid, hydroxycitric acid, tartaric acid, malic acid, ascorbic acid, or salicylic acid was added to mSBF [11.81].

Hybrid NPs can also be synthesized via particle-stabilized emulsion polymerization (Pickering emulsion polymerization) technique (Fig. 11.8c). In Pickering emulsion polymerization, the surfactants are replaced with particle stabilizers [11.83]. Inorganic NPs used in the Pickering emulsion polymerization need to be wettable by both phases in the emulsion, be dispersible in the continuous phase and be able to accumulate at the interface of two phases [11.83]. The most widely used inorganic NPs as Pickering stabilizers are silica NPs [11.83]. For example, hybrid

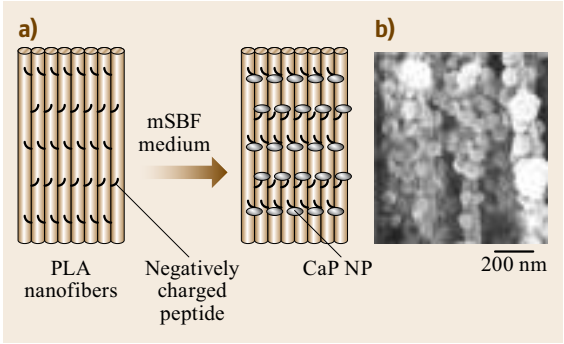

Fig. 11.9 **(a)** Schematic representation of the synthesis of CaP NPs on the surface of peptide functionalized PLA nanofibers. **(b)** SEM image of CaP NPs crystallized on the surface of peptide functionalized PLA nanofibers. Reproduced with permission from [11.81]

NPs were synthesized via Pickering emulsion polymerization of styrene, methyl methacrylate, *n*-butyl acrylate, or *n*-butyl methacrylate as a monomer and 4-vinylpyridine as a comonomer in the presence of silica NPs [11.84]. It was shown that a strong acid-base interaction between the copolymer and silica NPs is essential for the formation of hybrid NPs and hybrid NPs did not form in the absence of 4-vinylpyridine comonomer [11.84]. Silica-polystyrene hybrid NPs were synthesized via Pickering emulsion polymerization of styrene using a cationic azobisisobutyronitrile initiator (AIBN), glycerol functionalized silica and without using any comonomer [11.85]. The hybrid NPs had 200−400 nm diameter and 22−28 wt% silica [11.85]. In addition to silica, zinc oxide, titania, magnetite and graphene oxide NPs have been used as inorganic Pickering stabilizers in the synthesis of hybrid NPs [11.83]. For instance, ZnO-polystyrene hybrid NPs were prepared via emulsion polymerization of styrene in the presence of ZnO particles using AIBN as the initiator. The polystyrene formed the core while ZnO particles were positioned in the shell of the hybrid NPs [11.86].

Biological NPs

Biological NPs can be classified into two categories: Those that are naturally formed in biological systems from organic or inorganic materials (naturally occurring NPs) and those that are synthesized from biomolecules (e.g., proteins, peptides and polysaccharides).

Naturally Occurring NPs. Naturally occurring NPs are assembled in biological systems and include extracellular NPs (e.g., lipoproteins and viruses) and intracellular NPs (e.g., ferritin). Lipoproteins are self-assembled naturally occurring NPs made of lipids

and specialized proteins. Lipoproteins have a micellar structure with a core composed of triglycerides and cholesterol esters and a shell of phospholipids and amphipathic proteins [11.87, 88]. Lipoproteins are synthesized mainly by the liver and intestines and can be separated from plasma via ultracentrifugation [11.87, 88]. There are several classes of lipoproteins depending on size and density. The size of lipoproteins increases from 7−13 nm for high density lipoprotein (HDL) to 22−27 nm for low density lipoprotein (LDL), 27−30 nm for intermediate density lipoprotein (IDL), 35−80 nm for very low density lipoprotein (VLDL) and 80−1200 nm for chylomicrons [11.88]. Hydrophobic core of the lipoproteins can be loaded with water insoluble drugs for therapeutic applications. For example, valrubicin, an anticancer drug, was encapsulated in spherical HDL NPs [11.89]. The toxicity of valrubicin drug against ovarian and prostate cancer cell lines increased while its toxicity against normal prostate and ovarian epithelial cell lines decreased when the drug was encapsulated in HDL NPs compared with the drug alone [11.89].

Exosomes are 30−120 nm vesicles released by B cells, dendritic cells, mast cells, mesenchymal stem cells, adipocytes, neurons, endothelial cells and cancer cells in vivo [11.87, 90]. Further, exosomes are secreted by most cells in vitro [11.87]. In addition, exosomes can be isolated from extracellular fluids including blood, urine, saliva, and amniotic fluid [11.90]. The outer surface of exosomes is a lipid bilayer made of cholesterol, sphingolipids, ceramide and phosphoglycerides with saturated fatty-acyl chains [11.87]. The functions of exosomes in vivo include encapsulation and removal of excess membrane proteins and nucleotides from cells, encapsulation and delivery of signaling proteins and regulation of immune response through antigen presentation [11.91–93]. Proteins and nucleotides encapsulated in exosomes are protected from degradation and endocytosis by macrophages hence having a long circulation time [11.87]. Therefore, exosomes have been studied for the delivery of proteins and RNA in cancer treatment and tissue regeneration [11.90, 94].

Ferritin is an intracellular hollow nanoparticle with an outer diameter of 12 nm and interior cavity diameter of 8 nm [11.87]. Ferritin protein shell is composed of 24 subunits made up of the heavy-chain ferritin and the light-chain ferritin [11.87]. The interior cavity is naturally used to store iron oxides and to sequester the undesirable effects of iron ions. Ferritin NPs have been used as nanoreactors to synthesize ferrimagnetic iron oxide NPs in a constrained volume [11.95]. After the formation of inorganic core in the ferritin cavity, the protein shell can be removed to separate the inorganic NPs. In addition to iron oxide, inorganic cobalt oxide, chromium oxide and nickel hydroxide NPs have been synthesized in the cavity of ferritin NPs [11.96]. Further, semiconductor NPs including CdSe, ZnSe, CdS and ZnS NPs have been synthesized using ferritin [11.96]. It is shown that ferritin-iron oxide hybrid NPs bind to tumor cells that overexpress transferrin receptor 1 (TfR1) and undergo a color reaction that can be used to visualize tumor tissues [11.97].

Viruses are naturally occurring NPs (20−300 nm) with capsid proteins forming the shell and viral DNA or RNA forming the core [11.87]. Viruses have a wide range of sizes and morphologies including spherical, rod-shape, and icosahedral morphologies [11.87]. Virus-like particles with a native protein shell but without nucleic acid do not cause infection and can be used as carriers for drugs or proteins. Further, bioactive ligands can be conjugated to lysine or cysteine residues on the capsid protein [11.98]. For example, cell penetrating peptides conjugated to Cowpea mosaic virus (CPMV) increased the uptake efficiency of the virus by human cervical cancer cells [11.99]. In another example, conjugation of nucleoprotein of influenza to Bacteriophage P22 virus-like particles resulted in a vaccine that induced a protective $CD8^+$ T cell response against lethal doses of influenza while the virus-like particles alone did not provide immunity [11.100].

Protein NPs. Several techniques including desolvation, emulsion–solvent extraction and polyelectrolyte complexation have been employed for the synthesis of NPs from proteins [11.101]. The desolvation method is based on drop-wise addition of a desolvation agent such as alcohols, salts or other solvents to a protein solution with stirring to trigger precipitation of protein NPs [11.102]. Since the solubility and conformation of proteins in aqueous solution depends on pH, solvent polarity, and ionic strength of the solution, a change in these factors leads to conformational changes and nanoprecipitation of proteins [11.101]. The precipitation step is often followed by crosslinking of NPs with glutaraldehyde in order to stabilize the particles [11.102]. NPs of different proteins including albumin, gelatin and elastin have been synthesized via the desolvation method [11.101]. For example, human serum albumin (HSA) NPs were prepared via the slow addition of ethanol to HSA solution at room temperature followed by glutaraldehyde crosslinking [11.103]. The size of HSA NPs varied between 200−300 nm depending on pH of the desolvation solution [11.103]. The size of the albumin NPs prepared via desolvation decreased with increasing pH and increasing the ratio of antisolvent (e.g., ethanol) to solvent [11.101, 103]. Bovine serum albumin (BSA) NPs synthesized via desolvation and surface modified with cationic polyethylenimine were

employed for the encapsulation of bone morphogenic protein-2 (BMP-2) protein [11.104]. The NPs exhibited a sustained release of BMP-2 over 10 days and high retention of protein activity in vitro [11.104]. In another example, gelatin NPs were synthesized by slow addition of ethanol to the aqueous solution of gelatin with 65 : 35 ethanol/water ratio at 37 °C and pH = 7.0 followed by particle crosslinking with glyoxal [11.105]. The gelatin NPs had a 17 h half-life and 30 h mean residence time in the plasma of Lewis lung carcinoma-bearing mice [11.105].

The emulsion–solvent extraction method for the synthesis of protein NPs is based on emulsification of the aqueous solution of the protein in oil using a high-speed homogenizer or a sonicator in the presence of a surfactant such as phosphatidylcholine or Span 80 [11.101]. The oil phase is then removed using an organic solvent and NPs are separated via centrifugation [11.101]. NPs can be stabilized using a physical or chemical crosslinking technique. For example, NPs based on casein, a milk protein, were synthesized via oil-in-water emulsification in the presence of Span 80 [11.106]. Casein NPs were stabilized via ionic crosslinking using a polyanionic crosslinker sodium tripolyphosphate [11.106]. Casein NPs had 60−100 nm diameter and exhibited a sustained release of anticancer drug flutamide for four days in vitro [11.106]. NPs based on albumin protein were also synthesized using the emulsion–solvent extraction method [11.101, 107].

Polyelectrolyte complexation is typically used for the synthesis of DNA-laden protein NPs [11.101]. In this method, proteins are first charged cationic by adjusting the pH to below their isoelectric point (pI) (Fig. 11.10). Cationic proteins then form a polyelectrolyte complex with negatively charged DNA that undergo desolvation to form DNA-laden NPs [11.101]. For example, HSA-DNA-polyethylenimine (PEI) NPs were synthesized in a two-step process [11.108]. First, a solution of PEI and positively charged HSA was prepared at pH 4.1. Then, NPs were formed by adding sodium sulfate solution containing DNA to the HSA-PEI solution [11.108]. Positively charged poly(lysine) and chitosan were also used for the synthesis of NPs via the polyelectrolyte complexation method [11.24].

Peptide NPs. Several classes of peptides including surfactant-like peptides and polypeptides have been used for the synthesis of NPs [11.109, 110]. The surfactant-like peptides have a hydrophilic head and a hydrophobic tail similar to an organic surfactant. The peptides self-assemble in aqueous solution to form micelles with different morphologies including nanotubes, nanovesicles and nanofibers [11.111]. For instance, surfactant-like peptides with a tail of six hydrophobic amino acids and a head of two positively charged amino acids (e.g., V_6K_2, V=Valine, K=Lysine) self-assembled to nanotubes and spherical nanovesicles in aqueous solution [11.112]. The V_6K_2 peptide conjugated to a low molecular weight PLA molecule (PLA-V6K2) was self-assembled to spherical NPs with an average size of 100 nm (Fig. 11.11a) [11.113]. The PLA-V6K2 NPs had sustained release of an anticancer drug Doxorubicin (Dox) over 35 days (Fig. 11.11b) [11.113]. Further, 49% of the PLA-V6K2 NPs were taken up by 4T1 mouse breast carcinoma cells after 24 h (Fig. 11.11c) [11.113]. The release rate of Dox was slower and the percent uptake by 4T1 cells was higher for PLA-V6K2 NPs compared with PEG stabilized PLA (PLA-EG) NPs (Fig. 11.11b,c) [11.113].

When the hydrophobic tail of a surfactant-like peptide is an alkyl chain, the structure is called peptide amphiphile (PA). It is shown that PAs spontaneously self-assemble into a range of nanostructures including nanofibers, spherical micelles, nanovesicles and nanotubes [11.114, 115]. For example, a PA with the structure of C_{16}-KKFFVLK (F= Phenylalanine, L= Leucine) self-assembled into nanotubes and helical ribbons at room temperature [11.116].

A number of polypeptides have been used for synthesis of NPs [11.117]. For example, an elastin-like polypeptide (ELP) with a repeating unit of VPAVG (P=Proline, A=Alanine, G=Glycine) self-assembled to NPs when the temperature of polypeptide aqueous solution was raised from 4 to 37 °C [11.118]. The elastin-like polypeptide NPs exhibited a sustained release of encapsulated dexamethasone phosphate for 30 days in vitro at 37 °C [11.118]. In a recent example, NPs with 600 nm diameter were synthesized from an ELP conjugated to stromal cell-derived growth factor-1 (SDF1) for wound healing applications [11.119]. The wounds of diabetic mice treated with ELP-SDF1 NPs were closed after 28 days while those wounds treated with SDF1 alone were closed after 42 days [11.119]. pH sensitive polypeptide nanovesicles were synthesized from zwitterionic diblock poly(L-glutamic acid)-*b*-poly(L-lysine) copolymers. The hydrodynamic radius of the nanovesicles was 110 and 175 nm in acidic (pH < 4) and basic (pH > 10) aqueous solutions while the polypeptides did not self-assemble to nanovesicles at intermediate pH values (5 < pH < 9) [11.120].

Polysaccharide NPs. Polysaccharides are naturally derived polymers with monosaccharide repeat units joined together by glycosidic bonds [11.110]. Positively charged chitosan and negatively charged alginate, heparin, hyaluronic acid, dextran sulfate and der-

matan sulfate are the most widely used polysaccharides for synthesis of NPs [11.110]. Different approaches including polyelectrolyte complexation, crosslinking, and self-assembly have been employed for the synthesis of polysaccharide NPs [11.110]. For example, chitosan-alginate NPs were prepared by polyelectrolyte complexation between cationic chitosan and anionic alginate pregel particles [11.121]. Polysaccharide NPs prepared by polyelectrolyte complexation between dermatan and chitosan had 730 nm radius and were selectively taken up by H5V murine endothelial cells in the presence of Raw 264.7 murine macrophage cells [11.122]. Chitosan NPs (250 nm diameter) synthesized via water-in-oil emulsion method, stabilized by glutaraldehyde crosslinking, and coated with anionic polysaccharides were used for encapsulation of the anticancer drug 5-fluorouracil (5-FU) [11.123]. Self-assembling amphiphilic polysaccharides generated by hydrophobic modification of polysaccharides' backbone have also been used for the synthesis of NPs and micelles [11.110]. For instance, hydrophobically modified chitosan prepared via grafting *N*-acyl groups to the backbone of chitosan self-assembled to NPs with < 550 nm diameter at 38 °C and pH 7.4 [11.124]. In another example, polyglycolic acid (PGA) conjugated alginate self-assembled to NPs with 200–250 nm diameter through hydrophobic interactions between the PGA segments [11.125].

11.3 Properties of NPs

11.3.1 Size of NPs

A change in NP size significantly affects the surface area as well as mechanical, magnetic, electrical and biological properties of NPs. The surface to volume ratio increases when the particle size decreases. Therefore, the fraction of surface atoms or functional groups increases with decreasing the NP size. For example, the chemical reactivity of silica NPs increases with decreasing the particle size due to an increase in the density of silanol groups (Si–OH) on the NPs surface [11.126]. The superparamagnetism of magnetic NPs increases as the size decreases [11.127]. The elastic modulus and hardness of crystalline metal NPs is inversely correlated with particle size [11.95]. The capacitance of conductive NPs decreases and Coulomb energy increases with reducing the NP size [11.128]. Anticancer drug-loaded NPs with diameters < 100 nm can pass through the leaky vasculature of the tumor tissues [11.129]. The size of NPs can be controlled by adjusting the synthesis parameters including reactant–surfactant concentration, temperature and pH of the medium [11.12].

In the ball milling method, the size of synthesized NPs depends on milling time, rotation speed, ball-to-powder weight ratio as well as temperature and pressure [11.1]. The size of NPs synthesized via the vapor deposition method depends on target to substrate distance, type of substrate, substrate temperature, deposition time, chamber pressure and the electrical power for deposition [11.6]. In the laser-based vapor deposition method, number of pulses, deposition time, gas pressure and substrate temperature significantly affects the size and morphology of NPs [11.7, 8] The size of NPs synthesized via reduction and precipitation methods can be controlled by changing pH of the synthesis medium. The adsorption of proton or hydroxide ions on the surface of growing particles decreases the surface energy of growing NPs, hence increases the stability of small particles [11.130]. Therefore, adjusting pH of the synthesis medium to values that increase the surface charge density of growing particles decreases the size of NPs [11.130]. For instance, in the synthesis of TiO_2 NPs via precipitation method, the surface charge density increased from 0 to 0.2 and the size of NPs decreased from 9 to 5 nm by decreasing pH of the synthesis medium from 5.3 to 2 [11.14].

In the microemulsion method, NPs of smaller size can be synthesized by reducing water to surfactant ratio. An increase in the water to surfactant ratio, increases the droplet size as well as the aggregation of particles, hence increases size of the synthesized NPs. For example, Pd NPs were synthesized via the microemulsion technique in a water/isooctane medium using sodium bis(2-ethylhexyl) sulfosuccinate as the surfactant and N_2H_4 as the reducing agent [11.131]. The size of Pd NPs after 10 min of reaction increased from 8.1 to 11.7 nm with increasing the water to surfactant ratio from 3 to 7 at reducing agent to metal molar ratio of 60 [11.131]. In another example, a higher concentration of PVA stabilizer in the single-emulsion synthesis of PLGA polymer NPs decreased the size of particles significantly [11.132]. Further, the size of NPs in the microemulsion technique can be reduced by using a more viscous oil phase [11.133]. In addition, high-energy mixing (e.g., sonication) of microemulsion systems decreases the size of synthesized NPs [11.12]. An increase in the concentration of the reactants in the microemulsion technique decreased the size of NPs which was due to a transition from intermicellar nucleation to intramicellar nucleation [11.134, 135].

The size of polymer NPs prepared via dialysis or nanoprecipitation depends on the polymer composition and concentration and the solvent used. The size of nanoprecipitated NPs decreases with increasing solvent–nonsolvent affinity as well as polymer-solvent affinity [11.136]. For example, the size of PLGA NPs decreased with changing the solvent from dimethylacetamide (DMAc) to dimethylsulfoxide (DMSO) and dimethylformamide (DMF) in the dialysis method [11.137]. In another example, the size of poly(lactide-*co*-glycolide fumarate) (PLGF) NPs synthesized by the dialysis method was smaller than poly(lactide fumarate) (PLAF) NPs due to the higher hydrophilicity of the PLGF macromer [11.138].

11.3.2 Shape of NPs

The shape of NPs significantly affects their physicochemical and biological properties. For example, the catalytic activity of Pt NPs is shape dependent [11.139] or the circulation time and cell uptake of drug-loaded NPs varies with the NPs' morphology [11.140]. NPs generally favor a morphology that is associated with minimal surface free energy [11.15]. For amorphous materials with an isotropic surface, a spherical morphology minimizes the surface free energy by lowering the surface to volume ratio [11.15]. In an anisotropic crystalline structure, each crystal plane has a specific surface free energy [11.130]. For example, in noble metals (e.g., Ag, Au and Pt), the surface free energy of (100), (110) and (111) planes is lower than those of high-index crystal planes. Therefore, the standard morphology of NPs made of single crystalline noble metals is a truncated octahedron that is a linear combination of the aforementioned low-index planes [11.15]. However, the shape of crystalline metal or metal oxide NPs synthesized via solution-based methods can be modified by adjusting the nucleation and growth steps. For example, the shape uniformity of NPs increases by increasing the rate of crystal nucleation in the salt reduction method [11.15]. Further, adsorbates that selectively adsorb to specific crystal planes in the growth step can be employed to control the crystal morphology [11.15]. The crystal growth continues on the plane that has weak interaction with the adsorbate. Surfactants, poly(vinyl pyrrolidone) and metal ions have been used as adsorbates in the synthesis of crystalline NPs [11.15]. For instance, single crystalline Ag NPs with several morphologies including cube, octahedral, truncated cube, truncated octahedra and cuboctahedra were synthesized via reduction of $AgNO_3$ in 1,5-pentanediol in the presence of poly(vinyl pyrrolidone) as an adsorbate at 180 °C [11.141]. The morphology of Ag NPs depended on the rate of injection of $AgNO_3$ solution in the reducing solvent [11.141]. The morphology of inorganic NPs can also be controlled by adjusting the reaction parameters such as temperature, pH and relative concentration of metal ions. For example, manganese dioxide (MnO_2) NPs with a number of morphologies including needle-like, lamellar and spherical were synthesized by varying the Mn(VII) to Mn(II) ratio and pH of the reducing medium [11.130].

Due to the semicrystalline nature of polymers, the favorable morphology of polymeric NPs is spherical [11.142]. Polymeric NPs with nonspherical morphologies have been synthesized via top-down and bottom-up approaches. For example, several morphologies of polystyrene NPs including ellipsoids, rods and disks were synthesized by embedding the spherical polystyrene NPs in a poly(vinyl alcohol) film and stretching the film [11.143]. Further, several morphologies of polyethylene glycol (PEG) based NPs including spheres, cylinders, cubes and disks were synthesized via spraying or drop-casting the polymer precursor solution on a perfluoropolyether nonwetting template [11.144]. Polymer and peptide based NPs with a range of morphologies have been synthesized via the self-assembly method. For example, worm-like micelles were synthesized via self-assembly of poly(ethylene glycol)-poly(ethylethylene) diblock copolymers [11.145]. Surfactant-like peptides with a tail of six hydrophobic amino acids and a head of two positively charged amino acids (e.g., V_6K_2) self-assembled to nanotubes and spherical nanovesicles in aqueous solution [11.112]. Furthermore, it was shown that peptide amphiphiles spontaneously self-assemble into a variety of nano-objects including spherical micelles, nanovesicles and nanotubes [11.114, 115].

11.3.3 Magnetic Properties of NPs

Magnetic NPs have been synthesized with several compositions including iron oxides, pure metals, alloys (e.g., FePt) and spinel-type compounds (e.g., $MnFe_2O_4$ or $CoFe_2O_4$) [11.146]. Further, a number of approaches including coprecipitation, microemulsion, thermal decomposition and hydrothermal synthesis have been applied for the synthesis of magnetic NPs [11.146]. The majority of magnetic NPs are classified into either ferromagnetic or superparamagnetic materials [11.127]. In ferromagnetic materials, atomic magnetic dipoles are aligned and there exists a net magnetic moment in the absence of an external magnetic field. Paramagnetic materials have magnetic dipoles but these dipoles are not aligned and fluctuate randomly, hence the net magnetic moment is zero in the absence of an external magnetic field above a material-specific temperature called the Curie temperature. Ferromagnetic or fer-

rimagnetic NPs with sizes below a material-specific threshold have zero net magnetic moment in the absence of an external field and they become magnetic and their magnetic moment rapidly increases with the application of an external magnetic field (Fig. 11.12). This property of magnetic NPs which is called superparamagnetism occurs at temperatures above a blocking temperature (T_B) wherein thermal fluctuations exceed the energy barrier for random flipping of magnetic moments within NPs [11.127].

The T_B of NPs correlates with particle volume and rapidly increases with particle diameter [11.148]. The maximum on the magnetization curve (Fig. 11.12) is called saturation magnetization (M_s) which happens when all magnetic dipoles are aligned with the external magnetic field [11.127, 147]. The remaining magnetization after the removal of an external magnetic field (the intercept of y-axis and the magnetization curve in Fig. 11.12) is called remanent magnetization (M_r) [11.147]. The strength of an external field required to force the magnetization to zero (the intercept of x-axis and the magnetization curve in Fig. 11.12) is called coercivity (H_c) [11.147]. The M_r and H_c are both zero for paramagnetic and superparamagnetic materials as opposed to ferromagnetic materials (Fig. 11.12) [11.147]. The magnetization of superparamagnetic materials increases rapidly upon applying an external field as opposed to the linear trend of paramagnetic materials (Fig. 11.12) [11.147]. The M_s increases linearly with NP size and reaches a plateau corresponding to the bulk M_s [11.127]. Therefore, smaller NPs have lower M_s but higher superparamagnetism. For example the M_s of $Fe_{2.66}O_4$ NPs decreased from 77 to 29 emu/g and T_B decreased from 100 to 10 K when the NP size was reduced from 14 to 2.5 nm [11.149]. In addition to size, the morphology of NPs affects magnetization. For example, the T_B of Fe_3O_4 NPs decreased when the NPs morphology was changed from spherical to cubic [11.150]. Further, the M_s of Fe_3O_4 NPs increased from 18 to 40 and 80 emu/g when the NPs morphology was changed from rods to cubes and spheres, respectively [11.107]. The composition and method of synthesis of NPs also significantly affects magnetic properties of NPs. For instance, the size at which a transition to superparamagnetism happens decreased when the composition of NPs was changed from Fe_2O_3 to Fe_3O_4 and FePt [11.151]. Alloyed magnetic NPs generally have higher M_s than the corresponding pure metals or iron oxide based NPs [11.127]. In another example, metal-doped NPs with the composition of MFe_2O_4 (M = Mn, Fe, Co or Ni) were synthesized via a nonhydrolytic reaction between iron tris-2,4-pentadionate and divalent metal chloride (MCl_2). The M_s of MFe_2O_4 NPs with the same size of 12 nm varied from 85 to 99, 101 and 110 emu/g by changing the metal (M) from Ni to Co, Fe and Mn, respectively [11.152]. The highest M_s of $MnFe_2O_4$ was related to a mixed spinel structure as opposed to an inverse structure for $NiFe_2O_4$, $CoFe_2O_4$ and $FeFe_2O_4$ NPs [11.152]. Particle coating generally decreases the magnetization of NPs [11.127]. For example, M_s of Fe_3O_4 NPs decreased from 75 to 51 emu/g and coercivity increased from 1.1 to 5 when the NPs were coated with PNIPAM polymer [11.153].

11.3.4 Mechanical Properties of NPs

The mechanical properties of NPs including elastic modulus, hardness, and frication are significantly different from those of bulk materials [11.154]. Results of several studies have shown that the hardness, yield strength, and elastic modulus of crystalline metal NPs are higher than those of bulk metals and inversely correlated with particle size [11.155–158]. For example, the mechanical properties of gold NPs with a sixfold icosahedral symmetry and 22 nm size were measured via the nano-indentation method [11.157]. The hardness and elastic modulus of gold NPs were 1.72 and 100 GPa, respectively, which were significantly higher than the hardness (216 MPa) and elastic modulus (79 GPa) of gold [11.157]. The increase in yield strength or hardness with decreasing size for single crystalline NPs is due to the absence of dislocations in the crystalline structure leading to higher resistance to plastic deformation [11.154]. For polycrystalline NPs, the enhanced mechanical properties are due to an increase in the den-

sity and entanglement of dislocations with decreasing the grain size that limits the motion of dislocations (Hall–Petch effect) [11.159]. However, the hardness and yield strength of crystalline NPs decrease significantly if the NPs are smaller than a critical size due to the inverse Hall–Petch effect [11.154]. In this case, the grain is too small to support a high density of dislocations hence the deformation is dominated by grain boundary sliding [11.154]. For example, the modulus of nanocrystalline titania NPs increased with reducing the particle size down to 15 nm [11.160]. The modulus of titania NPs then decreased with decreasing particle size below 15 nm [11.160]. The mechanical properties of polymeric NPs depend on the glass transition temperature, crystallinity of the polymer as well as the surface properties of NPs [11.161]. For instance, the compressive modulus of surface-charged polystyrene NPs was slightly less than that of bulk polystyrene but the elastic modulus of polypropylene NPs was higher than that of bulk polypropylene [11.162, 163].

The friction coefficient of nano-objects is proportional to the contact area as opposed to the macroscopic dry sliding friction. Results of a number of studies showed that the friction of NPs increases with particle size [11.154, 161]. For example, an increase in the size of gold NPs from 30 to 90 nm, increased the dry friction of particles under 300 nN load by threefold [11.164]. Further, gold nanorods with 50 nm diameter and 200 nm length had a higher friction in air or water than gold NPs with 50 nm diameter [11.154]. The friction force between single polystyrene NPs (30–230 nm) and a silicon substrate was correlated with two thirds power of the particle radius [11.165]. Further, the frication of nano-objects increased logarithmically with the sliding velocity as opposed to the macroscopic frication which was independent of sliding velocity [11.166].

11.3.5 Electrical Properties of NPs

The semicontinuous electronic band structure of bulk metals changes to discrete electronic levels when decreasing the size in the nanoscale. This phenomenon is called the size quantization effect, which is responsible for the unique electrical properties of metallic and semiconductive NPs. A transition from a conductive bulk material to semiconductive NP happens due to the size quantization effect and formation of a band gap if the size of NP is sufficiently low. Metallic NPs with a diameter lower than 2 nm start to undergo transition from conductor to semiconductor [11.167]. Further, the band gap that normally exists in semiconductive materials grows with decreasing size from bulk to NPs. However, the quantization effect in semiconductor materials happens at relatively larger scales (1–10 nm) [11.167]. The electrical current in bulk materials obeys Ohm's law

$$V = IR\,, \tag{11.4}$$

where V is the applied voltage, I is current and R is resistance of the material. Ohm's law is not valid when quantization happens at the nanoscale and the Coulomb energy of NPs exceeds the thermal energy

$$k_{\mathrm{B}}T < \frac{e^2}{2C}\,, \tag{11.5}$$

where k_{B} is the Boltzmann constant, T is temperature, e is elementary charge and C is capacitance. The capacitance of a nanoparticle depends on its size as [11.128]

$$C = 4\pi r\varepsilon\varepsilon_0\,, \tag{11.6}$$

where r is the NP radius, ε and ε_0 are dielectric constant of the medium and vacuum, respectively. Therefore, capacitance decreases and Coulomb energy increases with reducing NPs size. When the NPs are sufficiently small such that Coulomb energy exceeds thermal energy (11.5), charge transfer occurs through the NPs via a single electron tunneling. In this case, the external voltage $\Delta V = e/2C$ is required to transfer a single charge to the NP leading to a tunneling current $\Delta I = e/RC$. Therefore, the current–voltage curve in quantum dots is like a staircase with height of ΔI and width of ΔV, due to tunneling of multiple single electrons [11.128]. For example, Au NPs with 5.8 nm diameter at 77 °K had a staircase current–voltage curve with a width of $\Delta V =$ 200 mV [11.168].

11.4 Applications of NPs

NPs have been used for sensing biological analytes including DNA and proteins as well as small molecules such as glucose [11.11]. In biosensing, specific receptors conjugated to the surface of NPs interact with specific biological analytes and the biological recognition event is translated into detectable optical, magnetic or electrochemical signals [11.169, 170]. The increased sensitivity and lower detection limit of NP-based biosensors compared with macroscale biosensors are due to high surface to volume ratio of NPs resulting in a larger density of biospecific receptors per unit volume of NPs [11.11]. Further, unique magnetic,

optical and electrical properties of NPs contribute to the translation of recognition event to detectable signals [11.11]. For example, Au NPs were used for colorimetric sensing of oligonucleotides [11.169]. Au NPs functionalized with single-stranded DNA aggregated in the presence of oligonucleotides leading to a change in the color of solution [11.169]. In another example, interleukin-6 (IL-6) protein in the unprocessed human sera was detected using IL-6 antibody conjugated magnetic FeCo NPs and a giant magnetoresistive (GMR) sensor functionalized with IL-6 antibody [11.171]. The IL-6 analyte and antibody-conjugated magnetic NPs were captured and formed a sandwich on the surface of the GMR sensor [11.171]. The change in electrical resistance of the GMR sensor was correlated to the amount of captured magnetic FeCo NPs, which was related to the concentration of IL-6 protein [11.171].

One of the major applications of NPs is the localized or targeted delivery of drugs and biomolecules to cells and tissues [11.172]. NPs as delivery vehicles protect drugs or biomolecules from degradation, transport them into the cells or tissues and release them in a sustained manner [11.169]. The uptake efficiency of bioactive molecules by cells is significantly higher for NPs compared with microparticles. For example, PLGA NPs (100 nm) had 15–250-fold higher gastrointestinal tissue uptake in a rat model than microparticles (10 μm) [11.173]. Anticancer-drug-loaded NPs with diameters < 100 nm can pass the leaky vasculature of tumors and enter the interstitial space of tumor tissue [11.129]. Several biodegradable NPs based on PLA, PLGA, PCL and polyacrylate polymers as well as natural alginate, chitosan and gelatin have been synthesized for the delivery of drugs or proteins [11.172]. The drug or protein may be entrapped within the NPs or conjugated on the surface of NPs. Further, targeting antibodies can be attached to the surface of NPs for recognition and binding to target cells [11.174]. The release rate of encapsulated drugs or proteins from biodegradable polymer NPs can be tuned from a few days to months by altering the composition or length of the polymer chains [11.172]. For example, anticancer drug Paclitaxel encapsulated in the more hydrophobic NPs based on poly(lactide-fumarate) (PLAF) displayed a sustained release of Paclitaxel over 28 days whereas the less hydrophobic poly(lactide-co-glycolide fumarate) (PLGF) NPs released the encapsulated drug in 15 days [11.175]. The viability of HCT116 human colon carcinoma cells significantly decreased when they were exposed to Paclitaxel encapsulated in PLGF or PLAF NPs compared with the drug alone [11.175]. In a recent example, recombinant human bone morphogenetic protein-2 (BMP2) and vascular endothelial growth factor (VEGF) were grafted to nanogels based on polyethylene glycol (PEG) macromers chain-extended with short lactide and glycolide segments [11.32]. The release rate of BMP2 and VEGF proteins from nanogels depended on PEG molecular weight, lactide/glycolide segment length and lactide–glycolide molar ratio in the polymer [11.32]. Nanogels with 12 kDa PEG molecular weight, 24 lactide-glycolide segment length, and 60 : 40 lactide/glycolide ratio released the grafted VEGF in 10 days and induced vasculogenic differentiation of human endothelial colony-forming cells while nanogels with 8 kDa PEG molecular weight, 26 lactide-glycolide segment length, and 60 : 40 lactide–glycolide ratio released the grafted BMP2 in 21 days and induced osteogenic differentiation of human mesenchymal stem cells [11.32].

Several types of NPs including noble metal NPs, quantum dots, polymer NPs and fluorescently doped silica NPs have been used for imaging of cells and tissues [11.176]. For example, self-illuminating quantum dots were synthesized by conjugation of a modified bioluminescent protein *Renilla reniformis* luciferase to fluorescent semiconductor CdSe/ZnS quantum dots [11.177]. The conjugate emitted long-wavelength bioluminescent light without a need for external excitation of quantum dots [11.177]. Further, magnetic NPs have been used as contrast agents in magnetic resonance imaging (MRI) [11.178]. MRI signal intensity is related to the spin–lattice relaxation time (T_1) and spin–spin relaxation time (T_2) of water protons [11.178]. When magnetic NPs accumulate in the tissue that is being imaged, they reduce the relaxation time which in turn enhance the image contrast [11.127]. The contrast enhancement is correlated with the M_s of the magnetic NPs [11.127]. For example, Fe_3O_4 NPs shorten the T_2 relaxation time and have been used as a contrast agent in imaging liver, spleen and bone marrow [11.179].

One of the earliest commercial applications of NPs was in catalyzed reactions such as the synthesis of reformulated gasoline and hydrosilylation reactions [11.180]. Metal NPs have been used as catalysts in quasihomogeneous catalyzed reactions including hydrogenation, cross-coupling, oxidation and electron transfer in organic or aqueous solutions [11.180]. For instance, hydrogenation of cyclooctene to cyclooctane was performed via quasihomogeneous catalysis using chitosan-stabilized Pt and Pd NPs (1.9–2.2 nm in size) as catalysts in acetic acid/methanol solution [11.181]. Further, metal NPs deposited on carbon, silica, and metal oxide supports have been used as catalysts in heterogeneous catalysis [11.180]. Several techniques including physical adsorption, grafting, flame spraying, ion exchange and the Langmuir–Blodgett method

have been employed for deposition of NPs on supports for heterogeneous catalysis [11.182–184]. The size, shape and composition of NPs significantly affect the catalytic properties of supported metal catalysts [11.180]. For example, Pt NPs of different shapes (cubic and cuboctahedral) deposited on silicon wafer supports via Langmuir–Blodgett technique were used for hydrogenation of benzene [11.183]. Selectivity of the heterogeneously catalyzed reaction depended significantly on the shape of Pt NPs. While cyclohexane and cyclohexene were formed on cuboctahedral NPs, only cyclohexane was formed on cubic NPs [11.183].

Metal, metal oxide, silicon and carbon-based NPs have been used as additives to lubricants in order to reduce the friction and wear between contacting surfaces [11.161]. The reduction of friction and wear in the presence of NPs is related to the rolling of the spherical NPs or sliding of the nonspherical NPs between tribopair surfaces [11.161]. For example, the friction and wear of PAO-6 polyalphaolefin lubricant was reduced by 20 and 50%, respectively, when 0.5% ZnO or ZrO_2 was added to the lubricant [11.185]. Abrasive NPs have been used for chemical and mechanical polishing (CMP) of silicon wafers in manufacturing of integrated circuits (IC) [11.161]. For instance, silicon wafers were polished by CeO_2-coated SiO_2 NPs (150−200 nm) with material removal rate of 454 nm/min [11.186].

Ceramic or carbon-based NPs have been added to polymer or metal matrices to make nanocomposites with improved mechanical properties [11.161]. For example, the hardness and tensile strength of an aluminum matrix increased by 115 and 67%, respectively, with the addition of 7 vol.% Al_2O_3 NPs (50 nm) to the matrix [11.187]. The tensile strength and tensile modulus of rubbery epoxy resin increased by fivefold with incorporation of 10 wt% silica NPs [11.188].

In addition of the aforementioned applications, NPs have applications in electronics, textile manufacturing, and water treatment. Semiconducting polymer NPs have been used in organic photovoltaics, field-effect transistors and light-emitting diodes [11.189]. Carbon-coated Sn NPs and Si NPs distributed on graphene sheets were used as anodes while $LiCoPO_4$ NPs were used as cathodes in lithium ion batteries [11.190–192]. Ag NPs due to their antimicrobial properties have been used to produce antimicrobial paints and coatings [11.193, 194]. ZnO and TiO_2 NPs due to their photocatalytic activity have applications in removal of chemical and biological contaminants from water [11.195].

11.5 Summary

NPs can be synthesized from several classes of materials including inorganic (e.g., metal oxide NPs), organic (e.g., polymeric NPs), hybrid and biological materials. Physical techniques (ball milling, vapor deposition and electrospraying) as well as chemical methods (reduction of metal salts, sol-gel, coprecipitation and thermal decomposition) are used for the synthesis of inorganic NPs. Organic NPs can be synthesized via microemulsion, nanoprecipitation, dialysis and rapid expansion of a supercritical solution. Hybrid NPs are composed of both organic and inorganic materials. The inorganic component can form the core or the shell of the hybrid NPs. In addition to the naturally occurring biological NPs, NPs can be synthesized from biomolecules including proteins, peptides and polysaccharides. The physico-mechanical properties of NPs are significantly different from those of bulk materials. For example, the catalytic activity, superparamagnetism, hardness and Coulomb energy of the NPs are higher than those of bulk materials. Due to their unique properties, NPs have applications in a wide range of areas including biosensing, drug delivery, bioimaging, catalysis, nanomanufacturing, lubrication, electronics, textile manufacturing, and water treatment.

12. Graphene

Aravind Vijayaraghavan, Maria Iliut

Graphene is the two-dimensional allotrope of carbon, consisting of a hexagonal arrangement of carbon atoms on a single plane. This chapter begins with a brief history of graphene, followed by a discussion of different methods to produce graphene. The atomic and electronic structure of graphene is then described. The intrinsic properties of graphene can be tailored by nanofabrication, chemistry, electromagnetic fields, etc. Various applications of graphene have been proposed in electronic, optoelectronic and mechanical products. In addition, graphene has emerged as a candidate in chemical, biochemical and biological applications. Derivatives of graphene such as graphene oxide or graphane are also of interest both in terms of fundamental properties and applications.

As a three-dimensional (3-D) material, carbon exists as three predominant allotropes: diamond, graphite and amorphous carbon (carbon black). Graphite has a layered structure, where the sp^2 hybridized carbon atoms are arranged in a hexagonal lattice in each place, while the planes themselves are most commonly AB (Bernal) stacked and held together by Van der Waals forces. A single layer of graphite is known as graphene, which is a two-dimensional (2-D) allotrope of carbon. Carbon nanotubes (CNTs) form its one-dimensional (1-D) counterpart, while fullerenes are the zero-dimensional (0-D) allotropes. These various forms of carbon are summarized in Fig. 12.1.

One might argue that because even a single atom has a finite thickness, graphene is not a 2-D material; this is however an incorrect analysis. Graphene is regarded as a 2-D material for two main reasons, one electronic and one structural. Firstly, the electrons residing in a plane of graphene are confined to move in two dimensions and are forbidden from out-of-plane displacement. The behavior of electrons in graphene is therefore described by two-dimensional physics. Sec-

ondly, a sheet of graphene can be extended by adding carbon atoms in two dimensions to produce a larger sheet of graphene, which essentially remains the same material. However, the addition of carbon atoms out of the plane of the graphene sheet produces materials that no longer shares the properties of a single atomic layer graphene material, and is therefore no longer graphene.

Despite serving as the fundamental building block for these carbon allotropes, graphene remained a concept until 2004, even though fullerenes were discovered and described in 1985 [12.1] while carbon nanotubes were synthesized and their atomic structure elucidated in 1991 [12.2]. The term graphene was coined in 1987 [12.3], to describe one of the two alternating layers in graphite intercalation compounds (GIC), the other layer being the intercalating agent. It was postulated that independent, freestanding graphene would not become a physical reality since it would voluntarily transform into a more stable allotrope in an attempt to minimize its surface energy. Supported monolayers of carbon, however, had been previously synthesized and described, including epitaxial graphene, which has been known since the 1970s. Chemical derivatives of graphite such as graphite oxide can be traced back to the 1950s and have been known to exist as single layers (graphene oxide).

Graphene occurs naturally as a constituent of bulk graphite, from which one can obtain freestanding graphene. This approach led to the successful exfoliation of a single sheet of carbon atoms by *A. Geim* and *K. Novoselov* at the University of Manchester in 2004 [12.4] using a technique referred to as micromechanical cleavage, or colloquially, the Scotch tape method. This discovery and the subsequent investigations into the properties of graphene earned them the Nobel Prize in Physics in 2010. The existence of graphene, however, does not contradict the physics that predicted that it could not exist. It was discovered that graphene is not truly flat; there exist atomic-scale ripples in the carbon sheet, which accommodates the excess surface energy, thereby stabilizing the structure of graphene.

A surge of research into the structure and properties of graphene ensued. The number of peer-reviewed publications on the topic of graphene has risen exponentially since the seminal publication in 2004, surpassing the number of papers on carbon nanotubes in 2013, and reaching over 50 000 papers in 2015 (Fig. 12.2). It is also interesting to note the emergence of other 2-D materials, such as molybdenum disulphide (MoS_2) in recent years, fueled by the achievements of graphene.

12.1 Methods of Production

Historically, graphene supported on substrates such as metals and SiC was synthesized first; however, such graphene was not liberated from the substrate support to form a truly 2-D structure. Freestanding graphene was not a reality until it was produced by a micromechanical cleavage method in 2004, and this will be discussed first, followed by the epitaxial synthesis as well as chemical vapor deposition on metallic substrates. Graphene can also be exfoliated from graphite by chemical or mechanical exfoliation in a fluid, followed by a purification step to extract the monolayers. Recently, islands of nanographene have also been synthesized by chemical routes, and this bottom-up approach will be discussed. Finally, a separate section will be devoted to the production of derivatives of graphene.

12.1.1 Micromechanical Exfoliation of Graphite (the Scotch Tape Technique)

Graphite is known to cleave preferentially along the interlayer direction where layers are held together by weak Van der Waals forces, rather than across the strong covalent bonds that bind the atoms within a layer. The most common procedure to accomplish this is using adhesive tape [12.4]. Attaching a thick graphite flake to adhesive tape on both its exposed faces, and then peeling the two pieces of tape apart, results in two thinner flakes of graphite stuck to each of the adhesive tape pieces. Repeating this process sufficient number of times results in some monolayers of carbon atoms, i. e., graphene, adhered to the adhesive tape. This must then be transferred to a suitable weakly coupling substrate or be suspended across supports. Different variations of this method exist. In the resultant sample, the flakes of graphene, bilayer graphene and few-layer graphene must be distinguished from among a sea of flakes of various thicknesses. Fortunately, when deposited on certain thicknesses of the SiO_2 surface layer of a Si wafer, for instance 300 nm, the interference contrast generated by graphene flakes on the surface makes them relatively easy to spot and identify in an optical microscope. A trained eye can, in fact, distinguish between graphene, bilayer graphene, and thicker flakes. Figure 12.3 shows the appearance of micromechanically exfoliated graphene flakes of different thicknesses in an optical microscope [12.5] and an atomic force microscope (AFM) [12.6].

It should be noted that the *best quality* of graphene currently available is undisputedly that produced by micromechanical exfoliation, where the graphene quality is defined in terms of crystalline domain size, number of defects, electronic charge carrier mobility, etc. The choice of initial graphite material having large grain size, using freshly cleaved graphite for further exfoliation, the cleanliness and quality of the adhesive tape and SiO_2 substrate are all variables that significantly affect the quality of the final flakes obtained. Flakes of graphene hundreds of micrometers across are routinely produced in laboratories all over the world by this method, predominantly for fundamental research purposes.

12.1.2 Chemical Vapor Deposition

Chemical vapor deposition (CVD) to produce graphene involves the thermal decomposition of gaseous hydrocarbon sources followed by dissolution and recrystallization of the cracked carbon on the surface of metallic substrates. The solubility of carbon in various metals, such as Rh, Ru, Ir and Re has been measured [12.7] along with the observation that excess carbon dissolved in such metals at high temperatures can segregate as graphite on the surface upon cooling.

At present, the two predominant metallic substrates for CVD graphene growth are Ni and Cu. Large (cm^2)-size films of monolayer and few-layer graphene have been grown on Ni [12.8] with monolayer regions as large as 20 µm in size. Cu does even better, and predominantly monolayer graphene covering many cm^2 are grown in various laboratories using methane CVD [12.9]. The low solubility of C in Cu appears to make the process self-limiting, and at most 5% of the surface is covered by small islands of bilayer graphene. Most importantly, methods have been developed to detach these films from the metallic substrate and transfer them intact onto a dielectric substrate (Fig. 12.4) where they can be lithographically patterned and processed for electronic or optical applications. Truly large-area (m^2) production of graphene is achieved by either continuous or batch CVD and transfer processes.

12.1.3 Decomposition of Carbides

The second substrate-supported route for graphene production involves the thermal decomposition of surface layers of carbides such as SiC. α-SiC is the most commonly encountered polymorph and, until recently, the primary focus of epitaxial graphene growth. α-SiC has a hexagonal crystal structure, similar to Wurtzite. The (0001) (Si) and (000-1) (C) faces of 6H-(α-SiC) [12.11–13] and 4C-(α-SiC) [12.14] are suitable for the growth of epitaxial graphene.

On the Si surface of the hexagonal SiC graphitization occurs at 1350 °C. On this face, the C atoms are in epitaxy with the SiC underneath after graphitization. The surface is passivated by the first C layer, the interface extends to two C layers, and subsequent C layers are decoupled from the substrate and exhibit the properties of graphene. Graphitization occurs at 1150 °C on the C face of the hexagonal SiC and the first C layer already exhibits graphene properties. However, this C layer is no longer epitaxial with the underlying SiC, so the long-range order of the SiC substrate no longer imposes itself upon the C layer. Therefore, it has not been possible to accomplish both long-range ordering as well as decoupling from the surface simultaneously using 6H-(α-SiC).

It was believed that due to its cubic structure, β-SiC would be unsuitable for graphene growth. However, recently scientists have succeeded in growing graphene in the Si-rich (100) surface of β-SiC by a series of annealing cycles with temperature increasing from 1200−1550 K [12.15]. The strong lattice mismatch between graphene and underlying SiC results in very weak coupling similar to the (000-1) C face of α-SiC. However, the graphene growth on β-SiC is was guided along the [110] crystallographic direction despite the lattice mismatch, raising hopes that both substrate-graphene decoupling as well as substrate-guided large domain size might be simultaneously achievable after further process optimization and characterization of the graphene on β-SiC.

SiC decomposition can be used to grow graphene nanoribbons [12.16]. Furthermore, there was significant research into the growth and characterization of graphene on other metal carbides [12.17–19] such as TiC, TaC and HfC, as early as the 1980s. Back then, it was referred to as *monolayer graphite*. As with SiC,

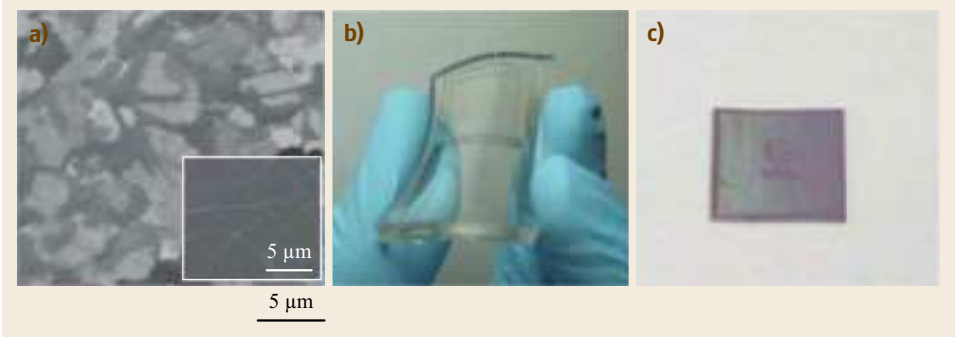

Fig. 12.4a–c (a) Scanning electron microscope (SEM) images of as-grown graphene films on thin (300 nm) nickel layers and thick (1 mm) Ni foils (inset). (b) Graphene films on the polydimethylsiloxane (PDMS) substrates are transparent and flexible. (c) The film transferred onto a SiO_2 substrate (after [12.10])

graphene nanoribbons as narrow as 1.3 nm with well-defined edge structures have been grown for instance on TiC (755) surfaces [12.20].

12.1.4 Exfoliation in a Solvent

The exfoliation of graphene from graphite involves overcoming the interlayer van der Waals bonds. Ultrasonication and high-shear mixing have been used to individualize graphene layers from graphite. This process can be facilitated if the interlayer attraction can be compromised by intercalates. The resultant flakes of graphene in a solvent can be stabilized to prevent aggregation, and separated into fractions that are enriched in particular flake thicknesses.

Graphene Oxide Route

Graphite can be oxidized to graphite oxide in various ways. In the *modified Staudenmaier method* [12.21], a mixture of 97% sulphuric acid and fuming nitric acid is cooled down to 5 °C in an ice bath, and graphite in flake or powder form is added, followed by repeated additions of potassium perchlorate every hour over a period of three days. The resulting solution, sometimes referred to as graphitic acid, is filtered and washed until the pH of the filtrate reaches five or more. The *Brodie method* [12.21] is identical, except that only nitric acid is used, and the potassium perchlorate is added every hour for three hrs. In the *Hummers method* [12.22], graphite is oxidized in a mixture of concentrated sulphuric acid, sodium nitrate and potassium permanganate at 45 °C for two hours. In the *electrochemical method* [12.21], a graphite sheet electrode is anodically polarized in perchloric acid with a platinum wire as the counter electrode. When dried, the above methods result in a powder consisting of graphite oxide flakes.

Graphite oxide is dispersed in a solvent by ultrasonication or high-shear mixing, resulting in graphene oxide (GO) dispersions (Fig. 12.5a). The phenol, carbonyl and epoxy groups resulting from the oxidation of graphite ensured colloidal stability in polar solvents [12.24]. Polymers, surfactants, DNA, etc. can be used to provide additional stabilization of the GO flakes in the colloidal suspensions in various solvents.

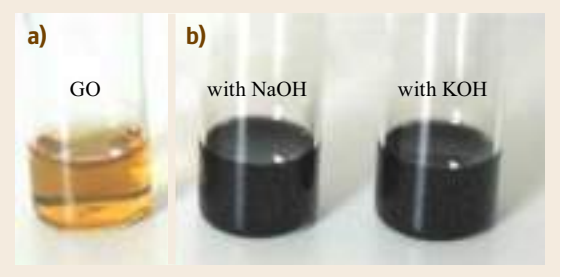

Fig. 12.5a,b Dispersion of (a) GO and (b) rGO reduced under alkaline conditions. Reprinted from [12.23], with permission

Exfoliated GO can be subsequently reduced to yield reduced (r) GO (Fig. 12.5b). It should not be referred to as graphene at this stage due to the incomplete nature of the reduction process. One route involves reduction in water with hydrazine hydrate [12.25, 26] or dimethylhydrazine [12.27]. A reduced GO suspension can also be obtained by heating the exfoliated GO suspension under strongly alkaline conditions [12.23]. Alternately, the GO flakes can be deposited on a substrate and reduced by hydrazine vapors or hydrogen plasma [12.28]. All these methods result in the formation of unsaturated and conjugated carbon atoms, which results in electrical conductivity and Raman signatures in between that of GO and pristine graphene.

Exfoliation Without Intercalation

In an effort to avoid disruption to the desirable structure and properties of graphene, efforts have been undertaken to directly exfoliate and disperse graphite in a solvent by ultrasonication and high-shear mixing. Certain solvents such as *N*-methylpyrolidone, *N*,*N*-dimethylamide (DMA), γ-buryrolacetone and 1,3-dimethyl-2-imidazolidinone are ideally suited to dissolve graphene in significant concentrations [12.29]. The procedure has been adopted successfully for using water as solvent in the presence of sodium dodecylbenzene sulfonate or sodium cholate as a stabilizing surfactant [12.30]. The predominant drawback of this process lies in the fact that the sonication breaks up the graphene into particularly small fragments, with the monolayer flake having lateral dimensions of, on average, 100 nm. This can be overcome to some extent by the use of high-shear mixing [12.31]. The aqueous graphene dispersion can now be processed by density gradient ultracentrifugation (DGU) using iodixanol as a density medium to yield fractions enriched in particular graphene thicknesses (Fig. 12.6) [12.32].

12.1.5 Synthetic Organic Chemistry Route

If the reduction of bulk graphite into graphene is viewed as a top-down approach, then the chemical synthesis of graphene from smaller aromatic hydrocarbons will constitute the bottom-up approach. If graphene is regarded as a polycyclic aromatic hydrocarbon (PAH), one the largest of these synthesized involves 222 carbon atoms or 37 benzene units in a hexagonal structure 3 nm in diameter [12.33] from an oligophenylene

precursor, which was planarized by oxidative cyclohydrogenation. These structures have also shown a high tendency to self-assemble on surfaces [12.34] and could potentially act as precursors to larger synthetic graphene.

Very narrow ribbons of graphene with widths of tens of nanometers and with well-defined edge structure and orientation are of particular importance in electronic applications, since such nanoribbons of graphene are one of the means to engineer an electronic bandgap in otherwise gapless graphene. Graphene nanoribbons, 8–12 nm in length and 2–3 nm width, have also been synthesized by surface-assisted coupling of molecular precursors into linear polyphenylenes and their subsequent cyclohydrogenation (Fig. 12.7a) [12.35].

12.1.6 Unzipping of Carbon Nanotubes

CNTs have been described as rolled up graphene sheets, and now graphene nanoribbons have been made from unraveling CNTs. Oxidized nanoribbons were obtained by suspending CNTs in concentrated sulphuric acid followed by treatment with 500 wt% $KMnO_4$ for 1 hr at 22 °C and 1 hr at 55–70 °C. The process described as unzipping of a CNT could occur as a linear longitudinal cut or in a spiraling manner depending on the chirality of the CNT (Fig. 12.7b) [12.36]. CNTs have also been converted to graphene nanoribbons by controlled plasma-etching of CNTs that are partially embedded in a polymer film (Fig. 12.7c) [12.37].

12.1.7 Derivatives of Graphene

Graphane, a fully saturated hydrocarbon derived from graphene, with a formula CH, was predicted to be stable based on first-principle total-energy calculations [12.38]. Experimentally, it was later shown that graphene can be hydrogenated and converted to graphane using a low-pressure (0.1 mbar) hydrogen-argon mixture (10% H_2) with direct current (DC plasma for 2 hrs [12.39]. The hydrogenation is stable, but reversible and the graphane can be reconverted to

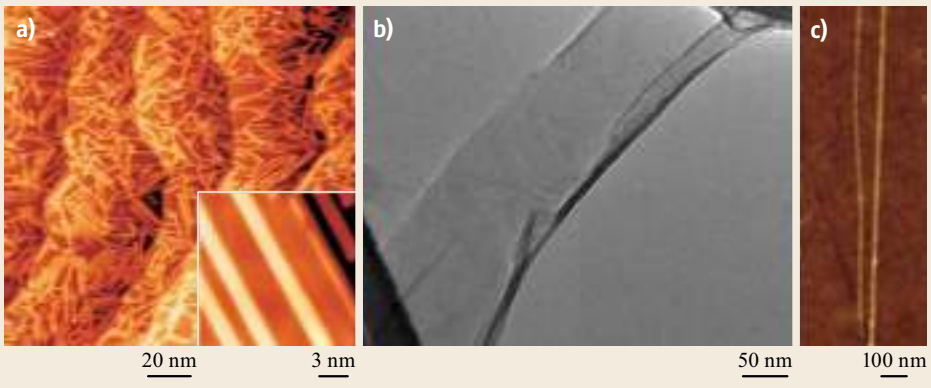

Fig. 12.7a–c Graphene nanoribbons formed by various means: **(a)** synthesized from polyphenylene precursors (after [12.35]), **(b)** unzipping of carbon nanotubes (after [12.36]) and **(c)** etching of carbon nanotubes embedded in a polymer (after [12.37])

graphene by annealing at 450 °C in Ar atmosphere for 24 hrs. The reconverted graphene, however, contains remnant defects just as vacancies and oxygenated or hydrogenated carbon atoms. In the case of substrate-supported graphene, only one side is hydrogenated, while both sides can be hydrogenated in the case of suspended graphene.

Graphene can also be fluorinated with XeF_2. When one side is exposed, F coverage saturates at 25% (C_4F), after which fluorination of both sides results in perfluorographene [12.40] and fluorographene [12.41], which are the nonstoichiometric and stoichiometric variations respectively. Hydrazine treatment has been shown to reverse the fluorination.

12.2 Properties

While its very existence as a freestanding 2-D material is a feather in graphene's cap, it is the properties of graphene that make it the truly exceptional material that has stoked feverish research in this field. The individual properties of pristine graphene will be discussed first, while the properties of graphene derivatives such as graphane and fluorographene will be discussed in the final section.

12.2.1 Structure and Physical Properties

Graphene shares most of its structure and physical properties with graphite, its parent material. The carbon atoms are arranged in a 2-D hexagonal lattice (Fig. 12.8), which can also be constructed as two interpenetrating triangular sublattices, which takes particular significance in bilayer and other multilayer graphenes. The carbon atoms are sp^2 hybridized, and the in-plane carbon–carbon bond length is $a = 1.42$ Å. The remaining p orbital is oriented perpendicular to the plane of carbon atoms and delocalized to form the π (valence) and π^* (conduction) electronic bands. The interplane spacing is 3.45 Å.

2-D structures like graphene had been postulated to be intrinsically unstable, and according to the Mermin–Wagner theorem [12.43], long-wavelength fluctuations destroy the long-range order of 2-D crystals. The puzzling stability of suspended 2-D graphene sheets has been attributed to intrinsic microscopic undulations in which the surface normal varies by several degrees and the out-of-plane deformation reaches 1 nm [12.44, 45]. Similar corrugation has also been reported in graphene supported on SiO_2 substrates [12.46]. Scrolling has been occasionally observed at the edges of graphene flakes, both suspended [12.47] and substrate supported [12.48], and this appears to rely on the fabrication method. Scrolling occurs when graphene is subjected to liquid-phase processing during microfabrication, while solid-phase or gas-phase processing appears to avoid this [12.42] (Fig. 12.9a). Graphene deposited on atomically flat terraces of cleaved mica surfaces are flat down to the atomic scale [12.49].

12.2.2 Mechanical Properties

Direct measurements of the elastic properties of graphene have been conducted by nanoindentation of suspended graphene layers in an AFM [12.51, 52]. For monolayer graphene, the force-displacement characteristics yield second- and third-order elastic stiffness

Resonances of metal beams (II) are also visible below 25 MHz. *Inset*: the graphene resonance at low driving power, and Lorentzian fit (*red line*) with $Q = 125$ (after [12.50])

of 340 Nm^{-1} and 690 Nm^{-1} respectively. The breaking strength is 42 Nm^{-1}, which represents the intrinsic strength of a defect-free sheet. This corresponds to a Young's modulus of $E = 1.0$ TPa, third-order elastic stiffness of 2.0 TPa and an intrinsic strength of 130 GPa. The figures mean that graphene is the strongest material ever measured.

Nonlinear finite elasticity theory for graphene resonators for both electrostatic and electrodynamic cases has been developed and agrees well with experiments on graphene resonators [12.53]. In general, natural resonance frequencies in the GHz regime are expected for graphene resonators, due to the combination of their extreme thinness and extraordinary stiffness. Experimentally, the mechanical vibrations in electrostatically actuated graphene resonators have been imaged by a special modification of atomic-force microscopy [12.54]. Resonance frequencies in the 10 s of MHz have been recorded in graphene resonators (Fig. 12.9), with quality factors of 4000 at room temperature [12.55, 56] and 10 000 at 5 K [12.50].

12.2.3 Electronic Properties

Monolayer, bilayer and trilayer graphenes are electronically distinct materials. Beyond three layers, graphene's electronic properties tend towards that of bulk graphite.

Monolayer Graphene

The electronic structure of graphene was first described in 1946 [12.28] as a theoretical building block to describe graphite. The valence and conduction bands of graphene are conical valleys that touch at the high-symmetry K and K′ points of the Brillouin zone. Near these points, the energy varies linearly with the magnitude of momentum, i. e., it follows a linear dispersion relation (Fig. 12.10a). In neutral graphene, this point of intersection coincides with the charge neutrality point, and is referred to as the Dirac point.

In 3-D electron systems, the electrons' behavior can be described by the Schrödinger equation. In graphene, on the other hand, electrons behave as relativistic particles, and are described by the Dirac equation [12.58, 59]. The interaction of electrons with the periodic potential of the graphene hexagonal lattice results in quasiparticles, which can be viewed as electrons devoid of their rest mass m_0 and therefore called massless Dirac fermions. The linear energy dispersion means that the speed of electrons in graphene is a constant, independent of momentum, as in the case of the speed of photons. The velocity of electrons in graphene is $\approx 10^6$ m/s, about 300 times slower than the speed of light (photons).

The electronic states near the Dirac point are composed of states belonging to the two graphene sublattices, and as a result the quasiparticles possess pseudospins, similar to the electron's spin [12.60]. These Dirac fermions are said to be chiral. Another relativistic phenomenon associated with these quasiparticles is the Klein paradox [12.60] wherein they tunnel through a potential barrier of any height and width with a transmission probability of 1 or without a reflected component. As a result, electrons in graphene can propagate over (relatively) vast distances on the order of microns through the graphene lattice, even in the presence of lattice defects or other external perturbing potentials.

Bilayer Graphene

In bilayer graphene, the AB (Bernal) stacking between the two graphene renders the two carbon atoms inequivalent and results in two graphene sublattices. As a result the unit-cell of bilayer graphene contains four atoms, and two additional bands in the π and π* states. If the inversion symmetry between the two layers is

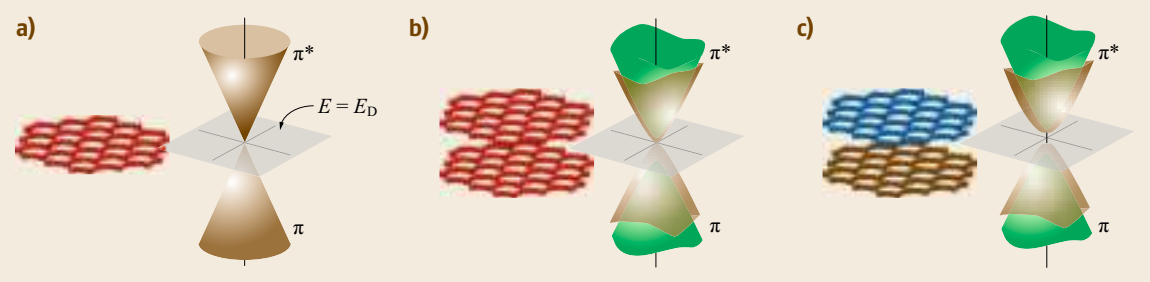

Fig. 12.10a–c Electronic structure of **(a)** monolayer, **(b)** symmetric bilayer, and **(c)** asymmetric bilayer graphene (after [12.57])

broken, then an energy gap between the low-energy valence and conduction bands forms at the Dirac point (Fig. 12.10b,c)

The electronic gap in bilayer graphene can be controlled by applying an external transverse electric field, such as by a gate bias, making it the only known semiconductor material with a tunable energy gap. Using a tight-binding model, the value of the gap was extracted as a function of electron density, and it was shown that it can be tuned to values larger than 0.2 eV.

12.2.4 Optical Properties

The successful exfoliation on monolayer graphene owes itself to recognizing the optical properties of graphene as much as the exfoliation procedure [12.5]. On a SiO_2 surface of a Si wafer, the contrast of a graphene flake depends on the SiO_2 thickness as well as the wavelength of light. Fig. 12.11 summarizes the expected contrast as a function of SiO_2 thickness as well as wavelength of monochromatic illumination. The observed contrast allows the determination of the number of graphene layers.

The absorbance of light by monolayer and bilayer graphene is 2.3 and 4.6% respectively in the visible spectrum (450–750 nm), and this linearity extends up to five layers. The optical transparency of noninteracting graphene is solely determined by the fine structure constant of quantum electrodynamics ($\alpha = e^2/\hbar c = 1/137$), which describes the coupling between light and relativistic electrons [12.61].

12.2.5 Thermal and Thermoelectric Properties

The thermal conductivity of suspended monolayer graphene is 5300 W/mK with a phonon mean free path of 775 nm near room temperature [12.62]. Interestingly, this value is higher than the bulk graphite limit of $K \approx 2000$ W/mK. The room-temperature thermal conductivity decreases from ≈ 2800 to ≈ 1300 W/mK as the number of graphene layers in few-layer graphene

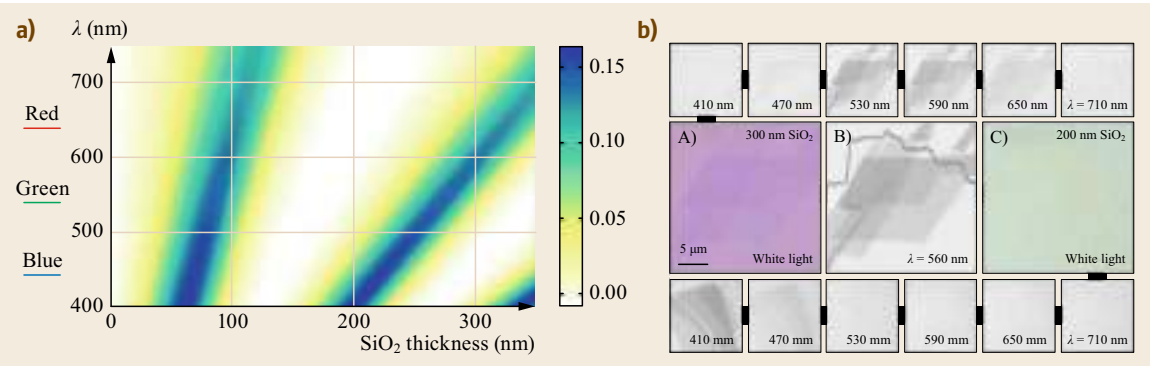

Fig. 12.11 **(a)** Color plot of the contrast as a function of wavelength and SiO_2 thickness. The color scale on the right shows the expected contrast. **(b)** Graphene crystallites on 300 nm SiO_2 imaged with white light (A), green light (B) and another graphene sample on 200 nm SiO_2 imaged with white light (C). Single-layer graphene is clearly visible on the left image (A), but even three layers are indiscernible on the right (C). Image sizes are $25 \times 25\,\mu m^2$. Top and bottom panels show the same flakes as in (A) and (C) respectively, but illuminated through various narrow bandpass filters with a bandwidth of ≈ 10 nm. Reprinted from [12.5], with the permission of AIP Publishing

(FLG) increases from two to four [12.63], corresponding to the evolution from 2-D graphene to bulk graphite.

Thermoelectric power (TEP) is the voltage developed across a sample when a constant temperature gradient is applied. TEP of graphene is $80\,\mu V/K$ at 300 K [12.64]. Similar to the quantum Hall effect in electronic transport, quantized TEP have also been observed in graphene at high magnetic fields. The TEP can be tuned in graphene, even to negative values, under the application of a gate bias or chemical potential [12.65]. Very large TEP values have been predicted for graphene nanoribbons, for instance, $4\,mV/K$ for a 1.6 nm-wide ribbon [12.66, 67]. A giant thermoelectric coefficient of $30\,mV/K$ has been observed in a nanostructure consisting of metallic electrodes periodically patterned over graphene, which is deposited on a SiO_2 substrate [12.68].

12.2.6 Chemical Properties

The chemistry of graphene is dominated entirely by its surface, since every carbon atom is a surface atom twice over. For graphene nanoribbons, the edges play a role in determining their reactivity.

It has been shown that for electron-transfer chemistries, single graphene sheets are almost 10 times more reactive than bilayer or multilayer graphene according to the relative intensity of the disorder (*D*) peak in the Raman spectrum examined before and after chemical reaction [12.69, 70]. Graphene can be readily functionalized through diazonium or nitrene [12.71] reactions, which can introduce reactive species covalently linked to graphene. These groups then serve as templates for further chemistry and grafting of functional groups, for instance through an azide linker. Chemical functionalization of graphene be monitored through its effect on the conductivity of graphene, and serve as a means of controlling the electrical transport properties of graphene [12.72]. Furthermore, p-doped and n-doped regions in graphene can be generated by suitably functionalizing them, for instance with diazonium salts and polyethyleneimine respectively [12.73]. Such chemical modification can also be performed on different parts of a single sheet to form p-n junctions in graphene [12.74].

12.2.7 Properties of Graphene Derivatives

Graphane has been theoretically predicted to take one of two configurations, a *chair* conformer with the hydrogen atoms alternating on both sides of the plane for the two graphene sublattices, and a *boat* conformer with the hydrogen atoms alternating in pairs [12.38]. The *chair* and *boat* conformers have a direct electronic bandgap of 3.5 eV and 3.7 eV respectively. Graphane is a completely insulating material; its resistivity changes by two orders of magnitude with decreasing temperature from 300 K to 4 K and carrier mobility decreases to $\approx 10\,cm^2V^{-1}s^{-1}$ at liquid-helium temperatures for typical carrier concentrations of $10^{12}\,cm^{-2}$ [12.39].

Similarly, fluorographene [12.41] is a high-quality insulator with a large optical bandgap of > 3 eV and room-temperature resistivity of $> 10^{12}\,\Omega$. The Young's modulus of fluorographene is 0.3 TPa, which is about 30% the stiffness of graphene. Similarly, fluorination reduces graphene's intrinsic breaking strength by 2.5 times. However, fluorographene is able to sustain the same ultimate strain of 15% as graphene. Fluorographene is also strongly hydrophobic, and can be considered the 2-D equivalent of Teflon.

12.3 Characterization

Each of the properties discussed in the previous section has to be measured and correlated using multiple characterization techniques. This is essential, since just one measurement, for instance electronic transport, might not be able to sufficiently distinguish between an electronic bandgap and a mobility gap. Similarly, mechanical properties have to be confirmed by a combination of tensile testing, electromechanical resonance and Raman spectroscopy.

12.3.1 Optical Microscopy

Based on the optical properties of graphene discussed in an earlier section, and the fact that green light is most comfortable for the eyes, optimal SiO_2 thicknesses of 90 and 280 nm can be recommended [12.5]. Similarly, it has been shown that graphene can be observed on 50 nm Si_3N_4 using blue light and on 90 nm poly(methyl methacrylate) (PMMA) using white light. Rayleigh scattering can identify the number of graphene layers as well as probe their dielectric constant [12.75].

12.3.2 Transmission Electron Microscopy

High-resolution transmission electron microscopy (TEM) can resolve individual carbon atoms as well as adatoms, defects and other anomalies in graphene (Fig. 12.12a) [12.47]. If folds occur in the transferred

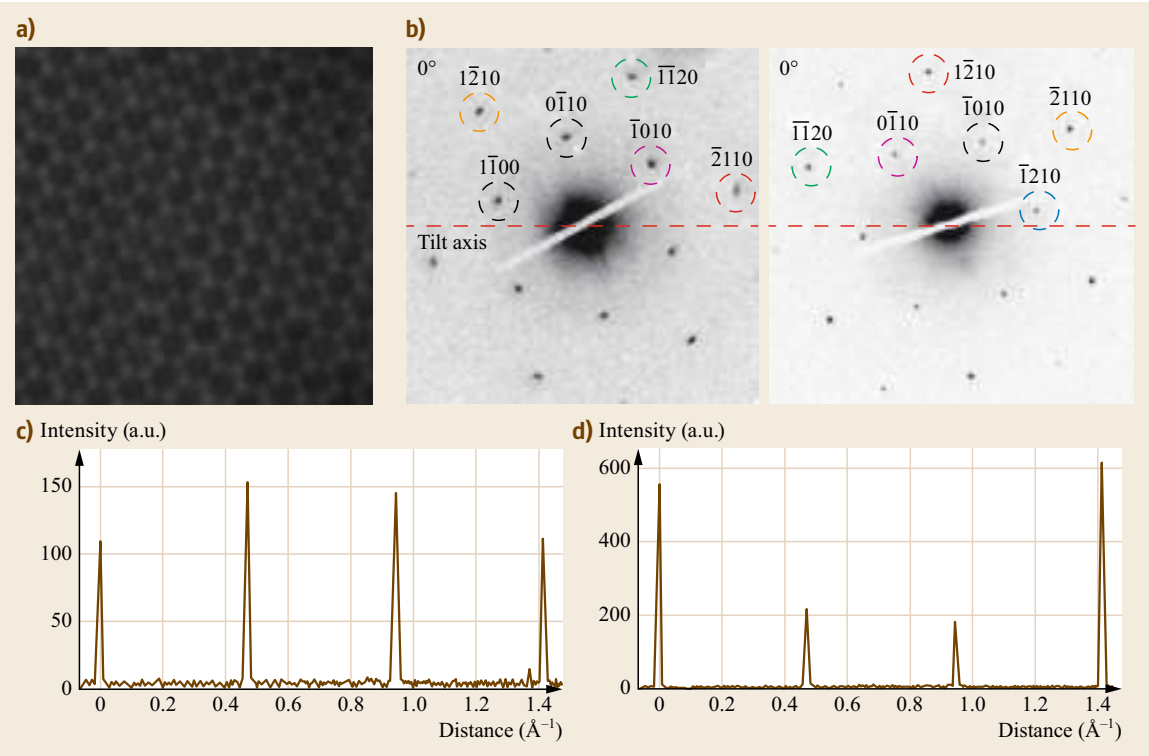

Fig. 12.12 **(a)** Atomic resolution transmission electron micrograph of graphene. **(b)** Nanobeam electron-diffraction patterns of monolayer and bilayer graphene. Relative intensities of 1-100 and 1-210 peaks in **(c)** monolayer and **(d)** bilayer graphene. Reprinted from [12.76] with permission from Elsevier

graphene flake, then observation of the folded edge can yield information about the number of layers in the graphene flake [12.45]; a monolayer fold-edge turns up as a single dark like while a bilayer fold-edge appears as two dark lines and so on. In addition, nanobeam electron diffraction (Fig. 12.12b) can also be used to quantify the layering in graphene [12.45]. Monolayer graphene can be distinguished from higher layered graphenes by the anomalous intensity ratio of the diffraction peaks; it's 0-110 peaks being more intense than the 1-210 peaks (Fig. 12.12c). The total (integrated) intensity of the 0-110 and 1-210 peaks of monolayer graphene varies weakly with tilt angle and no minima in intensity is observed. In contrast, the total intensity of bilayer graphene diffraction peaks varies strongly with tilt angle, including minima at certain angles where some peaks vanish [12.77]. However, while the total intensity in monolayer graphene only decreases slightly, significant peak broadening is observed with increasing tilt angle. This effect is most pronounced in monolayers, and decreases with increasing thickness of the graphene flake. This is attributed to nanoscale corrugations in 2-D graphene, with the surface normal deviating on average by $\pm 5°$ in monolayers and $\pm 2°$ in bilayers. This nanoscale corrugation extending into the third dimension is the reason for the existence of 2-D graphene considering the theoretical prediction that perfect 2-D atomic crystals cannot exist.

12.3.3 Scanning Probe Techniques

Atomic force microscopy (AFM) in tapping mode is commonly used to measure the thickness of graphene flakes on substrates; however, the correlation between measured thickness and actual thickness as well as number of layers is challenging [12.78]. Electrostatic interactions between the tip and the graphene, adsorbed moisture, and incorrect choice of AFM parameters such as free amplitude values can all influence the final measured thickness of a graphene flake. In addition, AFM is used to measure the flatness of graphene on various substrates. AFM can also be used in nanoindentation mode to probe the stiffness of suspended graphene [12.51].

Scanning tunneling microscopy (STM) can image graphene with atomic resolution, and the correlation of the graphene hexagonal lattice to the direction of the edge of an exfoliated flake reveals the orientation of

the edge as being either armchair or zigzag [12.79]. Scanning tunneling spectroscopy (STS) can be used to probe the atomically resolved local electronic structure of graphene [12.80, 81].

12.3.4 Angle-Resolved Photoemission Spectroscopy (ARPES)

ARPES is a direct experimental technique that has measured the electronic density of states in graphene with both energy and momentum information. The shape of the π and π* bands near E_F at the K point from ARPES reveals the transition from 2-D to bulk character for one to four layers of graphene [12.57], as well as the electronic band structures of bilayer graphene [12.57]. Fermi velocities and effective masses of the electrons can also be measured. ARPES also allows studies of electron–electron, electron–phonon and electron–plasmon interactions, and indicates that all three must be considered on an equal footing to understand the quasiparticle dynamics in graphene [12.82].

12.3.5 Raman Spectroscopy

The three significant Raman spectral features in graphene are the G peak at $\approx 1580\,\mathrm{cm}^{-1}$, the D peak at $\approx 1350\,\mathrm{cm}^{-1}$ and the 2D peak at $\approx 2700\,\mathrm{cm}^{-1}$, as seen in Fig. 12.13 [12.83]. The G peak is due to the E_{2g} mode, i. e., the in-plane vibrations of the carbon atoms. The D peak and 2D peak are strongly dispersive with excitation energy due to the Kohn anomaly at the K point, while the G peak is not.

The 2D peak is the second-order of the zone-boundary phonons and therefore does not require defects. For monolayer and few-layer graphene, the 2D peak serves as a fingerprint for identification. In general, the 2D peak of graphite has four components, $2D_{1B}$, $2D_{1A}$, $2D_{2A}$, and $2D_{2B}$. Monolayer graphene has a single sharp 2D peak, dominated by the $2D_{1A}$ component. In bilayer graphene, the $2D_{1A}$ and $2D_{2A}$ peaks have higher relative intensity compared to the other two, and the 2D peak appears upshifted and broader compared to monolayer graphene. It is also important to note here that non-AB stacked graphene, such as multilayer CVD graphene, also shows a single 2D peak [12.84]. However, this can be distinguished from monolayer graphene by its full-width at half-maximum (FWHM) of $50\,\mathrm{cm}^{-1}$, which is twice that of monolayer graphene. A similar observation can also be made with the D peak [12.83]. The D peak of monolayer graphene is a single sharp peak while in bulk graphite it can be resolved into two peaks, D_1 and D_2. The D peak is observed in defective graphene, and prominently at the edges of graphene flakes. A D′ peak at $\approx 1620\,\mathrm{cm}^{-1}$ is also observed in defective graphene.

The Raman spectrum of graphene also responds to doping, i. e., changes in the Fermi surface of graphene [12.85, 86]. The G peak upshifts for both hole and electron doping. The position of the 2D peak however decreases monotonically with increasing electron concentration or decreasing hole concentration, and the 2D peak can be used to distinguish between electron and hole doping. Taken together, a plot of 2D versus G peak positions can be used to distinguish between electron and hole doping in graphene, as seen in Fig. 12.14a [12.87].

Raman peaks in graphene can also be shifted by biaxial strain, induced for example by interaction with the

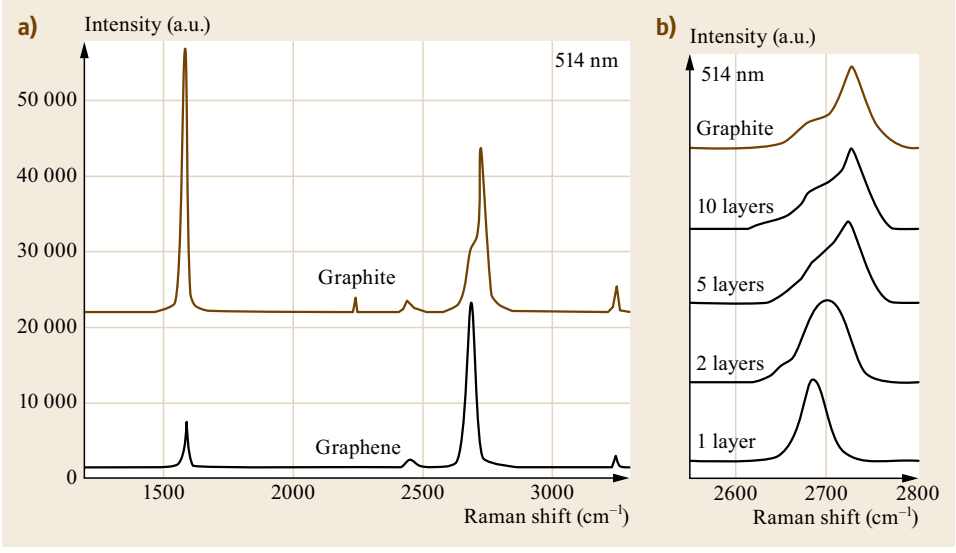

Fig. 12.13 **(a)** Comparison between Raman spectra of graphene and graphite. **(b)** Evolution of 2D peak shape with number of layers of AB stacked graphene. **(c)** Comparison of D peak between graphene and graphite (after [12.83])

substrate [12.88, 89]. The correlation between normalized shift of 2D and G peak positions, i. e., $\Delta 2D/2D_0$ and $\Delta G/G_0$, where $2D_0$ and G_0 are the peak positions for undoped graphene, indicates whether the shift arises from doping or strain [12.90]. When $\Delta 2D/2D_0$ versus $\Delta G/G_0$ is plotted from Raman spectra obtained at a number of points on a graphene sample, a linear fit with slope close to 1.58 ± 0.18 indicates that strain plays a predominant role, while a smaller slope indicates increasing influence of doping. Highly doped samples yield a slope of < 1. In another approach, if the plot of FWHM versus position of the G peak is monotonically decreasing, it is related to doping, while if it is monotonically increasing, it is caused by strain or disorder (Fig. 12.14b) [12.86]. Under uniaxial strain, the G peak splits into two bands, G^+ and G^-, analogous to the effect of curvature on the G peak of carbon nanotubes [12.91].

12.3.6 Electrical Characterization

The sheet resistivity ρ of graphene varies with applied gate-voltage, exhibiting a sharp peak of several kΩ and decaying to $\approx 100\,\Omega$ at high V_g (Fig. 12.15). The conductivity $\sigma = 1/\rho$ increases linearly with V_g on either side of the resistivity peak (conductivity valley). The Hall effect coefficient R_H reverses sign at the same V_G as the resistivity peak. This resembles an ambipolar semiconducting field-effect transistor, except that there is no zero-conductance region since there is no bandgap. This tunability of conductivity is achieved by transforming the graphene by electric-field doping from completely electron or completely hole conductor, passing through a mixed state where both electrons and holes contribute equally. This behavior holds true for monolayer graphene as well as undoped bilayer graphene. Also significant is the minimum conductivity of graphene at the charge neutrality point (σ_{min}), which has been shown to be about $4e^2/h$. This σ_{min} is not related to the physics of the Dirac point singularity, but instead related to the charge-density inhomogeneities (electron–hole puddles) induced by the substrate or charged impurities [12.92, 93]. Invariably, the position of the charge-neutrality point (ρ peak) is shifted to large positive V_G, leaving the ungated graphene as a hole-metal. This large shift is attributed to unintentional doping of the graphene by adsorbed species such as water. The peak position can also be shifted by intentional doping or removal of dopants by thermal or current-induced annealing [12.94] but such charged impurities do not affect σ_{min}. The mobility and minimum conductivity also decrease as a result of defects, which can be induced in a controlled fashion to study this effect, for instance by ion irradiation [12.95] or exposure to atomic hydrogen [12.96].

The carrier mobility in graphene on SiO_2 substrates is $\approx 10\,000\,cm^2/Vs$, which is independent of the absolute temperature, indicating that it is limited by scattering defects. Substrate-induced charge puddles are significantly reduced in suspended graphene and low-temperature mobility approaching $200\,000\,cm^2/Vs$ has been reported [12.97, 98]. In such devices, the con-

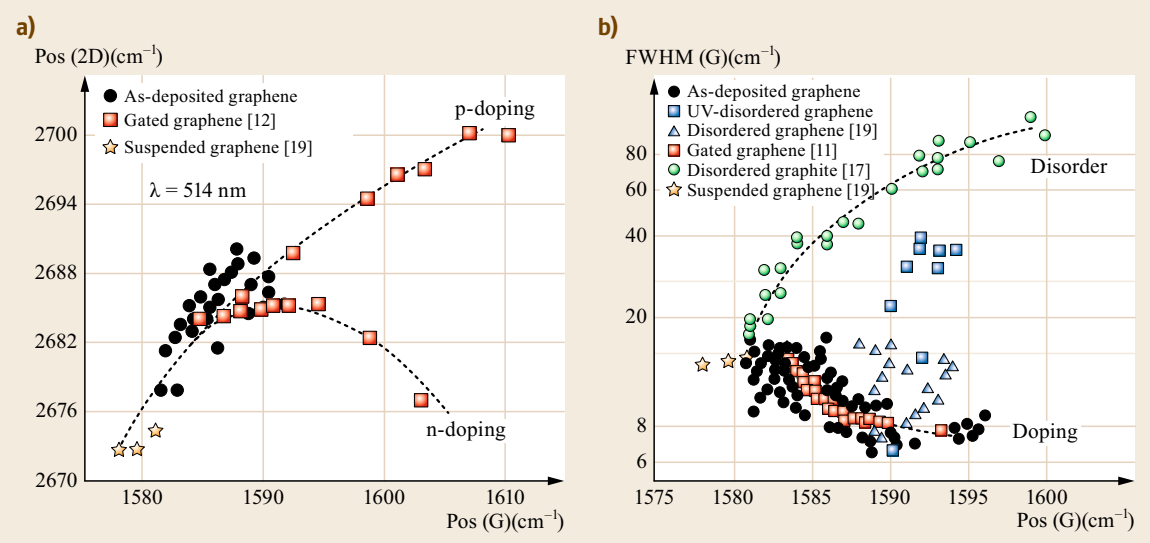

Fig. 12.14 **(a)** Pos(G) as a function of Pos(2D) for as-deposited graphene and gated graphene. **(b)** Pos(G) as a function of FWHM(G) for as-deposited graphene, compared with disordered graphene, disordered graphite and gated graphene. The *dotted lines* are only a guide for the eyes (after [12.87])

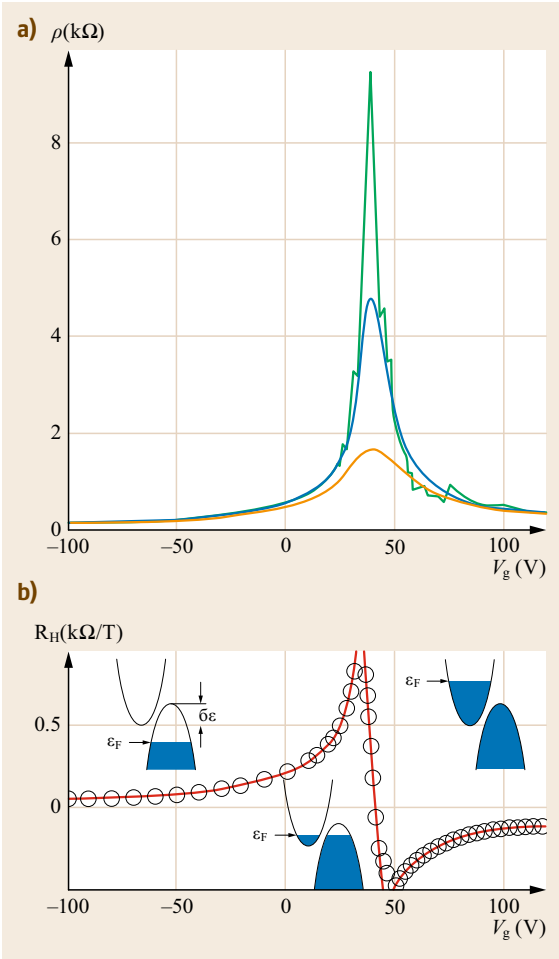

Fig. 12.15a,b Field effect in graphene. **(a)** Typical dependences of graphene's resistivity ρ on gate voltage for different temperatures ($T = 5$, 70 and 300 K for top to bottom curves respectively). **(b)** Hall coefficient R_H versus V_g for the same film at $T = 5$ K (after [12.4])

ductivity of suspended graphene at the Dirac point is strongly temperature dependent and approaches ballistic values at liquid helium temperatures. Due to the linear dispersion relation in graphene, intrinsic electron scattering by acoustic phonons is independent of carrier density and only contributed 30 Ω to the room-temperature resistivity of graphene. This would yield an intrinsic mobility of $2 \times 10^5\,\mathrm{cm}^2/\mathrm{Vs}$ at a carrier density of $1 \times 10^2\,/\mathrm{cm}^2$. However, a strong temperature dependence of mobility is observed in substrate-supported graphene devices, suggestive of extrinsic scattering, which limits the mobility to about $4 \times 10^4\,\mathrm{cm}^2/\mathrm{Vs}$ [12.99].

Graphene also exhibits pronounced Shubnikov–de Haas (ShdH) oscillations in both longitudinal resistivity ρ_{xx} and Hall resistivity ρ_{xy}. The oscillations depend only on the perpendicular component of the magnetic field $B\cos\Theta$, where Θ is the angle between the magnetic field and the graphene. The ShdH oscillations' frequency B_F depends linearly on V_G, indicating that the Fermi energies ε_F of holes and electrons are proportional to their concentration n. This is different from the 3-D dependence ε_F proportional to $n^{2/3}$, proving the 2-D nature of charge carriers in graphene.

The quantum Hall effect (QHE) has been observed in graphene even at room temperature, since the electrons suffer little scattering due to their relativistic nature and have a large cyclotron gap that exceeds the thermal energy $k_B T$ by a factor of 10. Fractional (F) QHE was reported in suspended graphene devices when a plateau at filling factor $\nu = 1/3$ was observed above a magnetic field as low as 2T [12.100, 101]. An insulating state was also observed at magnetic fields $B > 5$ T and filling factors $\nu < 0.15$, due to symmetry breaking of the zeroth Landau level by electron–electron interaction.

Under applied magnetic field, a plateau at zero Hall conductivity $\sigma_{xy} = 0$ occurs in biased bilayer graphene, as a result of the gap opened between the valence and conduction bands. Plateaus at $\sigma_{xy} = 4Ne^2/h$ occur as expected, including at $N = 0$. This is the standard integer QHE that is expected for an ambipolar semiconductor with an energy gap larger than the cyclotron energy. This plateau is absent in monolayer and unbiased bilayer graphene, which show an anomalous double-step of $8e^2/h$ at $n = 0$, indicative of the metallic state at the charge neutrality point. A huge peak in the longitudinal resistivity ρ_{xx} at $n = 0$ was also observed, exceeding 150 kΩ at 4 K compared to 6 kΩ for the unbiased case. From ShdH measurements, the cyclotron mass, m_c in biased bilayer graphene is found to be an asymmetric function of the carrier density, which is a clear signature of a bandgap. Measurements with dual-gated bilayer graphene have also confirmed these results [12.102].

12.4 Applications

While the field of experimental graphene research is still in its early years, graphene's potential for applications is already evident. Graphene is currently under evaluation for a wide range of applications, which will benefit from its unique combination of excellent mechanical, electronic, optical and chemical

properties. Commercial viability of most applications is severely limited by limited options available for large-scale production of graphene of appropriate quality and cost. Figure 12.16 summarizes the various methods of graphene production, the corresponding quality, scalability and cost, and potential applications for which each production method is appropriate.

12.4.1 Structural and Electrical Composites

The remarkable mechanical properties of graphene coupled with high electrical and thermal conductivity suggests that they would be ideal in composite materials for structural as well as electronic applications. GO and polystyrene composites show a low percolation threshold of ≈ 0.1 volume percent for room-temperature electrical conductivity and $\approx 0.1\,\mathrm{S/m}$ at 1 vol.%, which is sufficient for many electrical applications [12.27]. Such composites in thin-film form can show ambipolar field-effect behavior with electron and hole mobilities of 0.2 and $0.7\,\mathrm{cm^2/Vs}$ respectively [12.105]. GO-silica composites have been fabricated by spin coating GO-impregnated silica sols to yield transparent conducting composite films [12.106]. Layered GO-polymer composites have been fabricated by layer-by-layer (LBL) assembly, taking advantage of electrostatic interactions between anionic GO sheets and cationic polymer [12.56]. GO-P3HT/P3OT composites have been demonstrated as a superior acceptor layer in organic photovoltaics [12.107] while TiO_2-graphene composite has been demonstrated as a high-performance photocatalyst [12.108]. Composites of functionalized graphene derived from GO with polymers such as PMMA, poly(acrylonitrile) and poly(acrylicacid) show improvement of Young's modulus, glass transition temperature, ultimate strength and thermal degradation [12.109]. Composites of graphene with metal nanoparticles (Au, Pt, and Pd) have also been produced and the graphene-Pt composite has been demonstrated as a catalyst in direct-methanol fuel cells [12.110].

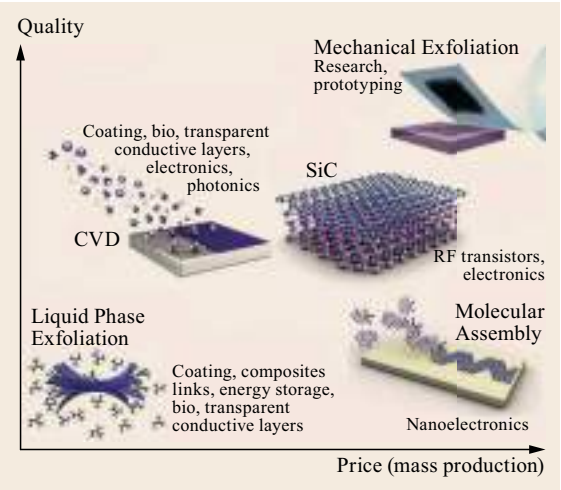

Fig. 12.16 Schematic representation of the various methods of graphene production as a function of the resulting quality and cost, and potential applications for which each production method is appropriate (after [12.103])

12.4.2 Transparent Conductive Films

Thin films have been deposited from solution-phase graphene with controllable thickness from a single monolayer to several layers over large areas (Fig. 12.17) [12.104]. The thickness of the film determines its conductivity, transparency and mechanical integrity. Electronic properties can be tuned from graphene-like ambipolar field-effect behavior for the thinnest films to graphite-like semimetal conductiv-

ity for thicker films. Flow-based deposition, vacuum filtration and layer-by-layer assembly are among the techniques used to deposit graphene thin films from solution.

Graphene conducting thin films are targeted as replacements for indium-tin oxide (ITO), which possesses a combination of 100 Ω per square sheet resistance at 90% transparency. Solution-processed rGO films [12.111] can achieve a sheet resistance of 1 KΩ per square at 90% transparency and have been demonstrated as transparent conductive anodes for inorganic, organic and dye-sensitized photovoltaic cells, but the short-circuit current and fill factor are still lower than that of control devices with ITO [12.112, 113]. However, they do have advantages such as tunable wettability and high chemical and thermal stability and flexibility.

Pristine graphene films grown by CVD on Ni or Cu substrates and transferred by a wet process can achieve ≈ 280 Ω per square at ≈ 80% transparency. The films show high electron mobility of 3700 $cm^2/V.s$ and exhibit the half-integer quantum-Hall effect typical of high-quality graphene, which cannot be accomplished with reduced or functionalized GO. Most importantly, the graphene films can recover their original resistance after being stretched by up to 6% and the resistance shows little variation up to a bending radius of 2.3 mm, corresponding to a tensile strain of 6.5%. This gives graphene films a significant advantage over ITO for applications in flexible electronics [12.10, 115].

A roll-to-roll dry transfer process has been developed for up to 35 inch monolayer graphene grown on Cu has yielded films with 97.4% transparency and 125 Ω per square sheet resistance (Fig. 12.18). The conductivity of graphene can be further improved by doping, for example p-doping with HNO_3, and resistance as low as 30 Ω per square can be achieved at 90% transparency, making graphene a strong potential candidate for ITO replacement, particularly in flexible electronics [12.114].

Solution-processed graphene as well as CVD graphene have been demonstrated as electrodes for organic

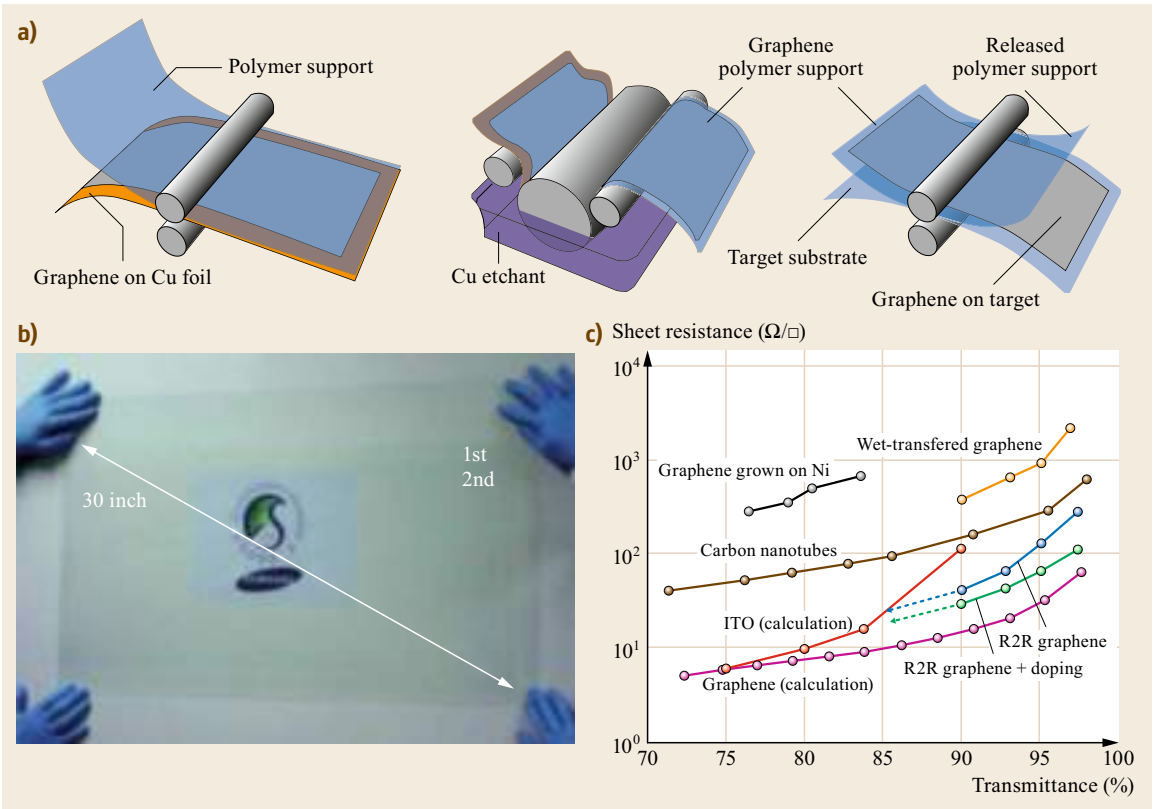

Fig. 12.18 **(a)** Schematic of the roll-based production of graphene films grown on a copper foil. The process includes adhesion of polymer supports, copper etching (rinsing) and dry transfer-printing on a target substrate. **(b)** A transparent ultralarge-area graphene film transferred on a 35-inch polyethylene terephthalate (PET) sheet. **(c)** Comparison of sheet resistance for graphene. The *dashed arrows* indicate the expected sheet resistances at lower transmittance (after [12.114])

light-emitting diodes [12.116]. This, combined with a graphene-based field-effect transistor and a graphene transparent conducting electrode allows for the fabrication of fully flexible and transparent touchscreen displays.

12.4.3 Sensors

The ultimate detection limit of any chemical sensor is the ability to detect individual molecules of a desired species (Fig. 12.19). The exceptionally low-noise electronic characteristics of graphene allows for such single-molecule sensitivity [12.117]. Adsorbed gas molecules change the local carrier concentration one electron at a time, which can be detected as stepwise changes in device resistance. Depending on the nature of the adsorbed species, the graphene can be either electron doped (NH_3) or hole doped (H_2O, NO_2). Graphene sensors are expected to be more sensitive than conventional semiconductor sensors.

rGO-based electronic device sensors have shown parts-per-billion sensitivity to chemical warfare agents and explosives [12.118] and parts-per-million sensitivity to gases such as NO_2 and NH_3 [12.119]. rGO-based surface acoustic wave sensors have shown parts-per-million sensitivity to H_2 and CO [12.120]. Electrolyte-gated graphene devices have been demonstrated as pH and biomolecule sensors with picomolar sensitivity [12.121].

Molecular structural mechanics modeling has shown that the principle frequency vibrations of monolayer graphene resonators are sensitive to added mass of $\approx 10^{-6}$ fg [12.122]. Mass sensitivity of ≈ 2 zg has been experimentally demonstrated using graphene resonators with a high quality factor of 14 000 at low temperature [12.50].

12.4.4 Electronic Applications

Field-Effect Transistors

In order for graphene to behave as a semiconductor for use in field-effect transistors (FETs), a bandgap needs to be generated in graphene, for example by exploiting lateral confinement of charge carriers in a graphene nanoribbon [12.123] (Fig. 12.20). A gap is observed for narrow ribbons, which scales inversely with ribbon width. Gaps in excess of 100 meV were observed for widths less than 20 nm.

It is also possible to fabricate quantum dot (QD) devices entirely out of graphene [12.124–126]. Such a device consists of a graphene island connected to the source and drain via two narrow graphene constrictions and three fully tunable graphene lateral gates, as shown in Fig. 12.21a. Graphene QDs show conventional single-electron transistor characteristics, with periodic Coulomb blockade peaks (Fig. 12.21c). This can be extended to a double-QD system (Fig. 12.21b) where the coupling of the dots to the leads and between the dots is tuned by graphene in-plane gates [12.127]. This structure has been proposed for the realization of spin qubits from graphene QDs.

Various approaches have been proposed to increase the performance of graphene devices, in particular to reduce impurity scattering and enhance mobility.

Ultrahigh current density-induced removal of adsorbents, photoresist or e-beam resist residue can be used to clean the graphene in situ during transport measurements [12.94]. A parylene-coated SiO_2 substrate used as dielectric stack for back-gating yields a stable charge-neutrality point and low hysteresis [12.128] and yields mobilities of up to $10\,000\,cm^2/Vs$. Similar results have been achieved by utilizing an organic polymer buffer between graphene and conventional top-gate dielectrics [12.129]. Large-scale integration of graphene devices can be achieved either by conventional top-down fabrication in the case of epitaxial graphene on SiC [12.67] or CVD graphene grown on metallic substrates and transferred to dielectric substrates. In the case of solution-phase graphene, bottom-up approaches such as dielectrophoretic trapping can achieve similar ultralarge-scale integration densities [12.130].

In an effort to realize commercial viability of graphene electronics, rGO has been explored as an alternative to pristine monolayer graphene. However, measurements in individual monolayer rGO flakes have yielded conductivities ranging between 0.05 and $2\,S/cm$ and field-effect mobilities of $2–200\,cm^2/Vs$ at room temperature. Conductivity decreases by up to three orders of magnitude when measured down to 4 K, following a $T^{-1/3}$ dependence, suggesting a variable range-hopping conduction between regions of highly reduced (nearly pristine) graphene islands separated by defective or poorly reduced regions.

High-Frequency Transistors

Charge carriers in graphene have very high mobility, which is not significantly affected by doping, leading to ballistic transport on a submicron scale even at room temperature. This is a much sought-after characteristic for the next generation of electronic materials, since it would allow for very fast switching times, perhaps less than 10^{-13} seconds. The low on-off ratio (< 100) in gapless graphene is not a fundamental limitation for high-frequency operation. Transistors fabricated on epitaxial graphene on SiC have achieved cutoff frequency of 100 GHz (Fig. 12.22) [12.131] and those fabricated on conventional Si/SiO_2 substrates have reached a cutoff frequency of 26 GHz [12.132].

Heterostructures and Tunneling Transistors

Graphene devices on standard SiO_2 substrates are highly disordered, exhibiting characteristics that are far inferior to the expected intrinsic properties of graphene. There is a need, therefore, for dielectrics that allow a substrate-supported geometry while retaining the intrinsic graphene quality. Hexagonal boron nitride, or hBN, offers an atomically smooth surface that is relatively free of dangling bonds and charge traps [12.133]. It also has a lattice constant similar to that of graphite, and has large optical phonon modes and a large electrical bandgap. A carrier mobility of $60\,000\,cm^2/V/s$ is obtained, which is three times larger than that on SiO_2.

An obstacle to the use of graphene as an alternative to silicon electronics has been the absence of

an energy gap between its conduction and valence bands, which makes it difficult to achieve low-power dissipation in the off state, as we have encountered previously. This can be overcome in a bipolar field-effect transistor that exploits the low density of states in graphene and its one-atomic-layer thickness. These devices consist of graphene heterostructures with atomically thin boron nitride or molybdenum disulfide acting as a vertical transport barrier (Fig. 12.23a) [12.134]. The flow of charge carriers between the top and bottom graphene electrode occurs by tunneling across the semiconducting transport barrier, which can be

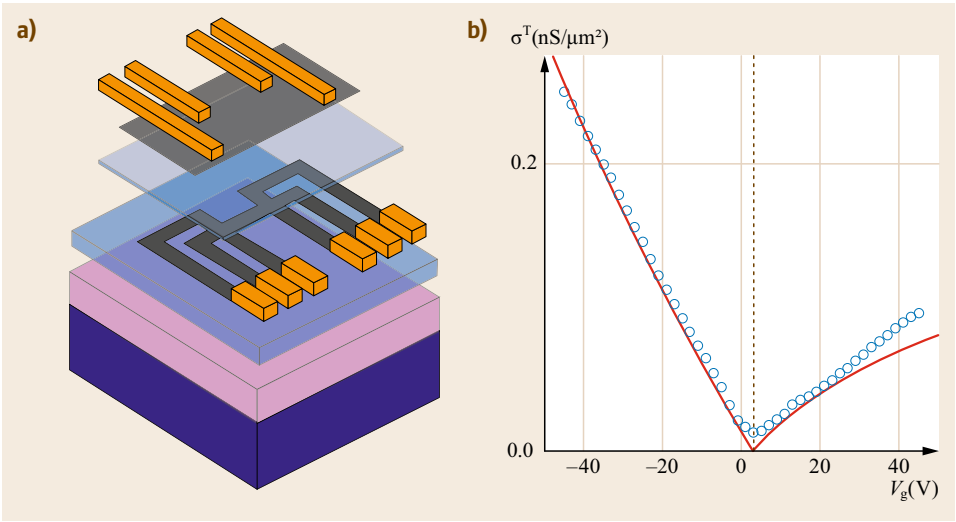

Fig. 12.23 **(a)** Schematic of a 2-D heterostructure device comprised of graphene (*black*) and hBN (*blue*) layers, on top if a SiO_2 surface (*purple*), and contacted by gold (*yellow*) electrodes. **(b)** Tunneling current versus gate voltage behavior (transfer characteristics of such a device) (after [12.134, 135])

modulated by a gate (Fig. 12.23b) [12.135]. Such devices exhibit room-temperature switching ratios of ≈ 50 for hBN and $\approx 10\,000$ for MoS_2 tunnel barriers.

As we have seen before, 2-D materials are also naturally transparent and often demonstrate a significant Young's modulus and breaking strength. 2-D materials-based heterostructures may be attractive solutions for transparent and flexible electronics. Tunneling transistors are only a few atomic layers thick and should not experience any bending-induced effects due to their vertical geometry. Therefore, vertical heterostructures have also been produced on a flexible substrates such as a polyethylene terephthalate (PET) film [12.136].

12.4.5 Spintronics

When graphene devices are fabricated with ferromagnetic electrodes, such as the soft magnetic NiFe or Co, it is possible to inject spin-polarized current into the graphene. A thin Al_2O_3 or MgO tunnel barrier is used at the ferromagnet-graphene interface. High-quality graphene enjoys ballistic transport with spin relaxation lengths between 1.5 μm and 2 μm even at room temperature, which is only weakly dependent on charge density [12.137]. The switching fields of the electrodes can be controlled by in-plane shape anisotropy. Graphene spin-valves have been constructed using either a local [12.138] or nonlocal [12.137, 139] geometry, and a clear bipolar spin signal has been observed, which is indicative of the relative magnetization directions of the electrodes (Fig. 12.24) and magnetoresistance of up to 12% has been reported in local geometry. An alternative configuration, comprised of a graphene monolayer sandwiched between two ferromagnetic layers, involves spin-polarized conduction perpendicular to the plane of the graphene in a CPP (conduction perpendicular to plan) geometry [12.140].

12.4.6 Photonics and Optoelectronics

Graphene enjoys broadband absorption of light, and therefore does not suffer from a *long-wavelength limit* of semiconductors, which become transparent at incident energies smaller than their bandgap. As a result, graphene-based photodetectors have been demonstrated to work over a much broader wavelength range. The photoresponse does not degrade for optical intensity modulations up to 40 GHz, with ultrafast response due to the high carrier mobility in graphene [12.141]. Graphene can also be used as the nonlinear saturable absorber in mode locking for ultrafast laser systems, which turns a continuous wave into a train of ultrafast optical pulses [12.142]. Graphene dispersions have been used as wideband optical limiters covering the visible and infrared regions of the spectrum [12.143].

12.4.7 Filters and Barriers

Graphene oxide sheets can be assembled into a paper-like material (Fig. 12.25a) under a directional flow, for instance by filtration of the aqueous colloidal GO through a membrane filter followed by air drying and peeling from the filter or dissolution of the fil-

ter [12.144]. The typical thickness of this paper ranges from submicron to tens of microns. The resulting GO paper can be cut and shaped with a knife or scissors similar to traditional paper. If the GO dispersion is first reduced, for example using hydrazine, to form a rGO colloid, followed by filtration, this results in a rGO paper (Fig. 12.25b) [12.77]. The as-prepared rGO paper displays a shiny metallic luster on both sides. These consist of well-packed layers through almost the entire cross-section of the paper.

Submicrometer-thick membranes of GO are completely impermeable to most liquids, vapors, and gases, including helium. However, for water, the evaporation rate through a GO paper is practically the same as in the absence of the GO film; that is, for the open aperture (Fig. 12.25c) [12.145]. A rGO membrane, in contrast, is

impermeable to water. Therefore, GO membranes can be used as barrier films in the design of filtration and separation materials and for selective removal of water, such as from alcohols, fuels, etc. GO membranes can also act as molecular sieves towards solutes dissolved in water, allowing fast permeation of solutes smaller than a sharp hydration radius cut-off, and acting as a barrier to solutes larger than this sharp cut-off [12.146].

It was observed that graphene films grown by chemical vapor deposition protect the surface of the metallic growth substrates of Cu and Cu/Ni alloys from air oxidation [12.147]. Unfortunately, it was found that while graphene indeed protects Cu from thermal oxidation reasonably well at high temperatures over relatively short timescales (minutes to hours), graphene greatly promotes galvanic corrosion of Cu at ambient temperature over long timescales (months to years) and can in fact be a much worse long-term anticorrosion barrier than no coating at all. Bare Cu forms a passivating native oxide, which limits further corrosion by blocking the half-reactions needed to continue oxidation [12.148]. A graphene coating on Cu slows diffusion of O_2/H_2O but assists long-term Cu corrosion in a number of ways: by maintaining a conductive pathway across the Cu surface and to selected regions of the Cu, where it maintains intimate contact; by causing nonuniform oxidation, beginning in locations of graphene defects, which leads to stress and cracking of the oxide; and providing an electrochemical driving force (graphitic materials are cathodic to many corrosion-prone metals). A solution-coated rGO membrane is one solution to accomplish large-area, multilayer and continuous barrier coatings, which also possess mechanical integrity, to avoid corrosion nucleation [12.149].

12.4.8 Supercapacitors

For capacitive energy storage, two types of systems can be used, either an electrical double-layer capacitor or a pseudocapacitor. Pure graphene electrodes are used for electrical double-layer capacitors [12.150], while polyaniline (PANI) is a material of choice for pseudocapacitors. In an electrical double-layer capacitor (EDLC), such as with graphene electrodes, the charge is stored electrostatically in a Helmholtz double layer at the electrode–electrolyte interface. There is no electrode–electrolyte charge transfer. In the case of pseudocapacitors, charge is stored electrochemically or Faradaically, where charge is reversibly transferred between the electrode and electrolyte through redox reactions. EDLCs possess good electrical conductivity and long cycle life, but relatively low specific capacitance, while pseudocapacitors have high specific capacitance but poor stability and slow charge–discharge rates. An emerging class of supercapacitors called hybrid supercapacitors utilize both ways of energy storage, and electrodes for such hybrid supercapacitors could be made of a graphene-PANI layered material [12.151].

12.4.9 Biomedical Applications

There have been multiple conflicting reports about the biocompatibility and antimicrobial activity of graphene oxide. Lately, it is perhaps becoming clearer that purified and well-prepared graphene oxide is not antibacterial. Bacteria have been shown to grow faster and to a higher optical density with GO added to the culture media or on a GO-coated surface than cultures without GO [12.152] indicating that GO is not a bactericidal or bacteriostatic material, but instead is a general growth enhancer that acts as a scaffold for cell-surface attachment and proliferation. Numerous papers have explored the biocompatibility and toxicology of GO with various animal and human cell types, and in general, GO has proven biocompatible and nontoxic at moderate dosages [12.153]. For example, GO is biocompatible with blood cells, so this will pave the way for further development of GO for targeted drug delivery and other biomedical applications. GO and rGO form excellent planar as well as 3-D scaffolds for a variety of cells, particularly promoting cell adhesion (Fig.12.26) [12.154, 155]. Graphene has the potential as a surface coating material for implants. Graphene and GO have also been shown to be biocompatible with stem cells and support stem cell attachment and proliferation [12.156]. Graphene could also serve as a scaffold for stem-cell differentiation and offer control over the differentiation pathway. Finally, due to its electrical conductivity, graphene can also form a conductive scaffold to electrically stimulate cells such as nerve cells [12.155].

While graphene is intrinsically nondispersible in water, various modifications and functionalizations can be undertaken to make it dispersible and stable in water and other aqueous physiological media. For applications in drug delivery, very small flakes of graphene known as nanographene or graphene quantum dots are used. For instance, a polyethyleneglycol (PEG) stabilized nanographene exhibited no apparent in vitro and in vivo toxicity [12.157]. Since these graphene quantum dots are intrinsically fluorescent, they could be used for bio-imaging and sensing platforms, and drug delivery systems.

Often, the graphene used for drug delivery is what is known as nanographene, with very small flake sizes of less than 100 nm, small enough to enter individual cells, and we will see an example of this later. Other approaches include graphene/polymer composite systems

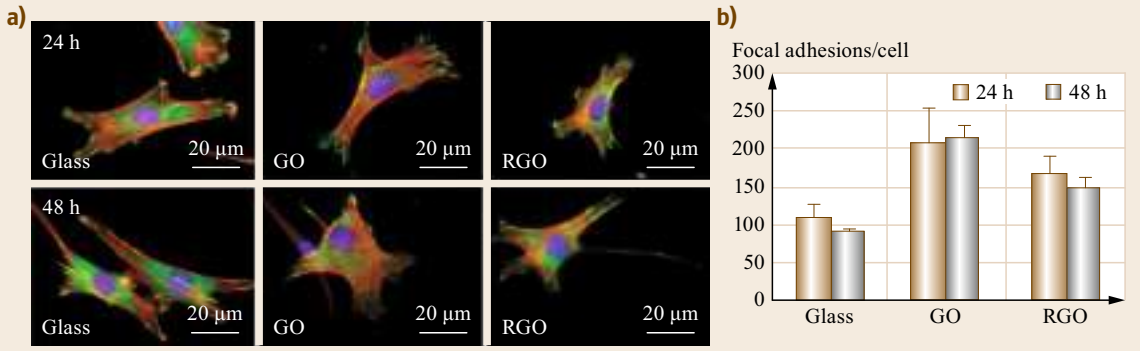

Fig. 12.26 **(a)** Cell adhesion patterns of NIH-3T3 fibroblasts on glass, GO and rGO. Reprinted with permission from [12.154]. Copyright (2010) American Chemical Society. **(b)** Quantitative analysis of cell adherence based on average focal adhesion number per cell

for stimulated drug delivery [12.158]. Graphene can also be used as a nontoxic nanovehicle for efficient gene transfection [12.159]. The PEGylated nanographene exhibits excellent tumor uptake and has strong optical absorbance in the near-infrared (NIR) region, which can be exploited for in vivo photothermal therapy, achieving ultra-efficient tumor ablation after intravenous administration and low-power NIR laser irradiation on the tumor [12.160]. Clinical use of various potent pharmacophoric molecules, many of which are aromatic, is often hampered by their poor solubility in water. Nanographene sheets exhibit a strong noncovalent association with hydrophobic aromatic drugs via physical adsorption and can be used as a vector to deliver such drugs [12.161].

With the development of its biomedical applications, the safety of GO, especially when it enters the body, is of concern to the scientific community and also the public. Towards this, the biodistribution of GO flakes of different sizes at different doses in healthy adult male mice by intravenous (IV) administration has been studied. After IV injection, small GO mainly accumulated in liver, while for large GO the lungs became the main accumulating organs [12.162]. On the other hand, PEG functionalized nanographene mainly accumulated in the reticuloendothelial system such as liver and spleen [12.163]. However, despite this accumulation, no obvious toxicity to mice was observed. Such investigations further strengthen the case for biomedical applications of graphene.

12.5 Conclusions and Outlook

The field of graphene research is still very much in its early stages, with a majority of researchers devoted to exploring the fundamental properties of graphene. Not only is graphene a new material, it is also quite literally a new dimension of possibilities. A lot of mystery still surrounds this exciting new material, and often one finds that theoretical predictions are well ahead of experimental data in an emerging field such as this. Exciting physics that only occurs in two dimensions and previously inaccessible in experiments is now being sought and new results are published regularly. Now that graphene has laid to rest the question of whether 2-D materials can exist in a stable self-supported form, researchers have started the hunt for other such 2-D materials. Boron nitride and molybdenum disulphide are the candidates that have attracted significant attention, particularly for their potential in combination with graphene.

Only recently, applications of the extraordinary properties of graphene have been experimentally demonstrated, and a still greater number of potential applications are still on the drawing board. In fact, only recently has the bulk production of graphene in sheet or solution form been achieved, but the economies of scale are still unfavorable for mass application. The commercial prospects of graphene remain unexplored, but it is hoped that in the near future, the substantial research and investment into graphene will be vindicated. But for a scientist motivated by the quest for new knowledge and understanding, graphene continues to reap rich rewards, as evidenced by the numerous results included here that were only published for the very first time during the duration of writing this chapter.

13. MEMS/NEMS Devices and Applications

Philip X.-L. Feng, Darrin J. Young, Christian A. Zorman

Microelectromechanical systems (MEMS) have played key roles in many important areas, for example, transportation, communication, automated manufacturing, environmental monitoring, healthcare, defense systems, and a wide range of consumer products. MEMS are inherently small, thus offering attractive characteristics such as reduced size, weight, and power dissipation and improved speed and precision compared to their macroscopic counterparts. Integrated circuits (IC) fabrication technology has been the primary enabling technology for MEMS besides a few special etching, bonding and assembly techniques. Microfabrication provides a powerful tool for batch processing and miniaturizing electromechanical devices and systems to a dimensional scale that is not accessible by conventional machining techniques. As IC fabrication technology continues to scale toward deep submicrometer and nanometer feature sizes, a variety of nanoelectromechanical systems (NEMS) have been rapidly emerging. Nanoscale mechanical devices and systems integrated with nanoelectronics will open a vast number of new exploratory research areas in science and engineering. NEMS will most likely serve as an enabling technology, merging engineering with the fundamental physics, quantum science, and life sciences in ways that are not currently feasible with microscale tools and technologies.

MEMS has been applied to a wide range of fields. Hundreds of microdevices have been developed for specific applications. It is thus difficult to provide an overview covering every aspect of the topic. In this chapter, key aspects of MEMS technology and applications are illustrated by selecting a few demonstrative device examples, such as pressure sensors, inertial sensors, optical and wireless communication devices. Microstructure examples with dimensions on the order of submicrometer are presented with fabrication technologies for emerging NEMS applications.

Although MEMS has experienced significant growth over the past decade, many challenges still remain. In broad terms, these challenges can be grouped into three general categories: (1) fabrication challenges; (2) packaging challenges; and (3) application challenges. Challenges in these areas will, in large measure, determine the commercial success of a particular MEMS device in both technical and economic terms. This chapter presents a brief discussion of some of these challenges as well as possible approaches to addressing them.

Microelectromechanical systems (MEMS) have enjoyed decades of research and development. Besides the traditional microfabricated sensors and actuators, the field covers microelectromechanical structures, components and devices integrated or microassembled with electronics on the same substrate or package, achieving operational systems with new enabling functions and high performance that are competitive with, or often superior to, those of their conventional counterparts. These devices and systems have played increasingly important roles in many important areas such as transportation, communication, positioning, navigation, timing, automated manufacturing, environmental monitoring, healthcare, defense systems and a wide range of

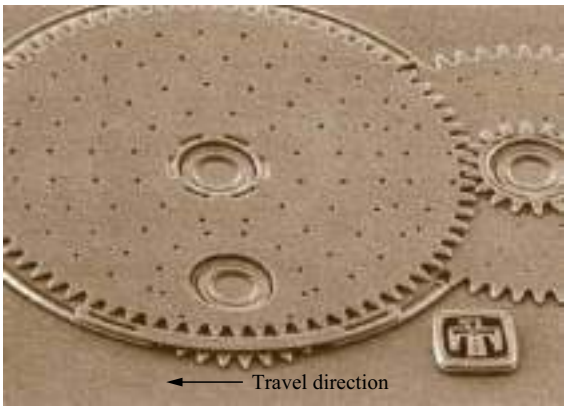

Fig. 13.2 SEM micrograph of polysilicon microgears (after [13.3])

consumer products. MEMS are inherently miniature, thus offering attractive characteristics such as reduced size and volume, low weight, low power dissipation and improved operating speed and precision compared to their macroscopic counterparts. The development of MEMS requires appropriate fabrication technologies that enable the definition of small geometries, precise dimension control, design flexibility, interfacing with microelectronics, repeatability, reliability, high yield and low cost. Relentless advances in integrated circuit (IC) fabrication technologies keep meeting all of the above criteria, and have been the primary enabling fabrication approaches for MEMS, besides some special lithography, etching, bonding and assembly techniques, as supplementary methods. Microfabrication provides a powerful tool for batch processing and miniaturization of electromechanical devices and systems into a dimensional scale, which is not accessible by conventional machining techniques. Most MEMS devices exhibit a length or width ranging from a few micrometers to several hundred micrometers with a thickness from less than a micrometer up to tens of micrometers, depending upon fabrication technique employed. Physical displacements of a sensor or an actuator are typically on the same order of magnitude as the thickness (or width), or smaller. Figure 13.1 shows a scanning electron microcopy (SEM) image of a microelectromechanical motor developed in the late 1980s [13.1]. Polycrystalline silicon (polysilicon or poly-Si) surface-micromachining technology was used to fabricate the micromotor achieving a diameter of 150 μm and a minimum vertical feature size on the order of a micrometer. A probe tip is also shown in the micrograph for a size comparison. This and similar devices [13.2] demonstrated what MEMS technology could accomplish in microscale machining at that time and served as a strong technology indicator for continued MEMS development. The field has expanded greatly over the last two decades along with rapid technology advances. Figure 13.2, for example, shows a photo of microgears fabricated in the mid-1990s using a five-level polysilicon surface-micromachining technology [13.3]. This device represents one of the most advanced surface-micromachining fabrication process developed in the early days. A wide range of sophisticated microelectromechanical devices and systems have been developed through applying such technologies since then.

Since the 1990s, in parallel to the rapid development of MEMS spurred by growing pervasive applications and advances in mainstream fabrication technologies in the semiconductor industry, physicists and engineers have also been actively exploring various means for patterning and fabricating suspended, mechanically free-to-move nanoscale structures, and engineering such nanostructures into nanoelectromechanical systems (NEMS). As IC fabrication technologies continue to scale toward deep submicron and nanometer feature sizes, this has been envisioned as a new reinforcing trend for more mature MEMS and has been rapidly emerging since the 2000s. Nanoscale electromechanical devices and systems integrated with nanoelectronics promise to open a vast number of new exploratory research areas in science and engineering. From a historical perspective, NEMS have been a fascinating frontier where mesoscopic physics meets advanced engineering, and where the *top-down* paradigm (e.g., nanolithography and nanomachining) meets the *bottom-up* nanofabrication approaches (e.g., growth, synthesis and

self-assembly processes). NEMS will most likely serve as an enabling technology merging engineering with the physical sciences, precision instruments, novel analytical tools for the life sciences and medicine, etc., in ways that are not currently feasible with the microscale tools and technologies.

This chapter will provide a general overview on MEMS and NEMS devices along with their mainstream and emerging applications. MEMS technology has been applied to a wide range of fields. Over hundreds of types of microdevices have been developed for specific applications. Thus, it is difficult to provide an overview covering every aspect of the field. It is the authors' intent to illustrate key aspects of MEMS technology and its impact to specific applications by selecting a few demonstrative device examples in this chapter. For a wide-ranging discussion of nearly all types of micromachined sensors and actuators, books by *Kovacs* [13.4] and *Senturia* [13.5] are recommended.

13.1 MEMS Devices and Applications

MEMS devices have played key roles in many areas of development. Microfabricated sensors, actuators and electronics for MEMS-IC integration are the most critical components required to implement a complete microsystem for a specific function. Microsensors and actuators can be fabricated by various micromachining processing technologies. In this section, a number of selected MEMS devices are presented to illustrate the basic device operating principles as well as to demonstrate key aspects of the microfabrication technology and application impact.

13.1.1 Pressure Sensor

Pressure sensors were one of the early devices developed by silicon (Si) micromachining technologies and have already become successful commercial products. MEMS pressure sensors and their variant devices have been widely used in various industrial and biomedical applications. These sensors can be based on piezoelectric, piezoresistive, capacitive and resonant sensing mechanisms. Si bulk and surface-micromachining techniques have been used for batch fabrication of pressure sensors, thus achieving size miniaturization and low cost. Two types of pressure sensors, piezoresistive and capacitive, are described here for an illustration purpose.

Piezoresistive Pressure Sensor

The piezoresistive effect in Si has been widely used for implementing pressure sensors. A pressure-induced strain changes the Si band structure, thus changing the resistivity of the crystal. The piezoresistive effect is typically crystal orientation-dependent and is also affected by doping and temperature. A practical piezoresistive pressure sensor can be implemented by fabricating four sensing resistors along the edges of a thin silicon diaphragm, which acts as a mechanical amplifier to increase the stress and strain at the sensor site. The four sensing elements are connected in a bridge configuration with push–pull signals to increase the responsivity and sensitivity. The measurable pressure range for such a sensor can be from 10^{-3} to 10^{6} Torr depending upon the design. An example of a piezoresistive pressure sensor is shown in Fig. 13.3. The device consists of a Si diaphragm suspended over a reference vacuum cavity to form an absolute pressure sensor. An external pressure applied over the diaphragm introduces a stress on the sensing resistors, thus resulting in a resistance value change corresponding to the pressure. The fabrication sequence is outlined as follows. The piezoresistors are typically first formed through a boron diffusion process followed by a high-temperature annealing step in order to achieve a resistance value on the order of a few kilo-ohms (kΩ). The wafer is then passivated with a silicon dioxide (SiO_2) layer and contact windows are opened for metallization. At this point, the wafer is patterned on the backside, followed by a timed Si wet etch to form the diaphragm, typically having a thickness around a few tens of micrometers. The diaphragm can have a length of several hundreds of micrometers. A second Si wafer is then bonded to the device wafer in vacuum to form a reference vacuum cavity, thus completing the fabrication process. The second wafer

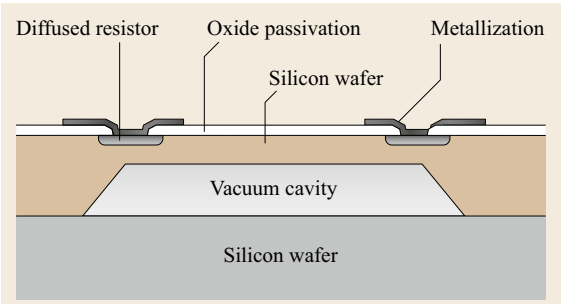

Fig. 13.3 Cross-sectional schematic of a piezoresistive pressure sensor

can also be further etched through to form an inlet port, implementing a gauge pressure sensor [13.6]. The piezoresistive sensors are simple to fabricate and can be readily interfaced with electronic systems. However, the resistors are temperature-dependent and consume DC power. Long-term characteristic drift and resistor thermal noise ultimately limit the sensor detection resolution.

Capacitive Pressure Sensor

Capacitive pressure sensors are attractive because they are virtually temperature-independent and consume zero DC power. The devices do not exhibit initial turn-on drift and are stable over time. Furthermore, CMOS (complementary metal-oxide-semiconductor) microelectronic circuits can be readily interfaced with the sensors to provide advanced signal conditioning and processing, thus improving overall system performance. An example of a capacitive pressure sensor is shown in Fig. 13.4. The device consists of an edge-clamped Si diaphragm suspended over a vacuum cavity. The diaphragm can be square or circular with a typical thickness of a few micrometers and a length or radius of a few hundred micrometers, respectively. The vacuum cavity typically has a depth of a few micrometers. The diaphragm and substrate form a pressure-dependent air-gap variable capacitor. An increased external pressure causes the diaphragm to deflect towards the substrate, thus resulting in an increase in the capacitance value. A simplified fabrication process can be outlined as follows. A Si wafer is first patterned and etched through to form the cavity. The wafer is then oxidized followed by bonding to a second Si wafer with a heavily-doped boron layer, which defines the diaphragm thickness, at the surface. The bonding process can be performed in vacuum to create the vacuum cavity. If the vacuum bonding is not performed at this stage, a low-pressure sealing process can be used to form the vacuum cavity after patterning the sensor diaphragm, provided that sealing channels are available. The Si substrate above the boron layer is then removed through a wet-etching process, followed by patterning to form the sensor diaphragm, which serves as the device top electrode. Contact pads are formed by metallization and patterning. This type of pressure sensor exhibits a nonlinear characteristic and a limited dynamic range. These phenomena, however, can be alleviated through applying an electrostatic force-balanced feedback architecture. A common practice is to introduce another electrode above the sensing diaphragm through wafer bonding [13.7], thus forming two capacitors in series with the diaphragm being the middle electrode. The capacitors are interfaced with electronic circuits, which convert the sensor capacitance value to an output voltage corresponding to the diaphragm position. This voltage is further processed to generate a feedback signal to the top electrode, thus introducing an electrostatic pull up force to maintain the deflectable diaphragm at its nominal position. This negative feedback loop would substantially minimize the device nonlinearity and also extend the sensor dynamic range.

A capacitive pressure sensor achieving an inherent linear characteristic response and a wide dynamic range can be implemented by employing a touch-mode architecture [13.8]. Figure 13.5 shows the cross-sectional view of a touch-mode pressure sensor. The device consists of an edge-clamped Si diaphragm suspended over a vacuum cavity. The diaphragm deflects under an increasing external pressure and touches the substrate, causing a linear increase in the sensor capacitance value beyond the touch-point pressure. Figure 13.6 shows a typical device characteristic curve. The touch-point pressure can be designed through engineering the sensor geometric parameters such as the diaphragm size, thickness, cavity depth, etc. for various application requirements. The device can be fabricated using a process flow similar to the flow outlined for the basic capacitive pressure sensor. Figure 13.7 presents a photo of a fabricated touch-mode sensor employing a circular diaphragm with a diameter of 800 μm and a thickness of 5 μm suspended over a 2.5 μm vacuum cavity. The device achieves a touch-point pressure of 8 psi and exhibits a linear capacitance range from 33 pF at 10 psi to 40 pF at 32 psi (absolute pressures).

The above processes use bulk Si materials for machining and are usually referred to as bulk microma-

chining. The same devices can also be fabricated using surface micromachining. Surface-micromachining technology is attractive for integrating MEMS sensors with on-chip electronic circuits. As a result, advanced signal processing capabilities such as data conversion, offset and noise cancellation, digital calibration, temperature compensation, etc. can be implemented adjacent to microsensors on the same substrate, providing a complete high-performance microsystem solution. The single chip approach also eliminates external wiring, which is critical for minimizing noise pickup and enhancing system performance. Surface micromachining, simply stated, is a method of fabricating MEMS through depositing, patterning and etching a sequence of thin films with thicknesses on the order of a micrometer. Figure 13.8 illustrates a typical surface-micromachining process flow [13.10]. The process starts by depositing a layer of sacrificial material such as SiO_2 over a wafer followed by anchor formation. A structural layer, typically a poly-Si film, is deposited and patterned. The underlying sacrificial layer

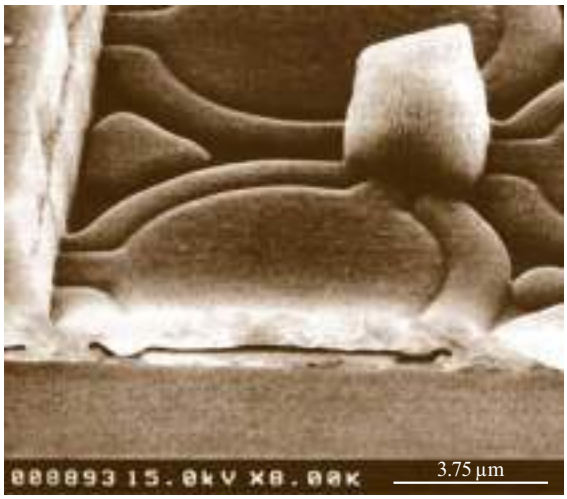

Fig. 13.10 SEM micrograph of a close-up view of a polysilicon surface-micromachined capacitive pressure sensor (after [13.9])

is then removed to freely release the suspended microstructure and to complete the fabrication sequence. The processing materials and steps are compatible with standard integrated circuit process, thus can be readily incorporated as an add-on module to an IC process [13.10–12]. A similar surface-micromachining technology has been developed to produce monolithic pressure sensor systems [13.13]. Figure 13.9 shows an SEM micrograph of an array of MEMS capacitive pressure sensors fabricated with BiCMOS electronics on the same substrate. Each sensor consists of a 0.8 µm thick circular poly-Si membrane with a diameter on the order of 20 µm suspended over a 0.3 µm deep vacuum cavity. The devices operate using the same principle as the sensor shown in Fig. 13.4. A close-up view of the sensor cross-section is shown in Fig. 13.10, which shows the suspended membrane and underneath air gap. These sensors have demonstrated operations in pressure ranges up to 400 bar with an accuracy of 1.5%.

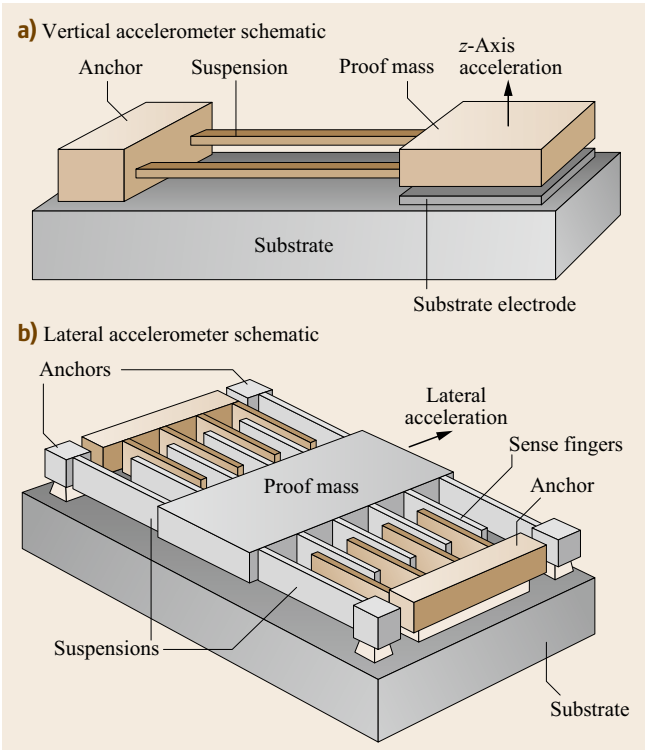

Fig. 13.11a,b Schematics of vertical (a) and lateral (b) accelerometers

13.1.2 Inertial Sensor

Micromachined inertial sensors consist of accelerometers and gyroscopes. These devices are one of the important representative types of Si MEMS sensors that have been successfully commercialized. MEMS accelerometers alone have the second largest sales volume after pressure sensors. Gyroscopes are expected to reach a comparable sales volume in the foreseeable future. Accelerometers have been used in a wide range of applications including automotive application for safety systems, active suspension and stability control, biomedical application for activity monitoring, and numerous consumer products such as head-mount displays, camcorders and three-dimensional mice. High-

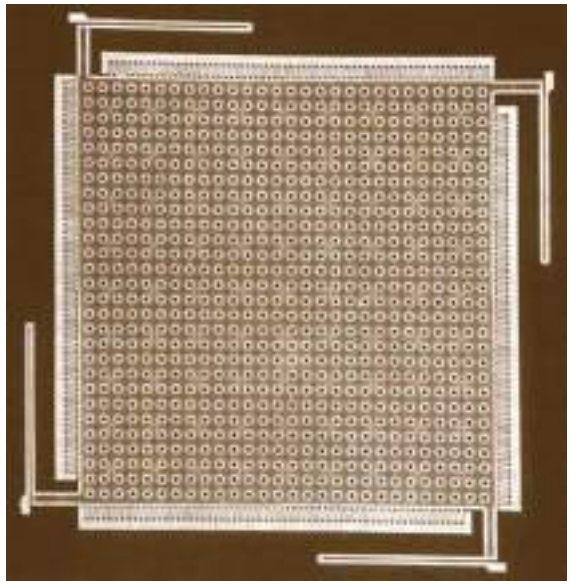

Fig. 13.12 SEM micrograph of a polysilicon surface-micromachined z-axis accelerometer (after [13.14])

sensitivity accelerometers are crucial for implementing self-contained navigation and guidance systems. A gyroscope is another type of inertial sensor that measures rate or angle of rotation. The devices can be used along with accelerometers to provide heading information in an inertial navigation system. Gyroscopes also are useful in applications such as automotive ride stabilization and rollover detection, camcorder stabilization and virtual reality. Inertial sensors fabricated by micromachining technology can achieve reduced size, weight and cost, all of which are critical for consumer applications. More importantly, these sensors can be integrated with microelectronic circuits to achieve a functional microsystem with high performance.

Accelerometer

An accelerometer generally consists of a proof mass suspended by compliant mechanical suspensions anchored to a fixed frame. An external acceleration displaces the support frame relative to the proof mass. The displacement can result in an internal stress change in the suspension, which can be detected by piezoresistive sensors as a measure of the external acceleration. The displacement can also be detected as a capacitance change in capacitive accelerometers. Capacitive sensors are attractive for various applications because they exhibit high sensitivity and low temperature-dependence, turn-on drift, power dissipation and noise. The sensors can also be readily integrated with CMOS electronics to perform advanced signal processing for high system-level performance. Capacitive accelerometers may be divided into two categories: vertical- and lateral-type sensors. Figure 13.11 shows sensor structures for the two versions. In a vertical device, the proof mass is suspended above the substrate electrode by a small gap typically on the order of a micrometer, forming a parallel-plate sense capacitance. The proof mass moves in the direction perpendicular to the substrate

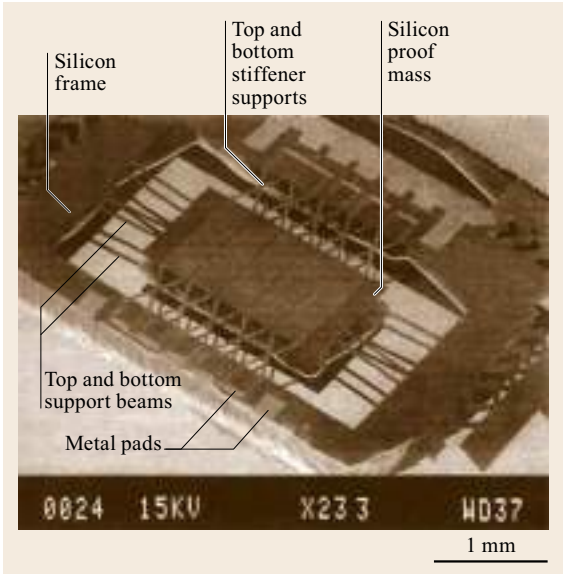

Fig. 13.13 SEM micrograph of a MEMS z-axis accelerometer fabricated using a combined-surface and bulk-micromachining technology (after [13.15])

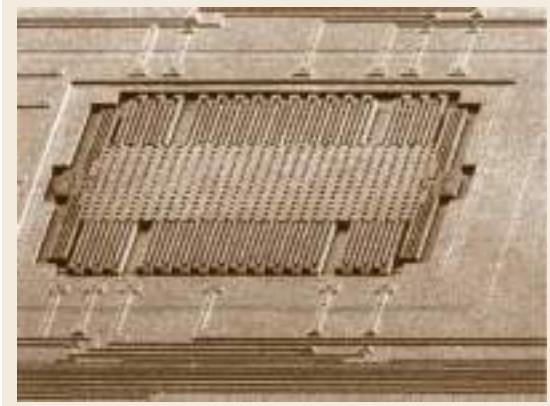

Fig. 13.14 SEM micrograph of a polysilicon surface-micromachined lateral accelerometer (Copyright Analog Devices Inc.)

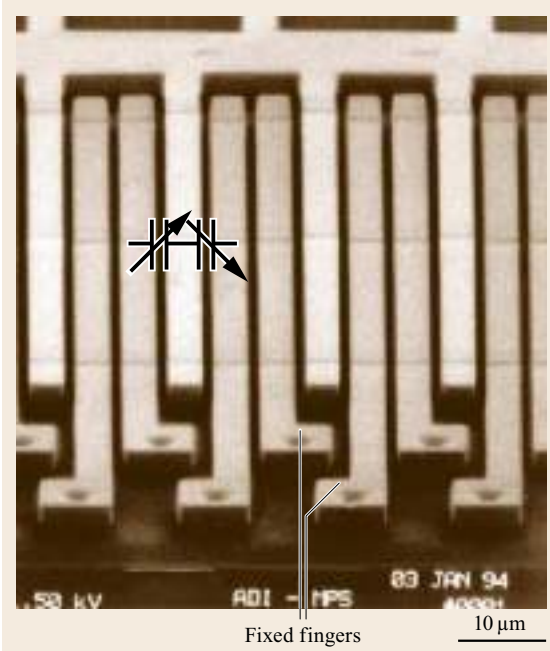

Fig. 13.15 SEM micrograph of a capacitive sensing finger structure

(z-axis) upon a vertical input acceleration, thus changing the gap and hence the capacitance value. The lateral accelerometer consists of a number of movable fingers attached to the proof mass, forming a sense capacitance with an array of fixed parallel fingers. The sensor proof mass moves in a plane parallel to the substrate when subjected to a lateral input acceleration, thus changing the overlap area of these fingers and hence the capacitance value. Figure 13.12 shows a top-view SEM image of a surface-micromachined poly-Si z-axis accelerometer [13.14]. The device consists of a 400 μm × 400 μm proof mass with a thickness of 2 μm suspended above the substrate electrode by four folded-beam suspensions with an air gap around 2 μm, thus achieving a sense capacitance of approximately 500 fF. The visible holes are used to ensure complete removal of the sacrificial oxide underneath the proof mass at the end of the fabrication process. The sensor can be interfaced with a microelectronic charge amplifier converting the capacitance value to an output voltage for further signal processing and analysis. Force-feedback architecture can be applied to stabilize the proof mass position. The combs around the periphery of the proof mass can exert an electrostatic levitation force on the proof mass to achieve the position control, thus improving the system frequency response and linearity performance [13.14].

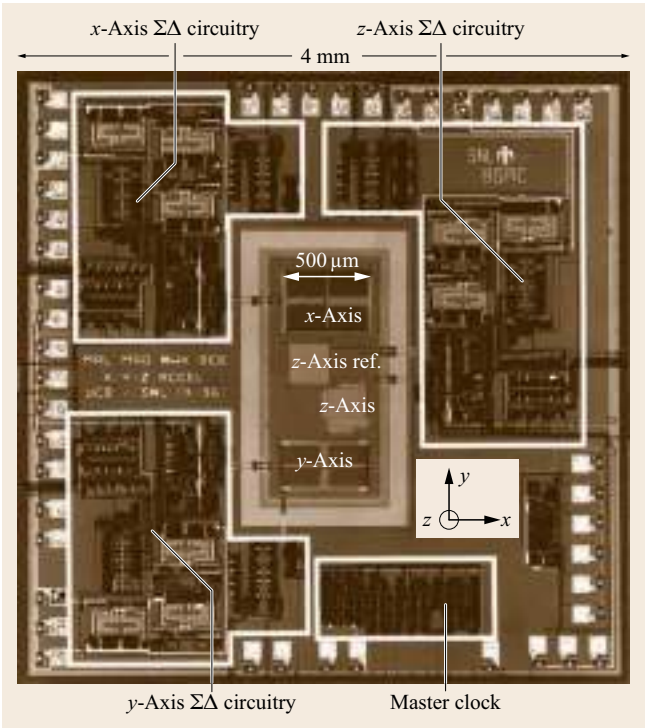

Fig. 13.16 Photo of a monolithic three-axis polysilicon surface-micromachined accelerometer with integrated interface and control electronics (after [13.16])

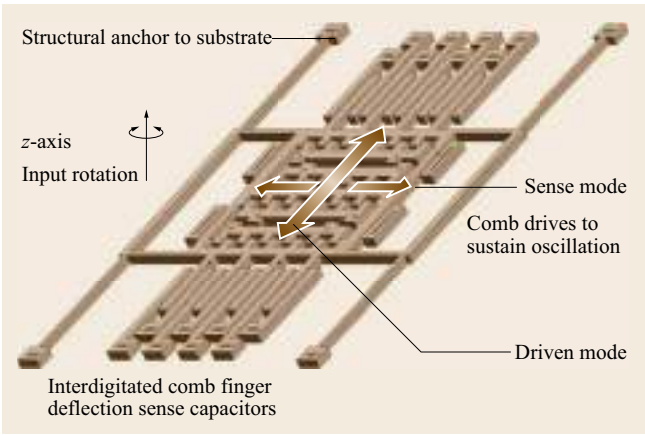

Fig. 13.17 Schematic of a vibratory rate gyroscope

Surface-micromachined accelerometers typically suffer from severe thermomechanical fluctuations, often referred to as Brownian motions [13.17], due to the small proof mass, thus can result in a high mechanical noise floor, which ultimately limits the sensor resolution. Vacuum packaging can be employed to minimize this adverse effect but with a penalty of increasing system complexity and cost. Accelerometers using large proof masses fabricated by bulk micromachining or a combination of surface- and bulk-micromachining techniques are attractive for circumventing this problem. Figure 13.13 shows an SEM micrograph of an all-Si z-axis accelerometer fabricated through a single silicon wafer by using combined-surface and bulk-micromachining processes to obtain a large proof mass with dimensions of approximately 2 mm × 1 mm × 450 μm [13.15]. The large mass suppresses the Brownian motion effect, achieving a high performance with a resolution on the order of several μg.

A surface-micromachined lateral accelerometer developed by Analog Devices Inc. is shown in Fig. 13.14. The sensor consists of a center proof mass supported by folded beam suspensions with arrays of attached movable fingers, forming a sense capacitance with the fixed parallel fingers. The device is fabricated using a 6 μm-thick poly-Si structural layer with a small air gap on the order of a micrometer to increase the sensor capacitance value, thus improving the device resolution. Figure 13.15 shows a close-up view of the finger structure for a typical lateral accelerometer. Each movable finger forms differential capacitances with two adjacent fixed fingers. This sensing capacitance configuration is attractive for interfacing with differential electronic detection circuits to suppress common-mode noise and other undesirable signal coupling. Monolithic accelerometers with a 3-axis sensing capability integrated

with on-chip electronic detection circuits have been developed using surfacing micromachining and CMOS microelectronics fabrication technologies [13.16]. Figure 13.16 shows a photo of one of these microsystem chips, which has an area of 4 mm × 4 mm. One vertical accelerometer and two lateral accelerometers are placed at the chip center with corresponding detection electronics along the periphery. A z-axis reference device, which is not movable, is used with the vertical sensor for electronic interfacing. The prototype system achieves a sensing resolution on the order of 1 mG with a 100 Hz bandwidth along each axis. The level of performance is adequate for automobile safety activation systems, vehicle stability and active suspension control, and various consumer products.

Gyroscope

Most micromachined gyroscopes employ vibrating mechanical elements to sense rotations. The sensors rely on energy transfer between two vibration modes of a structure caused by Coriolis acceleration. Figure 13.17 presents a schematic of a z-axis vibratory rate gyroscope. The device consists of an oscillating mass electrostatically driven into resonance along the drive-mode axis using comb fingers. An angular rotation along the vertical axis (z-axis) introduces a Coriolis acceleration, which results in a structure deflection along the sense-mode axis, shown in the figure. The deflection changes the differential sense capacitance value, which can be detected as a measure of input angular rotation. A z-axis vibratory rate gyroscope operating upon this principle is fabricated using surface-micromachining technology and integrated together with electronic detection circuits, as illustrated in Fig. 13.18 [13.18]. The micromachined sensor is fabricated using poly-Si structural material with a thickness around 2 μm and occupies an area of 1 mm × 1 mm. The sensor achieves a resolution of approximately $1^\circ s^{-1} Hz^{-1/2}$ under a vacuum pressure around 50 mTorr.

A dual-axis gyroscope based on a rotational disk at its resonance can be used to sense angular rotation along two lateral axes (x-axis and y-axis). Figure 13.19 shows a device schematic demonstrating the operating principle. A rotor disk supported by four mechanical suspensions can be driven into angular resonance along the z-axis. An input angular rotation along the x-axis will generate a Coriolis acceleration causing the disk to rotate along the y-axis and vice versa. This Coriolis acceleration-induced rotation will change the sensor capacitance values between the disk and different sensing electrodes underneath. The capacitance change can be detected and processed by electronic interface circuits. Angular rotations along the two lateral axes can be measured simultaneously using this device

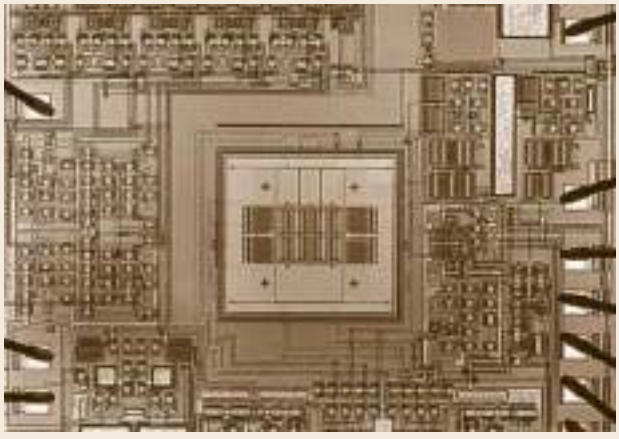

Fig. 13.18 Photo of a monolithic polysilicon surface-micromachined z-axis vibratory gyroscope with integrated interface and control electronics (after [13.18])

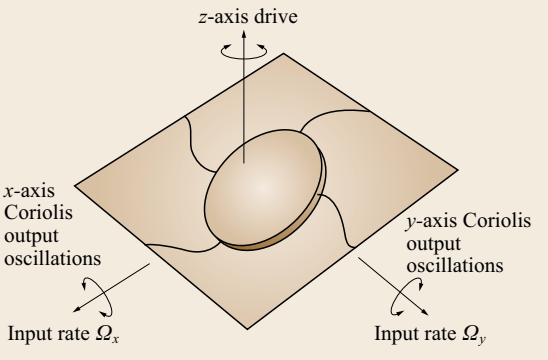

Fig. 13.19 Schematic of a dual-axis gyroscope

architecture. Figure 13.20 shows a photo of a dual-axis gyroscope fabricated using a 2 μm-thick poly-Si surface-micromachining technology [13.19]. As shown in the figure, curved electrostatic drive combs are positioned along the circumference of the rotor dick to drive it into resonance along the vertical axis. The gyroscope exhibits a low random walk of $1^\circ hr^{-1/2}$ under a vacuum pressure around 60 mTorr. With accelerometers and gyroscopes each capable of three-axis sensing, a micromachine-based inertial measurement system providing a six-degrees-of-freedom sensing capability can be obtained. Figure 13.21 presents a photo of such a system containing a dual-axis gyroscope, a z-axis gyroscope, and a three-axis accelerometer chip integrated with microelectronic circuitry. Due to the precision in device layout and fabrication, the system can measure angular rotation and acceleration without the need to align individual sensors.

13.1.3 Optical MEMS

Surface micromachining has served as a key enabling technology to develop microelectromechanical optical devices for various applications ranging from sophisticated visual information displays and fiber-optic telecommunication to barcode reading. Most of the existing optical systems are implemented using conventional optical components, which suffer from bulky size, high cost, large power consumption, poor efficiency and reliability issues. MEMS technology is promising for producing miniaturized, reliable, inexpensive optical components to revolutionize conventional optical systems [13.20]. In this section of the chapter, a few selected MEMS optical devices will be presented to illustrate their impact in the fields of visual display, precision optical platform and data switching for optical communication.

Visual Display

An early MEMS device successfully used for various display applications is the Texas Instruments digital micromirror device (DMD). The DMD technology can achieve higher performance in terms of resolution, brightness, contrast ratio and convergence than the conventional cathode ray tube and is critical for digital high-definition television applications. A DMD consists of a large array of small mirrors with a typical area of $16\,\mu m \times 16\,\mu m$ as illustrated in Fig. 13.22. A probe tip is shown in the figure for a size comparison. Figure 13.23 shows an SEM micrograph of a close-up view of a DMD pixel array [13.21]. Each mirror is capable of rotating by $\pm 10^\circ$ corresponding to either the *on* or *off* position due to an electrostatic actuation force. Light reflected from any on-mirrors passes through a projection lens and creates images on a large screen. Light from the remaining off-mirrors is reflected away from the projection lens to an absorber. The proportion of time during each video frame that a mirror remains in the on-state determines shades of gray, from black for zero on-time to white for a hundred percent on-time. Color can be added by a color wheel or a three-DMD chip setup. The three DMD chips are used for projecting red, green and blue colors. Each DMD pixel consists of a mirror connected by a mirror support post to an underlying yoke. The yoke, in turn, is connected by torsion hinges to hinge support posts, as shown in Fig. 13.24 [13.22]. The support post and hinges are hidden under the mirror to avoid light diffraction and thus improve contrast ratio

and optical efficiency. There are two gaps on the order of a micrometer, one between the mirror and the underlying hinges and address electrodes, and a second between the coplanar address electrodes and hinges and an underlying metal layer from the CMOS static random access memory (SRAM) structure. The yoke is tilted over the second gap by an electrostatic actuation force, thus rotating the mirror plate. The SRAM determines which angle the mirror needs to be tilted by applying proper actuation voltages to the mirror and address electrodes. The DMD is fabricated using an aluminum-based surface-micromachining technology. Three layers of aluminum thin film are deposited and patterned to form the mirror and its suspension system. Polymer material is used as a sacrificial layer and is removed by a plasma etch at the end of the process to freely release the micromirror structure. The micromachining process is compatible with standard CMOS fabrication, allowing the DMD to be monolithically integrated with a mature CMOS address circuit technology, thus achieving high yield and low cost. Figure 13.25 shows an SEM micrograph of a fabricated DMD pixel revealing its cross section after an ion milling. A close-up view on the yoke and hinge support under the mirror is shown in Fig. 13.26.

Precision Optical Platform

The growing optical communication and measurement industry requires low cost, high-performance optoelectronic modules, such as laser-to-fiber couplers, scanners, and interferometers. A precision alignment and

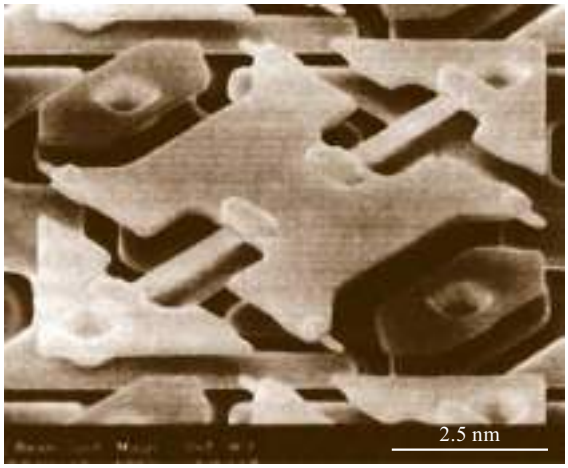

Fig. 13.26 SEM micrograph of a close-up view of a DMD yoke and hinges (after [13.22])

the ability to actuate optical components such as mirrors, gratings, and lenses with sufficient accuracy are critical for high-performance optical applications. Conventional hybrid optical integration approaches, such as the silicon optical bench, suffers from a limited alignment tolerance of $\pm 1\,\mu m$ and also lacks of component actuation capability [13.24, 25]. As a result, only simple optical systems can be constructed with no more than a few components, thus severely limiting the performance. Micromachining, however, provides a critical enabling technology, allowing movable optical components to be fabricated on a silicon substrate. Component movement with high precision can be achieved through electrostatic actuation. By combining micromachined movable optical components with lasers, lenses and fibers on the same substrate, an on-chip complex self-aligning optical system can be developed. Figure 13.27 a shows an SEM micrograph of a surface-micromachined, electrostatically actuated microreflector for laser-to-fiber coupling and external-cavity laser applications [13.23]. The device consists of a polysilicon mirror plate hinged to a support beam. The mirror and the support, in turn, are hinged to a vibromotor-actuator slider. The microhinge technology [13.26] allows the joints to rotate out of the substrate plane to achieve large aspect ratios. Common-mode actuation of the sliders results in a translational motion, while differential slider motion produces an out-of-plane mirror rotation. These motions permit the microreflector to redirect an optical beam in a desirable location. Each of the two slides is actuated with an integrated microvibromotor shown in Fig. 13.27b. The vibromotor consists of four electrostatic comb resonators with attached impact arms driving a slider through oblique impact. The two opposing impactors are used for each

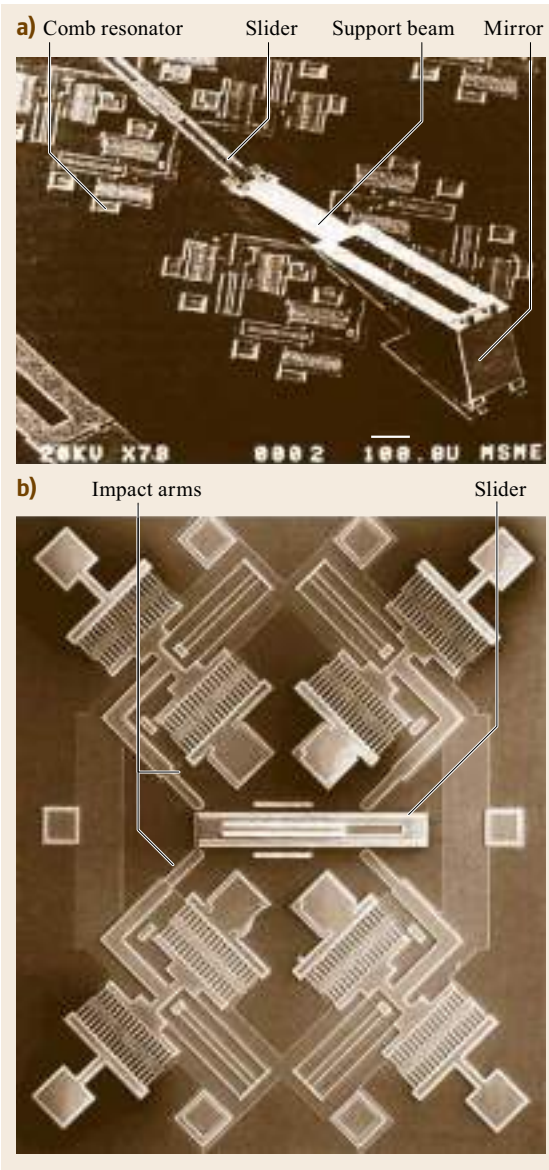

Fig. 13.27 **(a)** SEM micrograph of a surface-micromachined, electrostatically actuated microreflector; **(b)** SEM micrograph of a surface-micromachined vibromotor (after [13.23])

travel direction to balance the forces. The resonator is a capacitively driven mass anchored to the substrate through a folded beam flexure. The flexure compliance determines the resonant frequency and travel range of the resonator. When the comb structures are driven at their resonant frequency (around 8 KHz), the slider exhibits a maximum velocity of over 1 mm/s. Characterization of the vibromotor also shows that a slider step resolution of less than $0.3\,\mu m$ can be achieved [13.27],

making it attractive for precision alignment of various optical components. The prototype microreflector can obtain an angular travel range over 90° and a translational travel range of 60 μm. Using this device, beam steering, fiber coupling and optical scanning have been demonstrated.

Optical Data Switching

High-speed communication infrastructures are highly desirable for transferring and processing real-time voice and video information. Optical fiber communication technology has been identified as the critical backbone to support such systems. A high-performance optical data switching network, which routes various optical signals from sources to destinations, is one of the key building blocks for system implementation. At present, optical signal switching is performed using hybrid optical-electronic-optical (O-E-O) switches. These devices first convert incoming light from input fibers to electrical signals and then route the electrical signals to the proper output ports after signal analyses. At the output ports, the electrical signals are converted back to streams of photons or optical signals for further transmission over the fibers. The O-E-O switches are expensive to build, integrate and maintain. Furthermore, they consume substantial amount of power and introduce additional latency. It is therefore highly desirable to develop an all-optical switching network in which optical signals can be routed without intermediate conversion into electrical form, thus minimizing power dissipation and system delay. While a number of approaches are being considered for building all-optical switches, MEMS technology is attractive because it can provide arrays of tiny movable mirrors which can redirect incoming beams from input fibers to corresponding output fibers. As described in the previous sections, these micromirrors can be batch fabricated using Si micromachining technologies, thus achieving an integrated solution with the potential for low cost. A significant reduction in power dissipation is also expected.

Figure 13.28 shows an architecture of a two-dimensional micromirror array forming a switching matrix with rows of input fibers and columns of output fibers (or vice versa). An optical beam from an input fiber can be directed to an output fiber through activating the corresponding reflecting micromirror. Switches with eight inputs and eight outputs can be readily implemented using this technique, which can be further extended to a 64×64 matrix. The micromirrors are moved between two fixed stops by digital control, thus eliminating the need for precision motion control. Figure 13.29 presents an SEM micrograph of a simple 2×2 MEMS fiber optic switching network prototype for illustration purposes [13.28]. The network includes

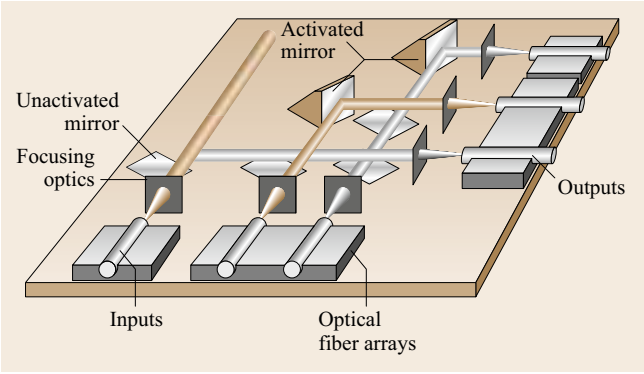

Fig. 13.28 Schematic of a two-dimensional micromirror-based fiber optic switching matrix

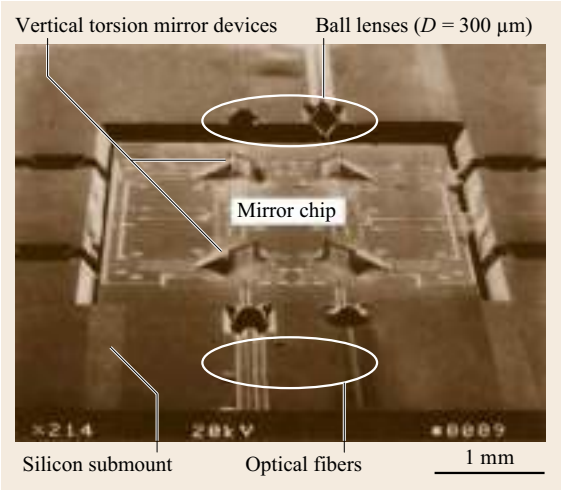

Fig. 13.29 SEM micrograph of a 2×2 MEMS fiber optic switching network (after [13.28])

a mirror chip passively integrated with a silicon submount, which contains optical fibers and ball lenses. The mirror chip consists of four surface-micromachined vertical torsion mirrors. The four mirrors are arranged such that in the *reflection* mode, the input beams are reflected by two 45° vertical torsion mirrors and coupled into the output fibers located on the same side of the chip. In the *transmission* mode, the vertical torsion mirrors are rotated out of the optical paths, thus allowing the input beams to be coupled into the opposing output fibers. Figure 13.30 shows an SEM micrograph of a polysilicon vertical torsion mirror. The device consists of a mirror plate attached to a vertical supporting frame by torsion beams and a vertical back electrode plate. The mirror plate is approximately 200 μm wide, 160 μm long, and 1.5 μm thick. The mirror surface is coated with a thin layer of gold to improve the optical reflectivity. The back plate is used to electrostatically

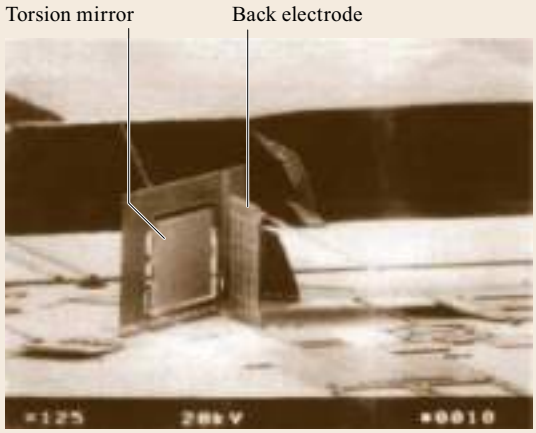

Fig. 13.30 SEM micrograph of a polysilicon surface-micromachined vertical torsion mirror (after [13.28])

actuate the mirror plate so that the mirror can be rotated out of the optical path in the *transmission* mode. Surface micromachining with microhinge technology is used to realize the overall structure. The back electrode plate is integrated with a scratch drive actuator array [13.29] for self-assembly. The self-assembly approach is critical when multiple vertical torsion mirrors are used to implement more advanced functions.

A more sophisticated optical switching network with a large scaling potential can be implemented using a three-dimensional (3-D) switching architecture as shown in Fig. 13.31. The network consists of arrays of two-axis mirrors to steer optical beams from input fibers to output fibers. A precision analog closed-loop mirror position control is required to accurately direct a beam along two angles so that one input fiber can be optically connected to any output fiber. The optical length depends little on which set of fibers are connected, thus achieving a more uniform switching characteristic, which is critical for implementing a large scale network. Two-axis mirrors are the crucial components for implementing the 3-D architecture. Figure 13.32 shows an SEM micrograph of a surface-micromachined two-axis beam-steering mirror positioned using a self-assembly technique [13.30]. The self-assembly is accomplished during the final release step of the mirror processing sequence. Mechanical energy is stored in a special high-stress layer during the deposition, which is put on top of the four assembly arms. Immediately after the assembly arms are released, the tensile stress in this layer causes the arms to bend up, pushing the mirror frame and lifting it above the silicon substrate. All mirrors used in the switching network can be fabricated simultaneously without any human intervention or external power supply.

Fig. 13.31 Schematic of a three-dimensional micromirror-based fiber optic switching matrix

13.1.4 RF MEMS

The increasing demand for wireless communication applications, such as mobile and cordless telephony, wireless data networks, two-way paging and global positioning system, motivates a growing interest in building miniaturized wireless transceivers with multistan-

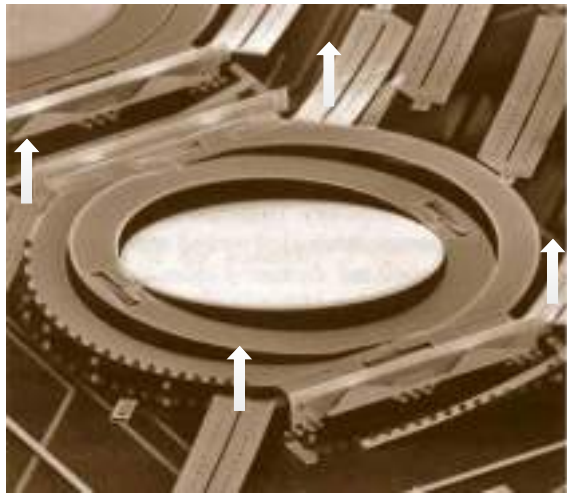

Fig. 13.32 SEM micrograph of a surface-micromachined two-axis beam-steering micromirror positioned using a self-assembly technique (after [13.30])

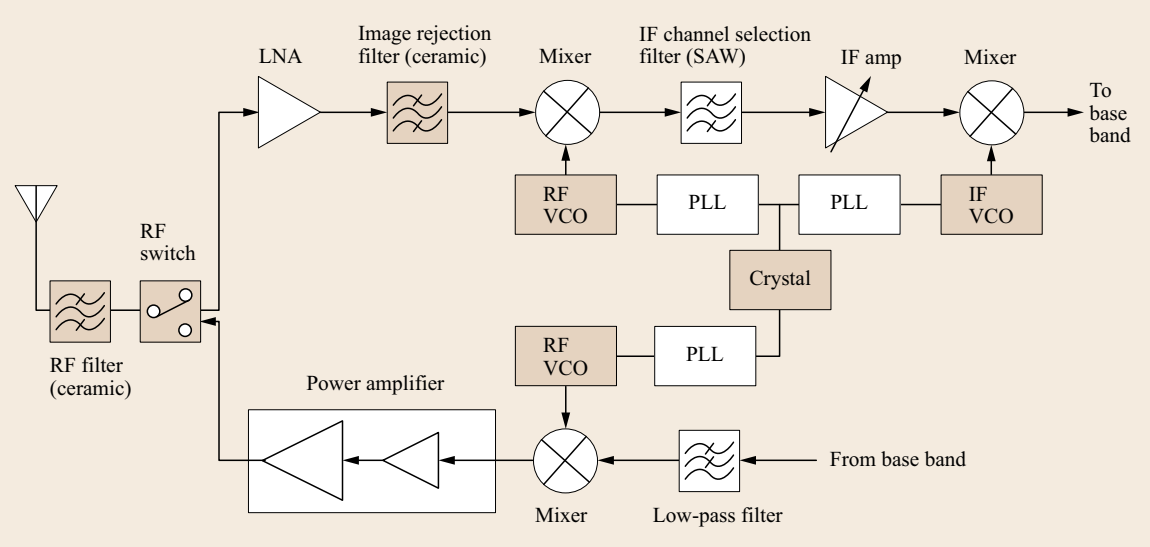

Fig. 13.33 Schematic of a superheterodyne radio architecture; *SAW*: surface acoustic wave, *VCO*: voltage controlled oscillator, *LNA*: low-noise amplifier, *PLL*: phase-locked loop

dard capabilities. Such transceivers will greatly enhance the convenience and accessibility of various wireless services independent of geographic location. Miniaturizing current single-standard transceivers, through a high level of integration, is a critical step towards building transceivers that are compatible with multiple standards. Highly integrated transceivers will also result in reduced package complexity, power consumption and cost. At present, most radio transceivers rely on a large number of discrete frequency-selection components, such as radio-frequency (RF) and intermediate-frequency (IF) band-pass filters, RF voltage-controlled oscillators (VCOs), quartz crystal oscillators and solid-state switches to perform the necessary analog signal processing. Figure 13.33 shows a schematic of a superheterodyne radio architecture, in which discrete components are shaded in dark color. Theses off-chip devices occupy the majority of the system area, thus severely hindering transceiver miniaturization. MEMS technology, however, offers a potential solution to integrate these discrete components onto silicon substrates with microelectronics, achieving a size reduction of a few orders of magnitude. It is therefore expected to become an enabling technology to ultimately miniaturize radio transceivers for future wireless communications.

MEMS Variable Capacitors

Integrated high-performance variable capacitors are critical for low-noise VCOs, antenna tuning, tunable matching networks, etc. Capacitors with high quality factors (Q), a large tuning range and linear characteristics are crucial for achieving system performance requirements. On-chip Si PN junction and MOS-based variable capacitors suffer from low quality factors (below 10 at 1 GHz), limited tuning range and poor linearity, thus are inadequate for building high-performance transceivers. MEMS technology has demonstrated monolithic variable capacitors achieving stringent performance requirements. These devices typically reply on an electrostatic actuation method to vary the air gap between a set of parallel plates [13.31–34], vary the capacitance area between a set of conductors [13.35] or mechanically displace a dielectric layer in an air-gap capacitor [13.36]. Improved tuning ranges have been achieved with various device configurations. Figure 13.34 shows SEM micrographs of an aluminum micromachined variable capacitor fabricated on a silicon substrate [13.31]. The device consists of a $200\,\mu m \times 200\,\mu m$ aluminum plate with a thickness of $1\,\mu m$ suspended above the bottom electrode by an air gap of $1.5\,\mu m$. Aluminum is selected as the structural material due to its low resistivity, which is critical for achieving a high quality factor at high frequencies. A DC voltage applied across the top and bottom electrodes introduces an electrostatic pull-down force, which pulls the top plate towards the bottom electrode, thus changing the device capacitance value. The capacitors are fabricated using aluminum-based surface-micromachining technology. Sputtered aluminum is used for building the capacitor top and bottom electrodes. Photoresist is served as the sacrificial layer, which is then removed through an oxygen-based plasma dry etch to release the microstructure. The processing technology requires a low thermal budget, thus allow-

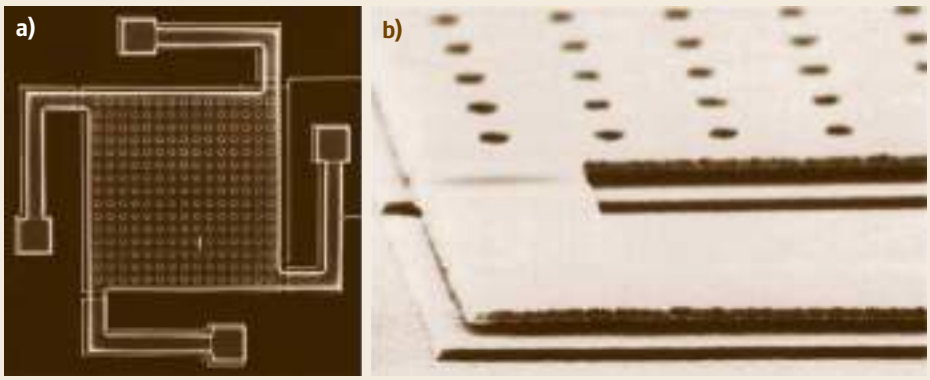

Fig. 13.34 **(a)** SEM micrograph of a top-view of an aluminum surface-micromachined variable capacitor; **(b)** SEM micrograph of a cross-sectional view of the variable capacitor (after [13.31])

ing the variable capacitors to be fabricated on top of wafers with completed electronic circuits without degrading the performance of active devices. Figure 13.35 presents an SEM micrograph of four MEMS tunable capacitors connected in parallel. This device achieves a nominal capacitance value of 2 pF and a tuning range of 15% with 3 V. A quality factor of 62 has been demonstrated at 1 GHz, which matches or exceeds that of discrete varactor diodes and is at least an order of magnitude larger than that of a typical junction capacitor implemented in a standard IC process.

MEMS tunable capacitors based upon varying the capacitance area between a set of conductors have been demonstrated. Figure 13.36 shows an SEM micrograph of such a device [13.35]. The capacitor comprises arrays of interdigitated electrodes, which can be electrostatically actuated to vary the electrode overlap area. A close-up view of the electrodes is shown in Fig. 13.37. The capacitor is fabricated using a silicon-on-insulator (SOI) substrate with a top silicon layer thickness around 20 μm to obtain a high aspect ratio for the electrodes, which is critical for achieving a large capacitance density and reduced tuning voltage. The silicon layer is etched to form the device structure followed by removing the underneath oxide to release the capacitor. A thin aluminum layer is then sputtered over the capacitor to reduce the series resistive loss. The device exhibits a quality factor of 34 at 500 MHz and can be tuned between 2.48 pF and 5.19 pF with an actuation voltage under 5 V, corresponding to a tuning range over 100%. Figure 13.38 shows the variation of electrode overlap area under different tuning voltages.

Tunable capacitors relying on a movable dielectric layer have been fabricated using MEMS technology. Figure 13.39 presents an SEM micrograph of a copper-based micromachined tunable capacitor [13.36]. The device consists of an array of copper top electrodes suspended above a bottom copper plate with an air gap of approximately 1 μm. A thin nitride layer is deposited, patterned, and suspended between the two copper layers

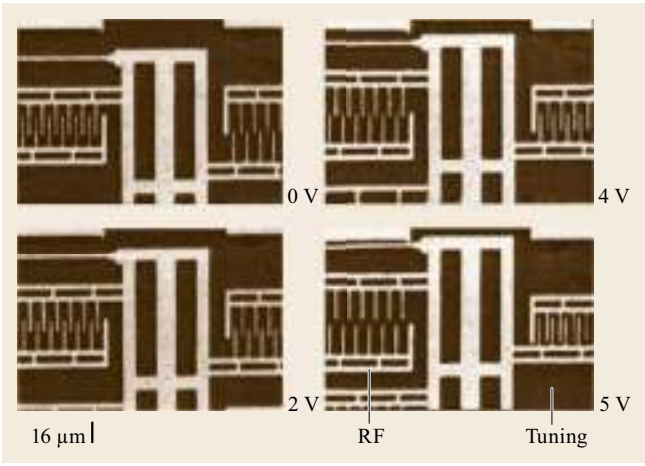

Fig. 13.38 Photos of comb fingers at different actuation voltages (after [13.35])

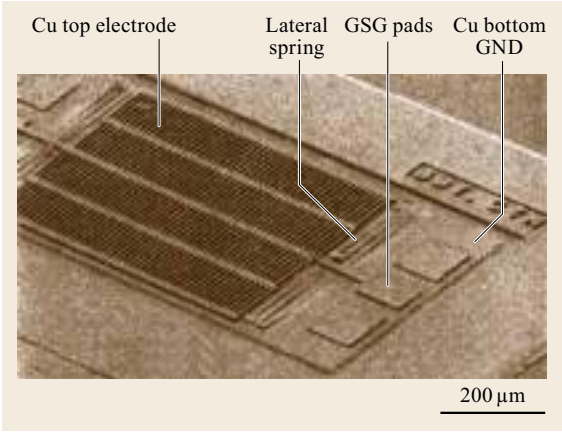

Fig. 13.39 SEM micrograph of a copper surface-micromachined tunable capacitor with a movable dielectric layer (after [13.36]); *GND*: ground, *GSG*: ground-signal-ground

by lateral mechanical spring suspensions after sacrificial release. A DC voltage applied across the copper layers introduces a lateral electrostatic pull-in force on the nitride, thus resulting in a movement that changes the overlapping area between each copper electrode and the bottom plate, and hence the device capacitance. The tunable capacitor achieves a quality factor over 200 at 1 GHz with 1 pF capacitance due to the highly conductive copper layers and a tuning range around 8% with 10 V.

Micromachined Inductors

Integrated inductors with high quality factors are as critical as the tunable capacitors for high-performance RF system implementation. They are the key components for building low-noise oscillators, low-loss matching networks, etc. Conventional on-chip spiral inductors suffer from limited quality factors of around 5 at 1 GHz, an order of magnitude lower than the required values from discrete counterparts. The poor performance is mainly caused by substrate loss and metal resistive loss at high frequencies. Micromachining technology provides an attractive solution to minimize these loss contributions, hence enhancing the device quality factors. Figure 13.40 shows an SEM micrograph of a 3-D coil inductor fabricated on a silicon substrate [13.37]. The device consists of 4-turn 5 µm-thick copper traces electroplated around an insulting core with a 650 µm × 500 µm cross-section. Compared to spiral inductors, this geometry minimizes the coil area, which is in close proximity to the substrate and hence the eddy-current loss, resulting in a maximized Q-factor and device self-resonant frequency. Copper is selected as the interconnect metal because of its low sheet resistance, which is critical for achieving a high Q-factor. The inductor achieves a 14 nH inductance value with a quality factor of 16 at 1 GHz. A single-turn 3-D device exhibits a Q-factor of 30 at 1 GHz, which matches the performance of discrete counterparts. The high-Q 3-D inductor and MEMS tunable capacitors, shown in Fig. 13.35, have been employed to implement a RF CMOS VCO achieving a low phase-noise performance suitable for typical wireless communication applications such as GMS cellular telephony [13.38].

Other 3-D inductor structures such as the levitated spiral inductors have been demonstrated using micromachining fabrication technology. Figure 13.41

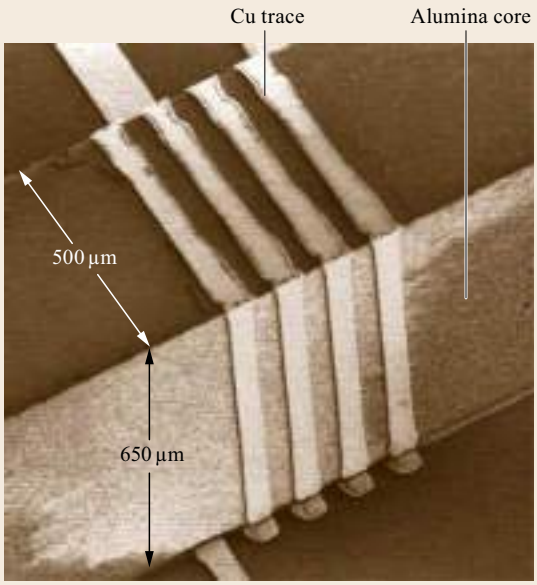

Fig. 13.40 SEM micrograph of a 3-D coil inductor fabricated on a silicon substrate (after [13.37])

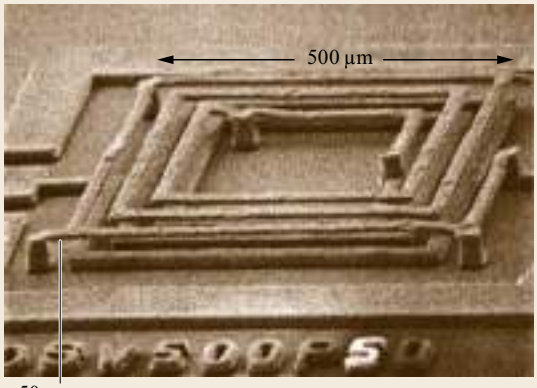

Fig. 13.41 SEM micrograph of a levitated spiral inductor fabricated on a glass substrate (after [13.39])

shows an SEM micrograph of a levitated copper inductor, which is suspended above the substrate through supporting posts [13.39]. The levitated geometry can minimize the substrate loss, thus achieving an improved quality factor. The inductor shown in the figure achieves a 14 nH inductance value with a Q-factor of 38 at 1.8 GHz using a glass substrate.

A self-assembled out-of-plane coil has been fabricated using micromachining technology. The inductor winding traces are made of refractory metals with controlled built-in stress such that the traces can curl out of the substrate surface upon release and interlock into

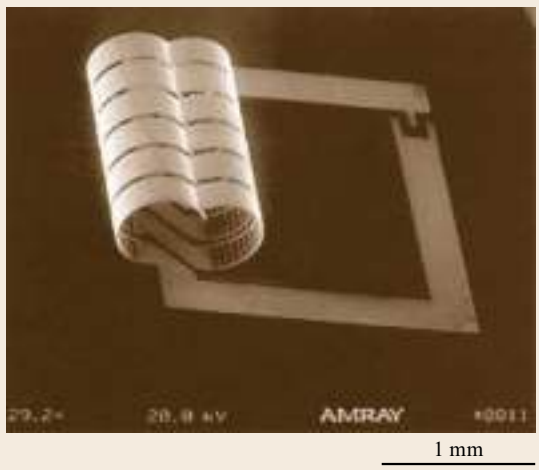

Fig. 13.42 SEM micrograph of a self-assembled out-of-plane coil inductor (after [13.40])

each other to form coil windings. Figure 13.42 shows an SEM micrograph of a self-assembled out-of-plane coil inductor [13.40]. A close-up view of an interlocking trace is shown in Fig. 13.43. Copper is plated on the interlocked traces to form highly conductive windings at the end of processing sequence. The inductor shown in Fig. 13.42 achieves a quality factor around 40 at 1 GHz.

MEMS Switches

The microelectromechanical switch is another potentially attractive miniaturized component enabled by micromachining technologies. These switches offer su-

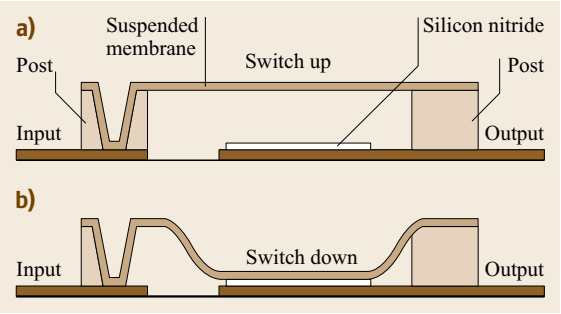

Fig. 13.44a,b Cross-sectional schematics of an RF MEMS capacitive switch; **(a)** Off state, **(b)** On state

perior electrical performance in terms of insertion loss, isolation, linearity, etc., and are intended to replace off-chip solid state counterparts, which provide switching between the receiver and transmitter signal paths. They are also critical for building phase shifters, tunable antennas, and filters. The MEMS switches can be characterized into two categories: capacitive and metal-to-metal contact types. Figure 13.44 presents a cross-sectional schematic of an RF MEMS capacitive switch. The device consists of a conductive membrane, typically made of aluminum or gold alloy suspended above a coplanar electrode by an air gap of a few micrometers. For RF or microwave applications, actual metal-to-metal contact is not necessary; rather, a step change in the plate-to-plate capacitance realizes the switching function. A thin silicon nitride layer with a thickness on the order of 1000 Å is typically deposited above the bottom electrode. When the switch is in the on-state, the membrane is high, resulting in a small plate-to-plate capacitance, and hence a minimum high-frequency signal coupling (high isolation) between the two electrodes. In the off-state (with a large enough applied DC voltage), the switch provides a large capacitance due to the thin dielectric layer, thus causing a strong signal coupling (low insertion loss). The capacitive switch consumes near-zero power, which is attractive for low-power portable applications. Switching cycles over millions for this type of device have been demonstrated. Figure 13.45 shows a top-view photo of a fabricated MEMS capacitive switch [13.41]. Surface-micromachining technology, using metal for the electrodes and polymer as the sacrificial layer, is used to fabricate the device. The switch can be actuated with a DC voltage on the order of 50 V and exhibits a low insertion loss of approximately −0.28 dB at 35 GHz and a high isolation of −35 dB at the same frequency.

Metal-to-metal contact switches are important for interfacing large bandwidth signals including DC. This type of device typically consists of a cantilever beam

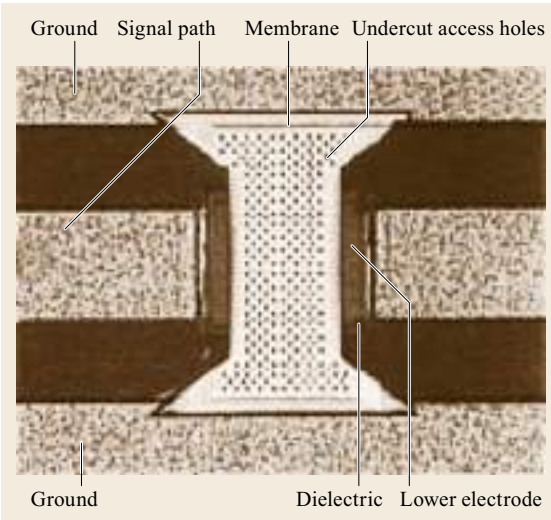

Fig. 13.45 Top-view photo of a fabricated RF MEMS capacitive switch (after [13.41])

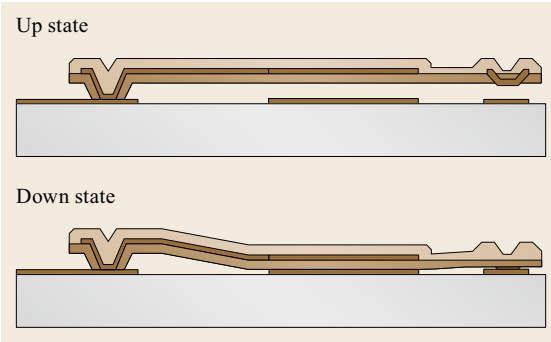

Fig. 13.46 Cross-sectional schematic of a metal-to-metal contact switch (after [13.44])

or clamped-clamped bridge with a metallic contact pad positioned at the beam tip or underneath the bridge center. Through an electrostatic actuation, a contact can be formed between the suspended contact pad and an underlying electrode on the substrate [13.42–44]. Figure 13.46 shows a cross-sectional schematic of a metal-to-metal contact switch [13.44]. The top-view of the fabricated device is presented in Fig. 13.47. The switch exhibits an actuation voltage of 30 V, a response time of 20 μs and mechanical strength to withstand 10^9 actuations. An isolation greater than 50 dB below 2 GHz and insertion loss less than 0.2 dB from DC through 40 GHz has been demonstrated.

MEMS Resonators

Microelectromechanical resonators based upon poly-Si comb-drive structures, suspended beams and center-pivoted disk configurations have been demonstrated

Fig. 13.47 Top-view photo of a fabricated metal-to-metal contact switch (after [13.44])

for performing analog signal processing [13.45–49]. These microresonators can be excited into mechanical resonance through an electrostatic drive. The mechanical motion causes a change of device capacitance resulting in an output electrical current when a proper DC bias voltage is used. The output current exhibits the same frequency as the mechanical resonance, thus achieving an electrical filtering function through the electromechanical coupling. Micromachined polysilicon flexural-mode mechanical resonators have demonstrated a quality factor greater than 80 000 in a 50 μTorr vacuum [13.50]. This level of performance is comparable to a typical quartz crystal and is thus attractive for implementing monolithic low-noise and low-drift reference signal sources. Figure 13.48 shows an SEM micrograph of a surface-micromachined comb-drive resonator integrated with CMOS sustaining electronics on a same substrate to form a monolithic high-Q MEMS resonator-based oscillator [13.45]. The oscillator achieves an operating frequency of 16.5 KHz with a clean spectral purity. A chip area of approximately 420 μm × 230 μm is consumed for fabricating the overall system, representing a size reduction by orders of magnitude compared to conventional quartz crystal oscillators.

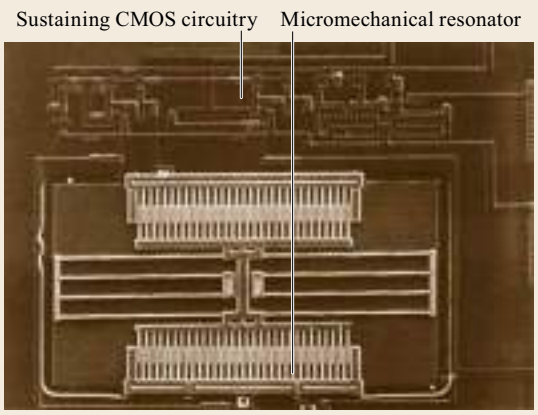

Fig. 13.48 SEM micrograph of a surface-micromachined comb-drive resonator integrated with CMOS sustaining electronics (after [13.45])

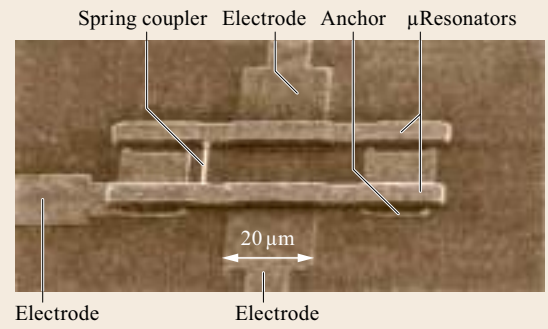

Fig. 13.49 SEM micrograph of a polysilicon surface-micromachined two-resonator spring-coupled bandpass micromechanical filter (after [13.47])

Micromachined high-Q resonators can be coupled to implement low-loss frequency selection filters. Figure 13.49 shows an SEM micrograph of a surface-micromachined polysilicon two-resonator, spring-coupled bandpass micromechanical filter [13.47]. The filter consists of two silicon micromechanical clamped-clamped beam resonators, coupled mechanically by a soft spring, all suspended 0.1 μm above the substrate. Poly-Si strip lines underlie the central regions of each resonator and serve as capacitive transducer electrodes positioned to induce resonator vibration in a direction perpendicular

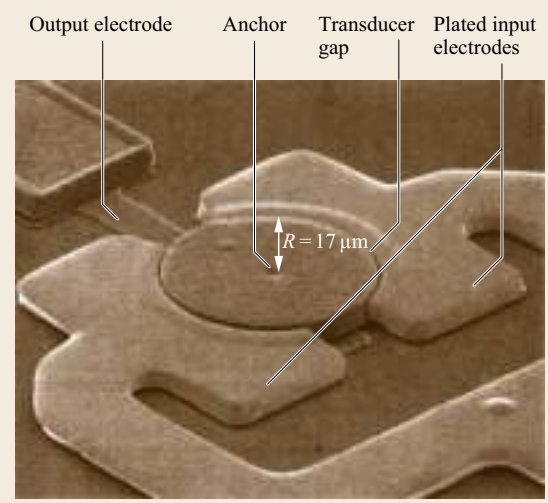

Fig. 13.50 SEM micrograph of a polysilicon surface-micromachined contour-mode disk resonator (after [13.49])

to the substrate. Under normal operation, the device is excited capacitively by a signal voltage applied to the input electrode. The output is taken at the other end of the structure, also by capacitive transduction. The filter achieves a center frequency of 7.81 MHz, a bandwidth of 0.23% and an insertion loss less than 2 dB. The achieved performance is attractive for implementing filters in the low MHz range.

To obtain a higher mechanical resonant frequency with low losses, a surface-micromachined contour-mode disk resonator has been proposed, as shown in Fig. 13.50 [13.49]. The resonator consists of a polysilicon disk suspended 5000 Å above the substrate with a single anchor at its center. Plated metal input electrodes surround the perimeter of the disk with a narrow separation of around 1000 Å, which defines the capacitive, electromechanical transducer of the device. To operate the device, a DC bias voltage is applied to the structure with an AC input signal applied to the electrodes, resulting in a time- varying electrostatic force acting radially on the disk. When the input signal matches the device resonant frequency, the resulting electrostatic force is amplified by the Q-factor of the resonator, producing expansion and contraction of the disk along its radius. This motion in turn produces a time-varying output current at the same frequency, thus achieving the desirable filtering. The prototype resonator demonstrates an operating frequency of 156 MHz with a Q-factor of 9400 in vacuum. The increased resonant frequency is comparable to the first intermediate frequency used in a typical wireless transceiver design and is thus suitable for implementing IF bandpass filters. A higher operating frequency is needed in order to potentially replace the RF frequency selection filters with microelectromechanical resonators.

13.2 NEMS Devices and Applications

Nanoelectromechanical systems (NEMS), if broadly defined, should include all structures and devices that satisfy (i) having both *electro* (conducting and/or semiconducting) and *mechanical* (movable) parts *and* having an *electromechanical transduction* function, and (ii) having at least one characteristic dimension in the $\approx 1-100$ nm size scale, according to the official National Nanotechnology Initiative (NNI) convention. For example, a simple cantilever- or beam-structured nanoelectromechanical resonator possesses both *electro* (resistance) and *mechanical* (suspended, movable beam) parts, and the beam's mechanical motion can be converted into an electrical signal and be read out with certain transduction schemes. Thus it is viewed as a NEMS device.

NEMS as an emerging and attractive field has very interesting historical perspectives, which could have important implications in transforming NEMS into enabling technologies. (i) From a physics viewpoint, the emergence of NEMS originated from some mesoscopic physics studies back in the late 1980s [13.51–53]. Even at that time, sub-100 nm and sub-10 nm structures (mesoscopic *systems*) were made by advanced nanofabrication for electronic transport measurements. In hindsight, it almost seemed natural to take further steps to suspend these mesoscopic systems and to excite them into mechanical motions for exploration of new physics and engineering. This has proven to be a significant and successful evolution. (ii) From the engineering point of view, NEMS could be viewed as MEMS further shrunk down to the nanoscale. This view is helpful in NEMS engineering as one can always first learn from the many techniques developed for MEMS (especially in fabrication processes and signal transduction), with the hope of benefiting the explorations with NEMS. A few classical and helpful introductory reviews of NEMS with intermingled physics and engineering viewpoints and focuses can be found in the literature [13.51, 54–58].

13.2.1 Fabrication Techniques for NEMS

Today, most genuine NEMS are based on nanostructures made either by *top-down* lithographical nanopatterning and nanomachining of thin films of crystalline materials that are also popular in MEMS (e.g., Si, SiC, AlN), or by *bottom-up* chemical synthesis and assembly, such as nanotubes (NTs), nanowires (NWs), nanoflakes, and even nanoparticles. In general, *top-down* approaches utilize nanometer-scale lithographic techniques to define and *carve* mechanically movable nanostructures from crystalline thin films (grown/deposited on substrates) or thick (*bulk*) substrates. *Bottom-up* approaches, meanwhile, build up nanoscale structures and devices in much the same way that mother nature constructs objects, by sequentially assembling atomic and molecular building blocks. During the last two decades, while many have optimistically envisioned or argued that bottom-up approaches will eventually dominate the fabrication of nanoelectronics and NEMS, most of the functional NEMS to date have been created by utilizing top-down techniques

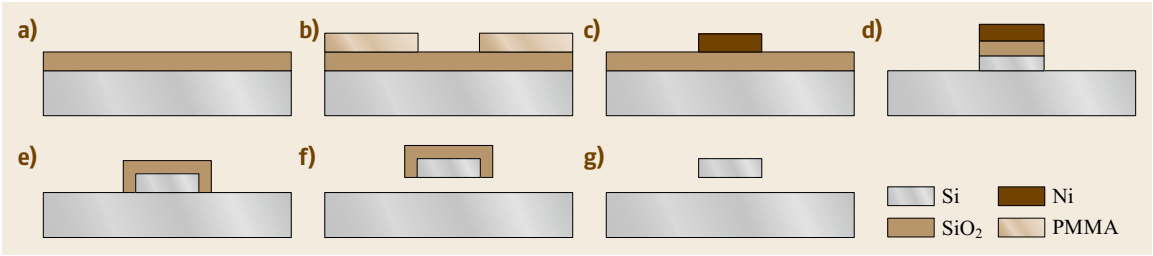

Fig. 13.51a–g Cross-sectional schematics of a process to fabricate nanomechanical beams directly from a silicon substrate: **(a)** after thermal oxidation; **(b)** after PMMA coating and electron-beam lithography; **(c)** after Ni deposition and lift-off; **(d)** after anisotropic SiO_2 and Si etching and Al removal; **(e)** after Ni etching, thermal oxidation and anisotropic SiO_2 etching; **(f)** after release by isotropic Si etching; **(g)** after oxide removal

that combine existing process technologies, such as submicron electron-beam lithography, mainstream film growth/deposition and chemical etching. Top-down approaches make integration with microscale packaging relatively straightforward since the only significant difference between the nanoscale and microscale processing steps is the method used to pattern the various features. We see exciting opportunities keep emerging in the regime where top-down meets bottom-up: many novel nanostructures and NEMS devices can be enabled by devising schemes to combine the bottom-up and top-down techniques, and leveraging their features.

Focusing on the majority and state of the art, NEMS has followed a developmental path similar to the route taken in the development of MEMS in that both have leveraged existing processing techniques. For instance, the electron-beam lithographic techniques used in top-down NEMS fabrication are converging with the techniques that have become standard in the fabrication of submicron ICs. Furthermore, the materials used in many of the first generation top-down NEMS devices (Si, GaAs, Si_3N_4, SiC) were first used in ICs and then in MEMS. Like the first MEMS devices, the first generation NEMS structures consist of free-standing nanomechanical beams, paddle oscillators, and tethered plates made using simple bulk and single-layer surface *nano*machining processes. As an introduction to this new and exciting class of devices, the following section reviews the development of some of these first-generation NEMS devices.

Like Si MEMS, Si NEMS capitalize on well-developed processing techniques for Si and the availability of high-quality substrates. *Cleland* et al. [13.59] reported a relatively simple process to fabricate nanomechanical clamped-clamped beams directly from single crystal (100) Si substrates. As illustrated in Fig. 13.51, the process begins with the thermal oxidation of a Si substrate (Fig. 13.51a). Large Ni contact pads were then fabricated using optical lithography and lift-off. A polymethyl methacrylate (PMMA) lift-off mold was then deposited and patterned using electron-beam lithography into the shape of nanomechanical beams (Fig. 13.51b). Ni was then deposited and patterned by lifting off the PMMA (Fig. 13.51c). Next, the underlying oxide film was patterned by RIE using the Ni film as an etch mask. After oxide etching, nanomechanical beams were patterned by etching the Si substrate using RIE, as shown in Fig. 13.51d. Following Si RIE, the Ni etch mask was removed and the sidewalls of the Si nanomechanical beams were lightly oxidized in order to protect them during the release step (Fig. 13.51e). After performing an anisotropic SiO_2 etch to clear any oxide from the field areas, the Si beams were released using an isotropic Si RIE step, as shown in Fig. 13.51f. After release, the protective SiO_2 film was removed by wet etching in HF (Fig. 13.51g). Using this process, the authors reported the successful fabrication of nanomechanical Si beams with micron-scale lengths ($\approx 8\,\mu m$) and submicron widths (330 nm) and heights (800 nm).

The advent of SOI substrates with high-quality, submicron-thick Si top layers enables the fabrication of nanomechanical Si beams with fewer processing steps than the aforementioned technique since the buried oxide layer makes these device structures relatively easy to pattern and release. Additionally, the buried SiO_2 layer electrically isolates the beams from the substrate. *Carr* et al. [13.60] detail a process that uses SOI substrates to fabricate submicron clamped-clamped mechanical beams and suspended plates with submicron tethers. The process, presented in Fig. 13.52, begins with the deposition of PMMA on an SOI substrate. The SOI substrate has a top Si layer that was either 50 nm or 200 nm in thickness. The PMMA is patterned into a metal lift-off mask by electron beam lithography (Fig. 13.52b). An aluminum film is then deposited and patterned by lift-off into a Si etch mask, as shown in Fig. 13.52c. The nanomechanical beams are then patterned by Si RIE and released by etching the underlying SiO_2 in a buffered hydrofluoric acid solution as shown

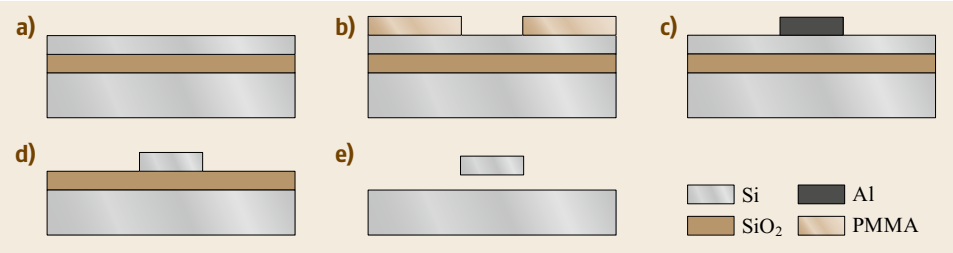

Fig. 13.52a–e Cross-sectional schematics of a process to fabricate nanomechanical structures using silicon-on-insulator (SOI) substrates: **(a)** starting SOI substrate; **(b)** after coating with PMMA and electron-beam lithography; **(c)** after Al deposition and lift-off; **(d)** after anisotropic Si etching and Al removal; **(e)** after release by SiO_2 etching

in Fig. 13.52d and Fig. 13.52e, respectively. Using this process, nanomechanical beams that were 7–16 μm in length, 120 to 200 nm in width and 50 or 200 nm in thickness were successfully fabricated.

Fabrication of NEMS structures is not limited to Si. In fact, III-V compounds, such as gallium arsenide (GaAs), make particularly good NEMS materials from a fabrication perspective because thin epitaxial GaAs films can be grown on lattice-matched materials that can be used as sacrificial release layers. A collection of clamped-clamped nanomechanical GaAs beams fabricated on lattice-matched sacrificial layers having micron-scale lengths and submicron widths and thicknesses is shown in Fig. 13.53. *Tighe* et al. [13.61] reported on the fabrication of GaAs plates suspended with nanomechanical tethers. The structures were made from single crystal GaAs films that were epitaxially grown on aluminum arsenide (AlAs) sacrificial layers. Ni etch masks were fabricated using electron beam lithography and lift-off as described previously. The GaAs films were patterned into beams using a chemically assisted ion beam etching (CAIBE) process and released using a highly selective AlAs etchant. Later, considerable efforts were made in engineering epitaxial GaAs heterostructures for making piezoelectric NEMS [13.62, 63], while GaAs has limited piezoelectric coupling coefficient and compromised elastic and acoustic properties (e.g., relatively low elastic modulus and speed of sound). It was then desirable to explore crystals with higher piezoelectric coupling efficiency, such as AlN, which has been more established in the MEMS areas [13.64, 65]. Among the principal challenges toward exploiting AlN for NEMS are obtaining nanometer-thick AlN films that retain excellent piezoelectric properties and devising efficient actuation and readout schemes. As very thin AlN piezolayers (such as down to 100 nm or sub-100 nm) are usually made to be sandwiched between two similarly thin electrode layers (e.g., Mo or Pt), considerable efforts have been made in designing and implementing multimask surface-nanomachining processes with nanoscale patterning techniques (e.g., electron-beam lithography) to enable AlN NEMS with reliable electrical access to both top and bottom electrode layers. For AlN layers down to 100 nm and thinner, very high-frequency (VHF) NEMS resonators have been demonstrated and it has been calibrated that the piezoelectric coupling coefficients are fairly close to that of bulk AlN crystals [13.66, 67].

Fig. 13.53 SEM micrograph of a set of nanomechanical GaAs clamped-clamped beam resonators (courtesy of Prof. Michael Roukes – Caltech)

As discussed above, it has been the combination and cooperation between both the bottom-up and top-down techniques that has enabled many milestone and representative devices to advance the field of NEMS. Nanowire NEMS is a family of important emerging NEMS devices for many emerging applications, promised by a number of attractive optical, electronic, mechanical and thermal properties of such wires. Regarding these devices, bottom-up grown nanowires can have some unique attributes such as being single-crystalline, atomically smooth and having naturally terminated surfaces [13.68]. In assembling high-quality crystals and as-grown nanowires into functional NEMS, an essential means is exploitation of both bottom-up and top-down nanofabrication and careful engineering in the regime

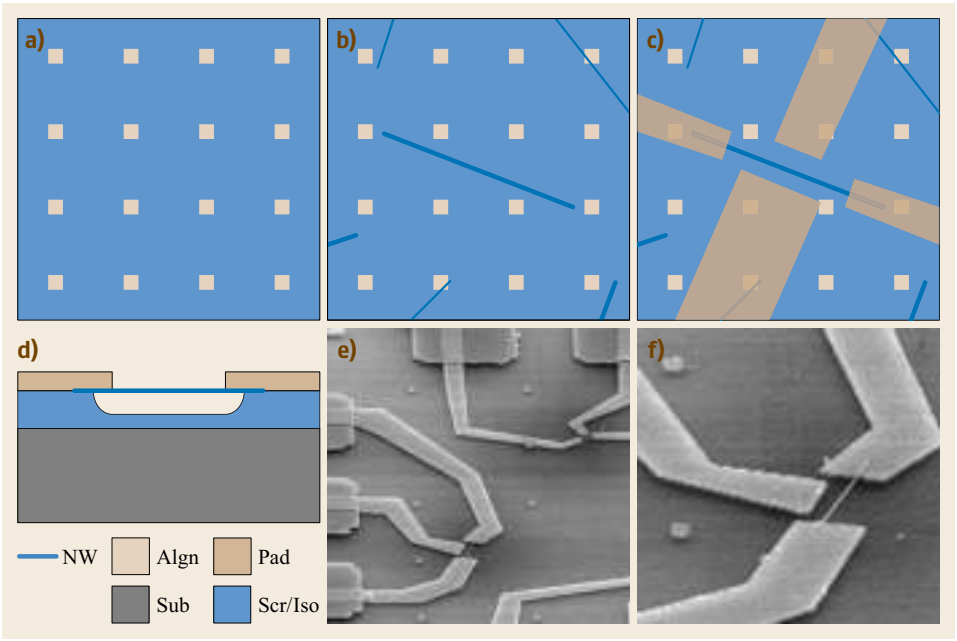

Fig. 13.54a–f Illustration of the fabrication process of conventional bottom-up chemically synthesized NWs and NW-based 1D NEMS devices. **(a)** Electron-beam lithography (EBL) patterned alignment (Algn) markers. **(b)** NWs are distributed on the substrate and coordinates are identified. **(c)** EBL patterning of electrodes. **(d)** Device suspension. **(e,f)** SEM images of representative devices. where they meet [13.68]. Figure 13.54 briefly illustrates the process of making functional and high-quality nanowire NEMS using bottom-up chemically synthesized nanowires.

As examples of top-down fabricated NEMS and arrays of NEMS, Fig. 13.55 shows a small array of SiC NWs with in-plane coupled gate electrodes. These 50 nm-thin SiC NWs make robust resonators and demonstrate interesting frequency tunability and nonlinear behavior. These NWs and arrays can be interrogated by either optical or all-electronic signal transduction techniques. Engineering such NW devices may help the demonstrations of novel coupled and tunable NW resonator arrays, and arrayed NW NEMS switches.

13.2.2 NEMS Measurement and Signal Transduction

Several unique approaches have been developed to actuate and sense the motion of NEMS devices. Electrostatic actuation can be used to actuate beams [13.70], tethered meshes [13.71] and paddle oscillators [13.72]. *Sekaric* et al. [13.73] recently showed that low-power lasers can be used to drive paddle oscillators into self-oscillation by induced thermal effects on the structures. In these examples, an optical detection scheme based on the modulation of incident laser light by a vibrating beam is used to detect the motion of the beams. *Cleland* et al. [13.59] described a magnetomotive transduction technique that capitalizes on a time-varying Lorentz force created by an alternating current in the presence of a strong magnetic field. In this case, the nanomechanical beam is positioned in the magnetic field so that an AC current passing through the beam is transverse to the field lines. The resulting Lorentz force causes the beam to oscillate, which creates an electromotive force along the beam that can be detected as a voltage. Thus, in this method, the excitation and detection are performed electrically. In all of the abovementioned cases, the measurements were performed in vacuum, presumably to minimize the effects of squeeze-film damping as well as mass loading due to adsorbates from the environment.

13.2.3 NEMS Devices and Emerging Applications

For the most part, NEMS technology is still in the initial stage of development. Technological challenges related to fabrication and packaging will require innovative solutions before such devices make a significant commercial impact. Nevertheless, NEMS devices have already been used for precision measurements [13.74] enabling researchers to probe the properties of matter [13.75, 76] on a nanoscopic level. Whether or not NEMS makes an impact in the commercial sector, they will undoubtedly prove to be useful platforms for a host of experiments and scientific discoveries in fields ranging from physics to biology.

Radio Frequency (RF) NEMS Resonators and Oscillators

It has been technologically compelling and challenging to pursue RF NEMS resonators and self-sustained feedback oscillators. Intrinsically, aggressive scaling from MEMS to NEMS promises to further scale up the operating frequency and greatly reduce the required operating power levels for RF/microwave signal processing functions. Important initiative explorations have been made in developing RF/microwave NEMS resonators while maintaining high Qs. Given that crystalline materials often possess decent or high speeds of sound, simply scaling the device dimensions can very effectively scale up the device operating frequency up to the RF and microwave bands. Among many crystalline materials for making NEMS, SiC has clearly stood out for a unique combination of outstanding mechanical, electrical, optical, and thermal properties (e.g., superior over those of Si), with wafer-scale micro/nanomachining (e.g., well beyond the manufacturability of diamond). SiC NEMS were the first to break the GHz barrier, with mechanical resonators that operate at > 1 GHz in their fundamental flexural modes. Figure 13.56 highlights the experimental results from the first GHz SiC NEMS resonators. Given a specific mode shape, such as the fundamental flexural mode of a doubly-clamped beam, simply scaling the device length can efficiently scale up the operating frequency. Nonetheless, the Q factor of this given mode is often observed to decrease with the increasing frequency. This is particularly true in the VHF/ultrahigh-frequency (UHF)/microwave regime. It has been revealed that clamping losses in such flexural resonators can be important and even strongly dominating the energy dissipation. To mitigate the clamping losses, an effective approach is to emulate the tuning forks, and design mechanical structures and their modes, so that they are supported or clamped at the nodal points. Figure 13.57 demonstrates one of the first free-free beam VHF NEMS resonators and their in-plane mode shape. It has been shown that given the same dimensions and same fabrication process, free-free beam NEMS resonators can obtain Q factors enhanced by a factor of two or even higher, as compared to their doubly-clamped counterparts [13.77].

Active oscillators spontaneously generate self-sustaining periodic signals by extracting power from steady (DC) sources. This distinguishes them from passive resonators that are characterized by a damped response to impulsive stimuli, which makes them invaluable for applications in precision timekeeping, communications and sensing, which require continuous AC signals. Simply and more often from an electrical engineers' viewpoint, an RF self-sustaining, active oscillator converts DC power into RF power, and it functions as an RF signal generator. Over the last two decades, there has been considerable incentive to miniaturize mechanical resonators to replace conventional crystal resonators in order to integrate frequency selection and tuning functions on-chip with ICs.

SiC NEMS resonators have been exploited to make the first NEMS-referenced, self-sustained feedback oscillator at UHF. Figure 13.58 shows an autonomous

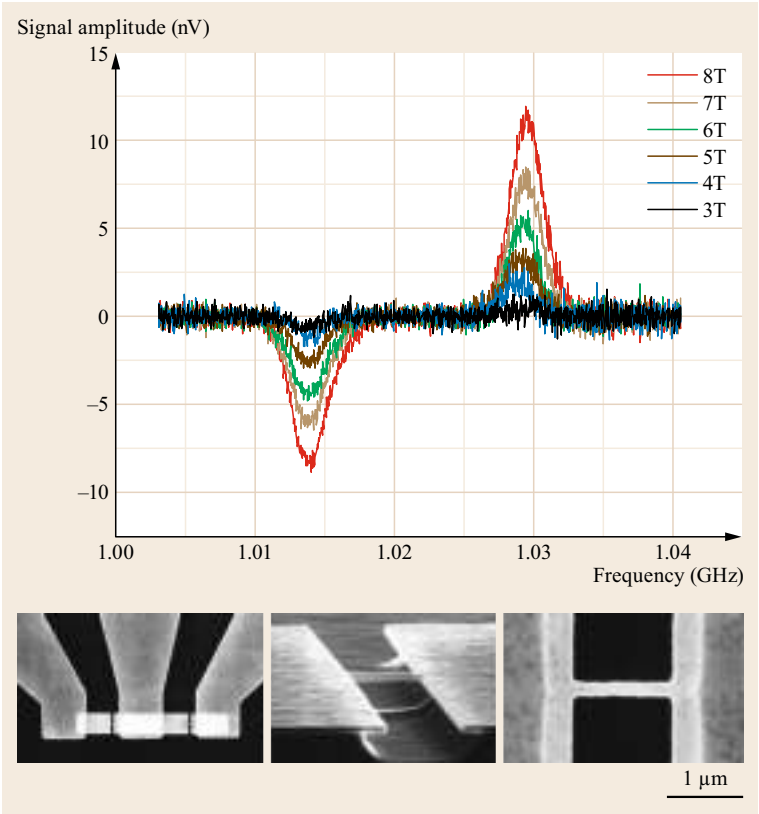

Fig. 13.56 The first resonant NEMS that beat the 1 GHz limit. The data plot shows the electrically measured ≈ 1 GHz NEMS resonances with amplitude dependence on sweeping excitation strength. The SEM images show the doubly-clamped beam SiC NEMS GHz resonators (after [13.78])

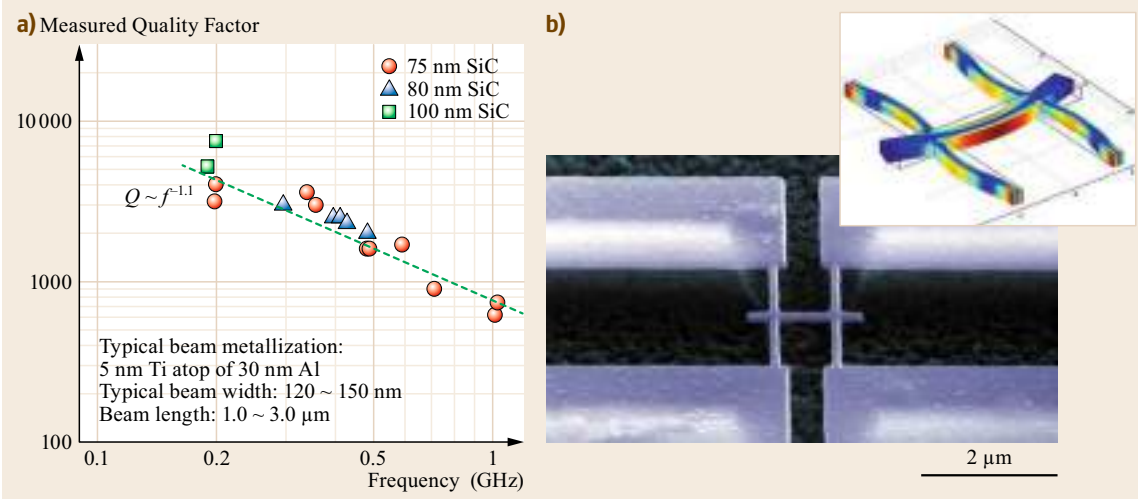

Fig. 13.57a,b Engineering with the frequency versus Q tradeoff. **(a)** The tradeoff between the resonance frequency and the Q factor of the fundamental mode resonance of doubly-clamped beam NEMS resonators, as the devices are scaled down in dimensions to scale up in frequency. **(b)** SEM image of a free-free beam VHF NEMS resonator (at ≈ 175 MHz) for reducing the clamping losses to boost Q [13.77]. and self-sustaining NEMS oscillator that generates continuous UHF signals when powered by a steady DC source. The frequency-determining element in the oscillator is a 428 MHz NEMS resonator that is embedded within a tunable electrical feedback network to generate active and stable self-oscillation [13.79]. Beyond this demonstration, careful measurements and analyses have also been done on the frequency stability and phase noise performance of this UHF NEMS oscillator. An interesting linewidth-narrowing effect has also been observed in the self-sustaining UHF NEMS oscillator [13.79].

NEMS Resonators: From Quantum Limits to Resonant Sensors

Since the early days of explorations from the mesoscopic physics studies, NEMS have already been playing increasingly important roles as enabling tools for

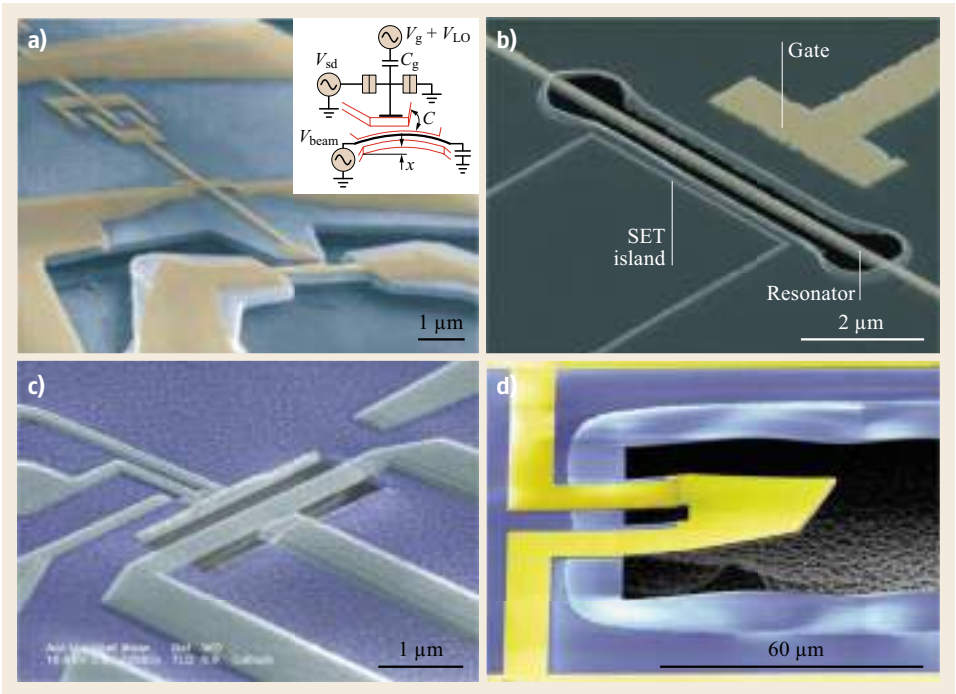

Fig. 13.59a–d Representative quantum NEMS devices that have enabled achieving key milestones in approaching the standard quantum mechanical limit (SQL) in human-made structures and devices. **(a)** SEM image of a doubly clamped GaAs beam with Al electrodes forming a single-electron transistor (SET) and beam electrode. *Inset*: a schematic of the mechanical and electrical operation of the device (after [13.80]). **(b)** A ≈ 20 MHz SiN nanomechanical resonator (200 nm wide, 8 μm long, coated with 20 nm Au atop 100 nm SiN), defined by etching through a suspended SiN membrane (after [13.81, 82]). **(c)** A SiN NEMS resonator with Al metallization, and coupled to the Al Cooper pair box (CPB) ≈ 300 nm away from the beam resonator (after [13.83]). **(d)** Colored SEM image of an AlN suspended film bulk acoustic resonator (130 nm Al on 330 nm AlN on 130 nm Al on 150 nm SiO_2) operating at the dilatational mode at ≈ 6.1 GHz (after [13.84])

scientific metrology, and for extending researchers' sensing and detection capabilities with unprecedented responsivities and sensitivities. In fundamental physics, NEMS make unique mesoscopic systems for probing quantum-limited phenomena [13.75, 85, 86] and for approaching and realizing bizarre quantum mechanical effects in manmade nano/microscale or even larger structures (contrary to just in fundamental particles) [13.86]. Toward such goals and to reach the standard quantum limit (SQL) in mesoscopic devices, significant progress has been made in the rapidly emerging fields of cavity quantum electromechanics (QEM) and cavity optomechanics. Remarkably, a few groups have recently reported cooling of NEMS/MEMS devices in their ground states, either by coupling superconducting quantum-bit (*qubit*) to UHF/microwave electromechanical (e.g., piezoelectric) MEMS resonators [13.84], by coupling mechanical resonators to microwave microstripline resonators [13.87, 88], or via optical cooling of strongly coupled optomechanical resonators [13.89, 90]. Figure 13.59 displays a few selected quantum NEMS devices that have enabled important milestones in this pursuit. These fundamental advances start to make it possible and promising for NEMS-enabled quantum information processing and technology.

In engineering and from a technological viewpoint, NEMS are highly attractive for resonant sensing and ultralow-power information processing in the classical domain. In particular, given their ultrasmall sizes, NEMS make exquisite sensors and detectors for various physical quantities. Numerous NEMS resonant sensors have been reported and many important and inspiring achievements have been made in the last decade. These include, but are not limited to, the following notable milestones:

1. Charge detection: ultrasensitive electronic charge detection with 0.1 electron/rtHz or better sensitivity [13.74].

2. Force sensing: attonewton-level ($1\,\mathrm{aN} = 10^{-18}\,\mathrm{N}$) force sensitivities that have led to magnetic resonance force detection of a single nuclear spin [13.91, 92].
3. Mass sensing: resonant mass sensing with imprecision at the level of a few zeptograms ($1\,\mathrm{zg} = 10^{-21}\,\mathrm{g}$, which is smaller than the mass of most proteins and biomolecules) and then quickly down to the levels of clusters of atoms [13.93–97] (all in vacuum), and attogram-level ($10^{-18}\,\mathrm{g}$) detection in fluids [13.98]. Figure 13.60 demonstrates the hallmark representative data of the zeptogram-scale resonant NEMS mass sensing, and the very first real-time detection of individual protein molecules landing on vibrating NEMS at UHF, as well as the first demonstration of the proof-of-concept NEMS mass spectrometry. Furthermore, these advances in sensitivities and devices technologies enabled new types of mass spectrometry with single-biomolecule resolution [13.94], a wide spectrum of NEMS-based biochemical sensing in fluids [13.99] and also a new avenue for probing the dynamics and fluctuations of physisorbed atoms/molecules on solid surfaces, with unprecedented sensitivities (enough to detect the effects of adsorption–desorption and diffusion at sub-monolayer coverage) [13.100].
4. Displacement and strain sensing: displacement detection in the quantum regime (as discussed above [13.80, 81]) has been rigorously pursued and it is now possible to achieve imprecision below the SQL. In the classical regime, femtometer ($1\,\mathrm{fm} = 10^{-15}\,\mathrm{m}$) displacement sensitivities have been achieved, as well as sensing of very low-level, fast-varying strains [13.101, 102].

NEMS Switches

Since early 2000s the idea of mechanical computing has been revisited with considerable efforts, enabled by scaling from MEMS to NEMS. In this context, contact-mode MEMS/NEMS logic switches (relays) have been rapidly emerging, and have been actively explored as a promising candidate for ultralow-power applications. Truly miniaturized and scaled, NEMS switches can offer compelling attributes and comparative advantages including ideally abrupt switching with minimal off-state leakage (zero-leakage when switched off), suitable for high temperature, extreme environments and small footprints. In this pursuit, however, major challenges remain: (i) all recently reported high-performance mechanical switches are still very much in the MEMS domain and are orders of magnitude larger in size/volume than today's mainstream transistors. In fact, recent MEMS switches with excellent cycle numbers have been all $\geq 10^3$ to $\geq 10^4$ times larger in *motional volume* than

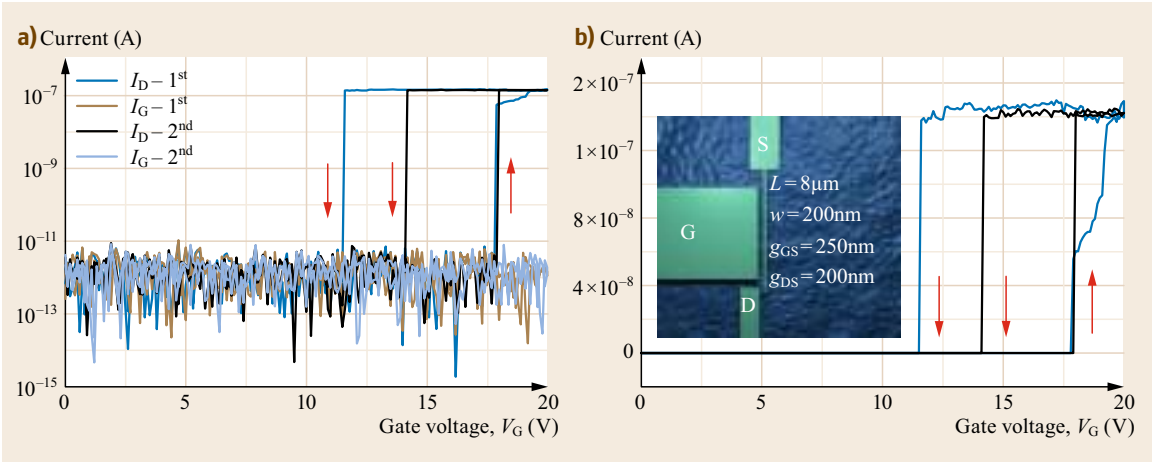

Fig. 13.61a,b First two switching cycles with hysteresis, measured in a SiC NEMS switch, with currents in logarithmic scale **(a)** and linear scale **(b)**, respectively (after [13.103])

genuine NEMS devices with nanometer-scale features. (ii) Most of today's truly nanoscale mechanical switches, however, suffer from a very short lifetime, and some can merely switch one or a few cycles before failure.

Among a number of cutting-edge efforts, the team at Case Western Reserve University [13.103–105] recently made efforts towards addressing one fundamental challenge in today's high-temperature, harsh-environment electronics – power consumption and off-state leakage in switching devices. The team has made SiC NEMS and exploit the unique properties of these SiC NEMS to develop logic building blocks from switches to inverters and subcircuits, which could offer new functionalities and advantages over traditional logic devices used in electronics at high temperatures and other extreme conditions. Here we briefly highlight the recently achieved milestones in the field:

1. SiC NEMS inverters that can operate at both room temperature and high temperature ($T \approx 500\,^{\circ}C$) [13.105]
2. NEMS switches based on ≈ 50 nm-thin nanowires with very low switch-on voltages ($V_{on} \approx 1$ V) [13.106]
3. Lateral three-terminal NEMS switches with robust performance and $> 10^6$ cycles of time evolution of the switching recorded in real time in ambient air [13.103]
4. Demonstration of dual-gate SiC NEMS switches and exploration of multiple-gate controls [13.107]
5. Design and implementation of various functional and reliable NEMS switches and logic gates [13.103, 105–108]
6. Nanoscale mechanical switches 10^3–10^4 times smaller in volume than state-of-the-art MEMS switches [13.103–108].

Figure 13.61 shows typical switching I–V curves measured from a generic three-terminal SiC NEMS switch, with $V_{on} = 17.9$ V and the on/off state current ratio $I_{on}/I_{off} > 10^5$. Beyond such generic lateral switch structures, we have also demonstrated four-terminal devices with a novel dual-gate configuration for enhanced gate control over electrostatic actuation. SiC NEMS switches and inverters have demonstrated very high cycle numbers in the millions and billions ($\approx 10^6$ to $\approx 10^9$) [13.105]. Given the ultrasmall sizes and volumes of these devices, such high performance is highly impressive, attractive and unique amongst NEMS switches [13.103]. Today, almost all contact-mode NEMS switches made of other important materials (Si, SiN, carbon nanotubes, etc.) still suffer from very low operating-cycle numbers. We have made considerable efforts on investigating nanoscale contacts in SiC NEMS, which are key to the devices' reliability and lifetime. We have recorded the complete time evolution of the switching events of robust SiC NEMS switches. Even in ambient air, for many devices, we have recorded $> 10^5$–10^6 switching cycles, without failure, over days of operations [13.103, 108].

13.3 Challenges and Perspectives

Although the field of MEMS has experienced significant growth over the past decade, many challenges still remain. These challenges can be grouped into three general categories:

1. Fabrication challenges
2. Packaging challenges
3. Application challenges.

Challenges in these areas will, in large measure, determine the commercial success of a particular MEMS device both in technical and economic terms. The following presents a brief discussion of some of these challenges as well as possible approaches to address them.

In terms of fabrication, MEMS is currently dominated by planar processing techniques, which find their roots in silicon IC fabrication. The planar approach and the strong dependence on silicon worked well in the early years, since many of the processing tools and methodologies commonplace in IC fabrication could be directly utilized in the fabrication of MEMS devices. This approach lends itself to the integration of MEMS with silicon ICs. Therefore, it is still popular for various applications. However, modular process integration of micromachining with standard IC fabrication is not straightforward and represents a great challenge in terms of processing material compatibility, thermal budget requirements, etc. Furthermore, planar processing places significant geometric restrictions on device designs, especially for complex mechanical components requiring high aspect ratio three-dimensional geometries, which are certain to increase as the application areas for MEMS continue to grow. Along the same lines, new applications will likely demand materials other than silicon, which may not be compatible with the conventional microfabrication approach, posing a significant challenge if integration with silicon microelectronics is required. Microassembly technique can become an attractive solution to alleviate these issues. Multifunctional microsystems can be implemented by assembling various MEMS devices and electronic building blocks fabricated through disparate processing technologies. Microsystems on a common substrate will likely become the ultimate solution. Development of sophisticated modeling programs for device design and performance will become increasingly important as fabrication processes and device designs become more complex. In terms of NEMS, the most significant challenge is likely the integration of nano- and microfabrication techniques into a unified process, since NEMS devices are likely to consist of both nanoscale and microscale structures. Integration will be particularly challenging for nanoscale devices fabricated using a *bottom-up* approach, since there is no analog in microfabrication. Nevertheless, hybrid systems consisting of nanoscale and microscale components will become increasingly common as the field continues to expand.

Fabrication issues notwithstanding, packaging is and will continue to be a significant challenge to the implementation of MEMS. MEMS is unlike IC packaging, which benefits from a high degree of standardization. MEMS devices inherently require interaction with the environment and since each application has in some way a unique environment, standardization of packaging becomes extremely difficult. This lack of standardization tends to drive up the costs associated with packaging, making MEMS less competitive with alternative approaches. In addition, packaging tends to negate the effects of miniaturization based upon microfabrication, especially for MEMS devices, requiring protection from certain environmental conditions. Moreover, packaging can cause performance degradation of MEMS devices, especially in situations where the environment exerts mechanical stresses on the package, which in turn results in a long-term device performance drift. To address many of these issues, wafer-level packaging schemes that are customized to the device of interest will likely become more common. In essence, the packaging of MEMS will move away from the conventional IC methods that utilize independently manufactured packages toward custom packages, which are created specifically for the device as a part of the batch fabrication process.

Without question, the increasing advancement of MEMS will open many new potential application areas to the technology. In most cases, MEMS will be one of several alternatives available for implementations. For cost-sensitive applications, the tradeoff between technical capabilities and cost will challenge those who desire to commercialize the technology. One of the biggest challenges to the field will be to identify application areas that are well suited for MEMS/NEMS technology and have no serious competitions. As MEMS technology moves away from component-level and more towards microsystems solutions, it is likely that such application areas will come to the fore.

14. Single-Walled Carbon Nanotube Sensor Concepts

Cosmin I. Roman, Thomas Helbling, Miroslav Haluška, Christofer Hierold

Carbon nanotubes are excellent nanocomponents that offer unique properties that can be exploited in next-generation devices. Sensing applications is perhaps the class that has most to gain from single-walled carbon nanotubes (SWNTs); virtually any property of SWNTs, such as electronic, electrical, mechanical and optical, can result or has already resulted in sensor concept demonstrators. The basic questions this chapter will attempt to address are, *why* use SWNTs? and *how* can SWNTs be used? in sensing applications. A tour through the gallery of basic nanotube properties is given in order to reveal the richness and uniqueness of this material's intrinsic properties. Together with examples from the literature, showing performance of SWNT-based sensors at least comparable to – but oftentimes surpassing – state-of-the-art micro- or macrodevices, nanotube properties should explain *why* there is so much effort currently being invested in this field. As nanotubes, like any other nano-object, are not easy to probe, a versatile strategy for accessing their properties, via the carbon nanotube field-effect transistor (CNFET) concept, will be described in this chapter. Furthermore, descriptions of CNFET device fabrication together with examples of SWNT sensor demonstrators utilizing the CNFET principle will be followed by proposals of *how* nanotubes can be utilized in sensors.

References 451

Sensors are only one possible application of SWNTs. Other notable applications include field emission devices, energy storage, composites, and nanoelectronics [14.1]. For example, *carbon-based nanoelectronics* has been identified by the International Technology Roadmap 2013 (ITRS) – edited by a consortium of scientists from all major semiconductor manufacturers and academic institutions – as the top contender to Silicon CMOS (complementary metal–oxide–semiconductor) technology. The focus of this chapter is however on sensing devices, for which carbon nanotubes (CNTs) present several key advantages including:

1. *Nanometer feature size*: Useful for building highly localized sensing units (active spots) and for large-scale integration (sensor arrays)
2. *Ultrahigh sensitivity and resolution*: Stemming from their unique structural and electronic properties (see Sect. 14.1.1) and high surface-to-volume ratio
3. *Ultralow power consumption*: Whether operating as transistors or mechanical resonators, the power needed to excite or probe an SWNT is in the order of 10 nW.

Because of these and other advantages, SWNTs have, in the relatively short time since their discovery, resulted in sensor device demonstrators that have been greeted with optimism worldwide. Many of these investigations have been published in prestigious research journals such as Science and Nature. There are, however, still some challenges to overcome before broader

acceptance in industrial product development activities will be observed. In fact, carbon nanotubes are today at a crossroad between basic science and engineering. Carbon nanotube device demonstrators and theoretical extrapolations often surpass in performance state-of-the-art devices, more than motivating any future attempts to solve the remaining issues. On the basis of the steep evolutionary slope experienced so far, it may not take long until carbon nanotube-based sensors appear on device and product roadmaps.

The remainder of this chapter is structured as follows. In Sect. 14.1 design considerations for SWNT sensors are described, starting with a brief survey of useful SWNT properties for sensing. The CNFET is introduced in Sect. 14.1.2 as a platform enabling access to individual SWNT properties during the sensing process. The current status of CNFET-based sensor characterization is captured in Sect. 14.1.3. Methods for fabricating, or supporting the fabrication of SWNT field-effect transistors (FETs) are reviewed in Sect. 14.2. Finally, Sect. 14.3 will be devoted to examples of CNT-based sensors, encompassing three main case studies, namely (bio)chemical, piezoresistive and resonator sensors, and recent advancements in those fields.

14.1 Sensor Design Considerations

The range of sensing schemes involving carbon nanotubes is considerable. A rough classification of CNT-based sensors can be done according to: *material*, *input*, and *output*. The carbon nanotube *material* utilized in sensors can vary from individual SWNTs, MWNTs and bundles, to CNT networks and composites and even to bulk (forests) CNT material (Table 14.1). Sensors based on nanotubes can respond to a wide range of *inputs*, including (bio)chemical (molecules), mechanical (deformation), optical (radiation), and electrical (fields by charges). Also different transduction mechanisms have been employed in CNT sensors to generate *outputs* such as electrical (conductive, capacitive), mechanical (resonance frequency), and optical (luminescence). A nonexhaustive CNT sensor catalog with references is given in Table 14.1.

For reasons of clarity and concreteness, in this chapter the discussion will be restricted to a particular class of CNT sensors, namely carbon nanotube field-effect transistor (CNFET) sensors. This class refers to FET configurations with *an individual single-walled carbon nanotube* (SWNT) channel that transforms *input stimuli of different origin* into *electrical signals at the output*. The CNFET is one of the simplest means to probe properties of an individual SWNT, and, at the same time, perhaps the most versatile building block available for engineering sensing devices. Furthermore, most of the knowledge gained in studying the rich variety of SWNT FET sensors is transferable to more complex devices involving MWNTs, bundles, or networks.

In the next subsection, some of the most important SWNT properties and property modulation mechanisms useful for sensing are listed and exemplified. The operation and particularities of CNFETs are reviewed in Sect. 14.1.2, whereas in Sect. 14.1.3, the current status of sensor characterization is briefly discussed.

14.1.1 CNT Properties for Sensing

SWNTs have many interesting properties for nanodevices in general, and nanosensors in particular. The properties of SWNTs are discussed in many textbooks [14.21–23]. In the following, we condense the most relevant SWNT properties, and support with examples on how these have been employed in sensor devices.

SWNTs are Nanometer-Thin Semiconducting or Metallic Wires

Structurally, SWNTs are molecular cylinders with monoatomic-thick walls, resembling a honeycomb lattice of carbon atoms (graphene) rolled into a tube (Fig. 14.1). The structure of an SWNT is uniquely identified by chiral indices (n, m) that give the so-called chiral vector $\boldsymbol{C}_\mathrm{h} = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$ determining the circumference of the nanotube upon rolling ($\boldsymbol{a}_{1,2}$ are the 2-D graphene lattice vectors, Fig. 14.1a). The (n, m) indices can be interchanged with (d_t, θ), where d_t is the nanotube diameter given by $d_\mathrm{t} \approx (a/\pi)\sqrt{n^2 + m^2 + nm}$ (nm) and θ is the chiral angle defined via $\tan\theta = \sqrt{3}m/(2n + m)$ ($a = 0.249$ nm is the graphene lattice constant). SWNTs can be classified with the help of θ, into zigzag ($\theta = 0$; $m = 0$), armchair ($\theta = \pi/6$; $n = m$), or chiral ($0 < \theta < \pi/6$; $n \neq m \neq 0$). In practice, SWNTs have diameters ranging from 0.4–3 nm, and lengths around a few μm, although tubes of almost cm in length have been produced [14.24].

From the *electronic* point of view, depending on chiral indices (n, m), SWNTs can be either semiconducting or metallic (hereafter labeled s-SWNT (semiconducting single-walled carbon nanotube) or m-SWNT (metallic single-walled carbon nanotube)). A simple model for the electronic structure of SWNTs (zone-folding

Table 14.1 Nonexhaustive catalog of CNT-based sensors with references

Sensor type	Sensor input	Sensor output	CNT material
Chemical sensors [14.2–4]	Gas molecules (i. e., NO_2, NH_3, O_2); organic vapor	Conductance change; CNFETs: Shift of gate threshold	Individual SWNT
Chemical sensors [14.5, 6]	Gas molecules, organic vapor	Conductance change; CNFETs: Shift of gate threshold	CNT networks; functionalization
Biochemical sensors [14.7]	Biomolecules (liquid phase)	Conductance change; CNFETs: Shift of gate threshold	Individual SWNT, CNT networks
Electromechanical sensors [14.8–12]	Pressure, displacement, strain	Conductance change	Individual SWNT
Pressure sensors [14.13]	Pressure	Conductance change	Macroscopic CNT block CNT composite
Resonant cantilevers [14.14, 15]	Molecules (mass loading)	Resonance frequency change, readout via field emission	MWNT, DWNT
Doubly clamped resonators [14.16–18]	Molecules (mass loading), strain	Resonance frequency change; readout via conductance change	Individual SWNT
Optical sensors [14.19, 20]	Photons, light	Photocurrent	Individual SWNT

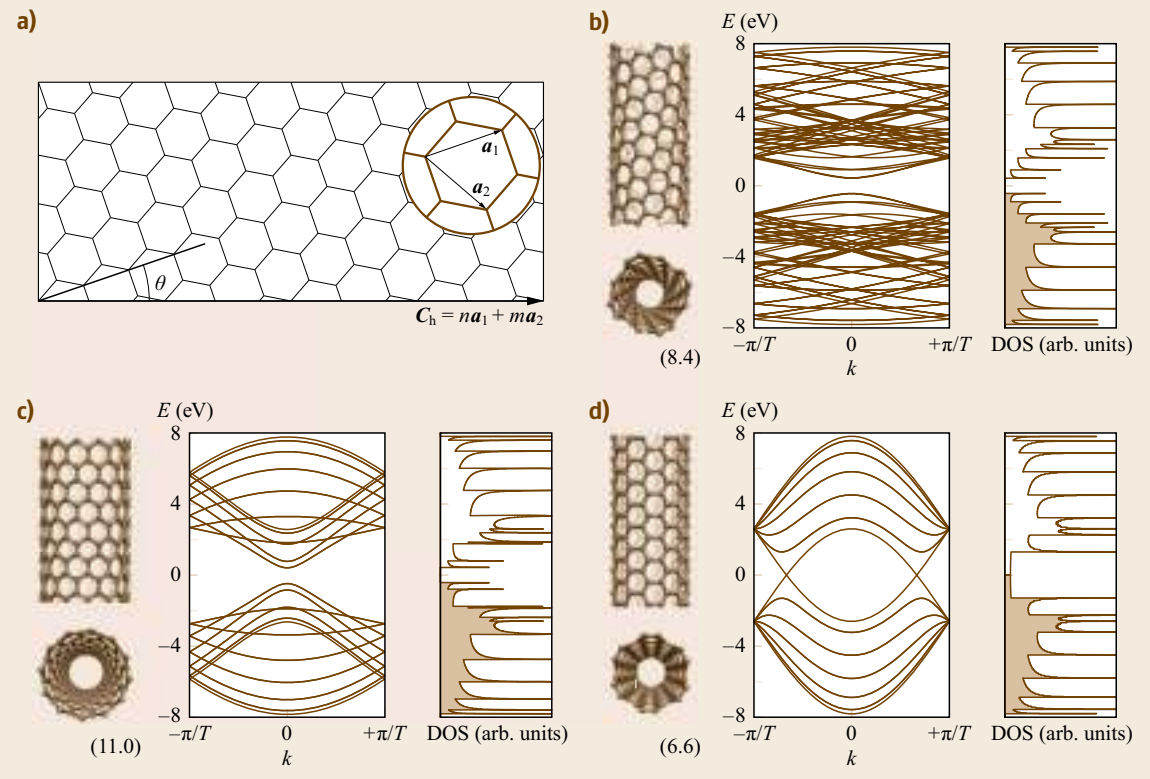

Fig. 14.1a–d Structural and electronic properties of SWNTs. **(a)** The *unfolded* unit cell of the chiral (8,4) CNT showing chiral vector $\boldsymbol{C}_h$, chiral angle θ, and 2-D graphene lattice vectors $\boldsymbol{a}_{1,2}$ (in *inset*). **(b)** The *folded* (8,4) structure, electronic band structure, and density of states (DOS). Bands are obtained via the zone-folding procedure applied to tight-binding dispersion relations (after [14.25]). **(c,d)** Band structure and DOS for zigzag (11,0) and armchair (6,6) nanotubes, respectively

of graphene tight-binding π bands) [14.25] predicts that those tubes for which $p \equiv (n-m) \bmod 3 = 0$ are metallic (1/3 of all SWNTs), the rest ($p = \pm 1$) being semiconducting (2/3 of all SWNTs). Structure, bands, and densities of states for three selected SWNTs (a chiral, a zigzag, and an armchair tube) are displayed in Fig. 14.1b–d. As for any 1-D structure, the density of states of SWNTs is singular at energies corresponding to sub-band extrema (van Hove singularities). A rough estimation for the electronic band gap of s-SWNTs is $E_g \approx (2at_0)/(\sqrt{3}d_t)$ (eV) [14.25] ($t_0 = 2.6$ eV is the so-called hopping tight-binding parameter for π orbitals). More accurate electronic structure calculations, taking into account the surface curvature of nanotubes, revealed that in fact only armchair (n,m) SWNTs are truly metallic; while other tubes with $p = 0$ actually do have a small band gap $E_g \approx 40/d_t^2$ [meV] [14.26] [these tubes are labeled SGS-SWNT (small-gap semiconducting single-walled carbon nanotube)].

The mentioned structural and electronic properties have resulted in a few SWNT sensor concepts. For example, FETs based on s-SWNTs have been utilized as charge detectors in flowmeters [14.27] or (bio)chemical sensors [14.2, 7] (more on this in Sect. 14.3.1). The high curvature ($d_t \approx 1$ nm) of carbon nanotubes (both tips and bodies) has been exploited for example in gas ionization sensors [14.28] and capacitance gas sensors [14.29].

SWNTs are Diamond-Stiff, Ultralight Strings

The basic *inertial* and *mechanical* properties of SWNTs are: linear mass density $\rho_L = 2.33 d_t$ (zg/nm) (1 zg = 10^{-21} g, and d_t is the tube diameter in nm as given above), Young's modulus E in the range of $\approx$ 1.25 TPa [14.30], max tensile strain 6%, and strength $\approx$ 45 GPa [14.31, 32]. These properties promote carbon nanotubes as ideal nanosized beams for mechanical sensors. For example, consider a straight, doubly clamped SWNT. Assuming that the SWNT can be treated as a continuum elastic beam, the resonance frequency of the fundamental flexural mode is given by [14.33]

$$\omega = \frac{4\pi^2}{L^2}\sqrt{\frac{EI}{3\rho A}\left(1 + \frac{L^2\sigma}{4\pi^2 EI}\right)},$$

where L is the tube length, I the moment of inertia, A the cross section area, ρ the mass density ($\rho_L = \rho A$), and σ the initial tension in the beam.

The dependence of ω on tension σ, has been utilized by *Sazonova* et al. [14.16] and others [14.17, 18] to demonstrate *tunable* CNT resonators. These devices can thus be employed as sensitive strain/stress sensors. Conversely, the attachment of a small mass on the tube increases the effective mass of the beam and as a result downshifts ω (via the ρ term in the above formula). This principle, known as resonant inertial balance, has been utilized in [14.14, 15, 17] to detect minute mass loading on a CNT. Sensing mechanisms for strain sensors and inertial balances are sketched in Fig. 14.2, and are discussed in more detail in Sect. 14.3.3.

SWNTs' Electronic Properties Can Be Tuned Mechanically

In analogy to crystalline semiconductors such as silicon, straining carbon nanotubes modifies their electronic band gap. With an extended version of the model that was used to obtain the bands in Fig. 14.1, *Yang* et al. [14.34] calculated the modulation of band gaps E_g of SWNTs of different chiralities under tensile (axial) and shear (torsional) strain (Fig. 14.3c,d). A linear approximation of the band gap change ΔE_g (in eV) with axial ε and torsional γ strain, was derived by the same group in [14.35]

$$\Delta E_g(\varepsilon,\gamma) \approx 3t_0 \mathrm{sgn}(2p+1) \times [(1+v)\varepsilon\cos 3\theta + \gamma \sin 3\theta]$$

with hopping parameter t_0, family p and chirality θ introduced earlier, and $v = 0.2$ the Poisson's ratio. The sign of ΔE_g depends on p, being positive for $p \in \{0, 1\}$ (band gap increases with strain), and negative for $p = -1$ (band gap decreases with strain). Also, the sensitivity with respect to strain, depends on the chiral angle; as such, armchair tubes ($\theta = \pi/6$) are insensitive to axial strain but maximally sensitive to torsional strain. Zigzag

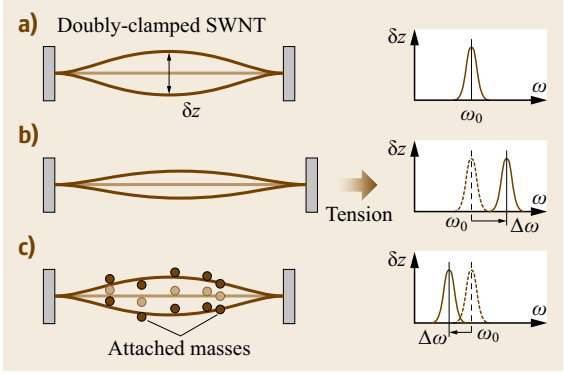

Fig. 14.2 **(a)** Sketch illustrating a doubly clamped SWNT beam and a resonance in the frequency response spectrum corresponding to the fundamental bending mode ω_0. **(b)** With applied tension the resonance frequency ω shifts upwards, whereas **(c)** with attached particles (mass loading) ω shifts downwards

tubes ($\theta = 0$) are just the opposite, whereas chiral tubes are sensitive to both types of strain.

For ordinary semiconductors such as silicon the conductance varies exponentially with band gap, i. e., $G \approx \exp(-E_g/(k_B T))$. This hindsight, has led to many sensor concepts (strain, torsion, force, pressure, etc.) that involve SWNTs as strain gauges [14.8–12]. More details about piezoresistive properties of SWNT in CNFET configurations will follow in Sect. 14.3.2.

SWNTs are Optically Active, Direct Gap Materials

Inspecting Fig. 14.1 reveals that sub-band extrema come in pairs at the same lattice wave number k (electron-hole symmetry). SWNTs are therefore optically active materials. The absorption of photons generates electron-hole (e^-–h^+) pairs, and conversely, e^-–h^+ recombination occurs over the nanotube band gap via photon emission. Resonant absorption of photons happens at energies corresponding to transitions between symmetric (with respect to E_F) van Hove singularities. These transition energies are labeled $E_{nn}^{s/m}$, where s/m denotes semiconducting or metallic, and $n = 1, 2, \ldots$ is the index of the van Hove singularity in increasing energy order ($E_{n+1n+1}^{s/m} > E_{nn}^{s/m}$, with $E_{11}^{s} \equiv E_g$).

Excited e^-–h^+ pairs with energies $E_{nn}^{s/m} > E_{11}^{s/m}$ (i. e., $n > 1$) de-excite nonradiatively into lower energy pairs whenever there is a continuum of states below $E_{nn}^{s/m}$, until an energy gap is reached. Therefore, no photoluminescent emission is possible for m-SWNTs, whereas s-SWNTs emit mainly over their band gap. Transition energies $E_{nn}^{s/m}$ cover a wide spectrum ($\subset (-9, 9)$ eV), thus SWNTs absorb light in UV (> 3.1 eV), visible and IR (< 1.8 eV) domains, but they emit mostly in IR ($d_t > 0.5$ nm corresponds to $E_g < 1.5$ eV). The basic optical properties of SWNTs are summarized in Fig. 14.4. In addition, because of the 1-D character, SWNTs only absorb and emit light linearly polarized along their axes. Optical properties of SWNTs have been exploited in devices such as polarized photodetectors [14.19, 20].

SWNTs are Sensitive to Molecule Adsorption

SWNTs are hollow structures, made of surface only. Molecular adsorption is therefore expected to have a huge impact on CNT electronic properties. Theoretically, the interaction of molecules with carbon nanotubes is a complex topic that can only be treated ab initio from quantum mechanics [14.36]. Generally speaking, molecules either physisorb or chemisorb at the CNT surface. Bond breaking is rare, as the sp^2 hybridized carbon network is very stable. Local sp^3 hybridization is however possible, and this adsorption mechanism is enhanced by curvature in small-diameter carbon nanotubes [14.37]. Defect sites in the nanotube wall greatly enhance adsorption as well [14.38].

At low molecular coverage, doping is the main effect, which is equivalent to a simple charge neutrality level shift E_F with respect to mid-gap (Fig. 14.5a). However, at large coverage densities, the bands of the tube itself can be distorted (by mixing with molecular orbitals). In addition to the charge neutrality level shift, in this regime, new bands may appear inside the nano-

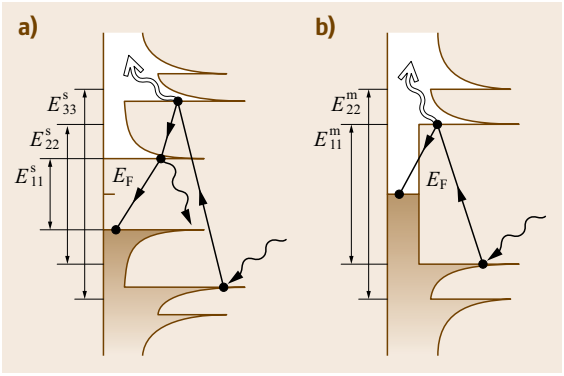

Fig. 14.4a,b Optical-related processes taking place in an SWNT after photon absorption. *Wiggly single lines* represent photons, solid lines electron transitions (excitation/de-excitation) and *wiggly double lines* stand for nonradiative processes (e.g., phonons). **(a)** A semiconducting tube can re-emit photons over the band gap, whereas in **(b)** metallic tubes, de-excitation is mostly nonradiative

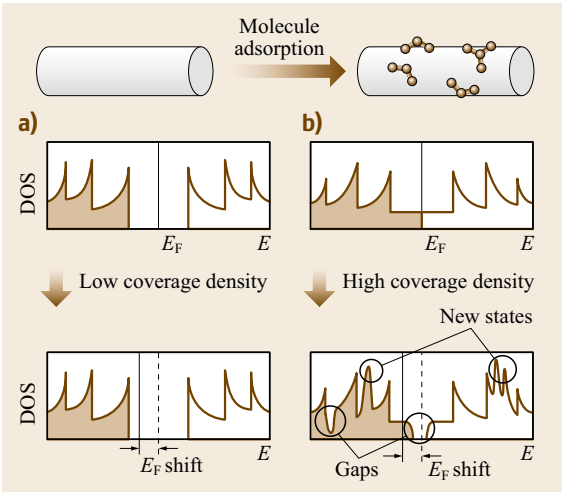

Fig. 14.5a,b The effect of molecular adsorbates on SWNT electronic properties. **(a)** An s-SWNT in the low coverage limit, suffers only a shift in the Fermi level E_F. **(b)** In the high coverage limit, new gaps and states, E_F shifts, and even work function changes are possible

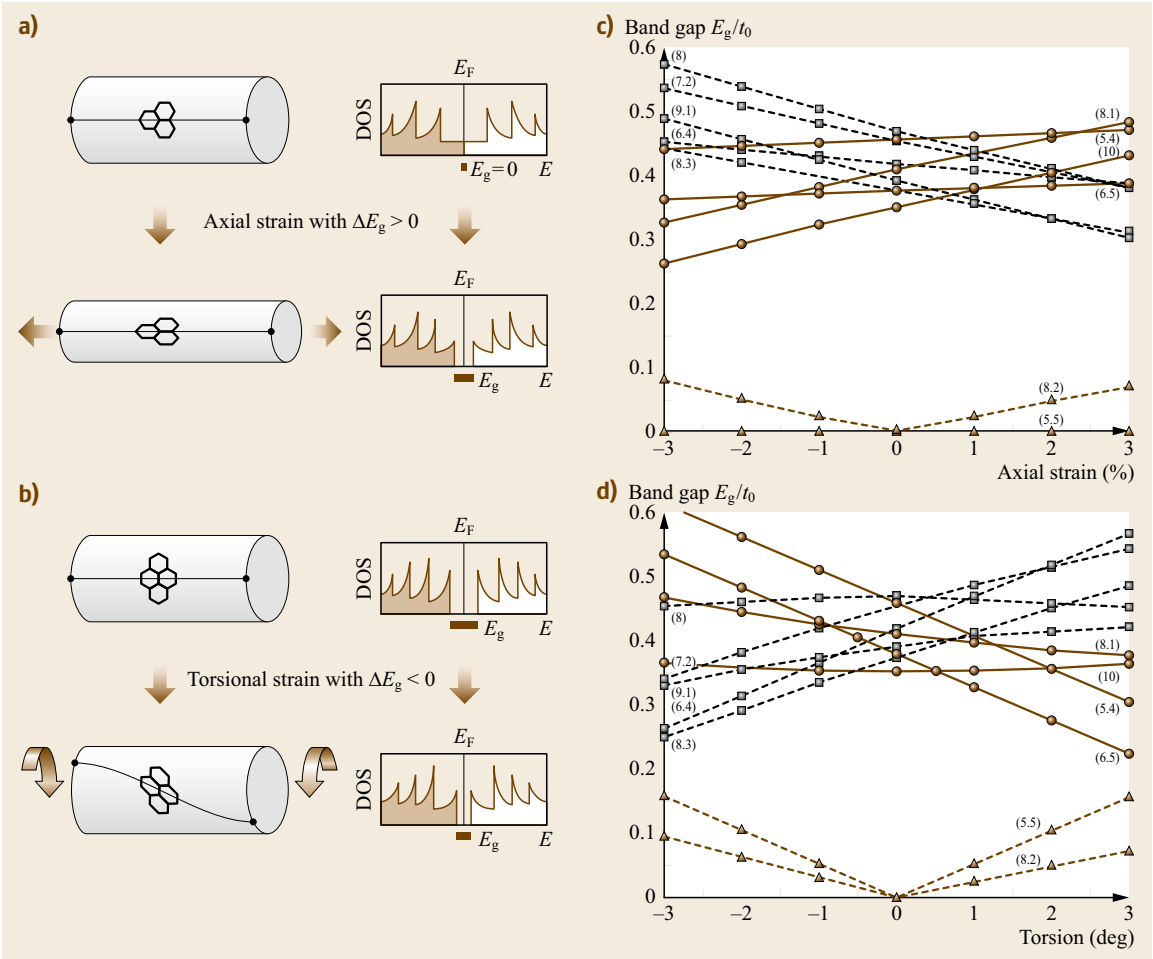

Fig. 14.3a–d Influence of strain on electronic properties of SWNTs. **(a,b)** Density of states modulation by strain. The example in **(a)** corresponds to tensile strain applied to a metallic zigzag CNT $p = 0$ (band gap opening), and the one in **(b)** to torsional strain applied to a chiral CNT with $p = 1$ (band gap closing). **(c,d)** Calculated band gaps as a function of tensile **(c)** and torsional **(d)** strain, for several chiralities belonging to each one of the three families ($p = 0$ *dotted*, $p = 1$ *dashed*, and $p = -1$ *solid lines*) (**(c,d)** after [14.34])

tube gap, or new gaps may open within the conduction or valence bands [14.39] (Fig. 14.5b). Even the electron affinity/work function of the nanotube can be modified in the process [14.37]. In m-SWNTs (as well as in the valence or conduction band of s-SWNTs), adsorbing molecules may create a disorder potential which results in band gap opening at the Fermi level.

Chemical and biochemical sensors based on the modulation of SWNTs' electronic properties upon exposure to target molecules, have been demonstrated in [14.2, 7]. The most widely used method for reading out these modulations is via transport measurements (CNFETs). However, capacitive [14.29] or optical [14.40] detection have also been employed. Chemical sensors will be treated in Sect. 14.3.1.

14.1.2 Carbon Nanotube FET Structures

The preceding section has focused on the properties of SWNTs and property modulation subject to mechanical, chemical, or optical stimuli. However, these properties are intrinsic to isolated SWNTs, and in order to become useful they need to be probed from the macroscopic world. A simple way to probe CNT properties is to electrically contact the nanotube with metallic leads. In combination with a nearby gate electrode it is a configuration known as the carbon nanotube field-effect transistor (CNFET). A basic CNFET is sketched in Fig. 14.6, and consists of an individual SWNT (the channel) placed on an insulator (typically SiO_2), contacted by source and drain electrodes, and gated by the

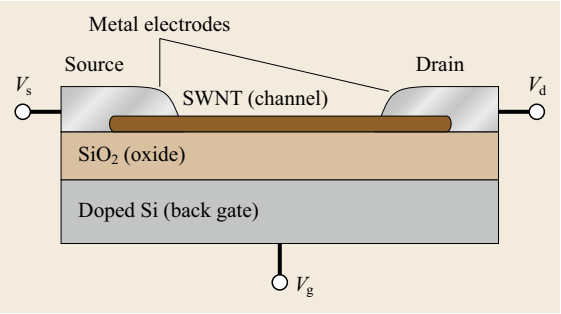

Fig. 14.6 Schematic representation of a simple SWNT field-effect transistor in cross-sectional view

conducting substrate (typically highly doped Si). The fabrication of such a structure (and of more advanced CNFETs) is covered in Sect. 14.2.2. Before giving examples of sensor demonstrators in Sect. 14.3 we review the basic operation and particularities of CNFETs. Understanding CNFET operation is important in identifying to what extent contacting SWNTs by metal leads affects their properties.

The right frameset to study transport in carbon nanotubes is mesoscopic physics, since nanotubes are crystalline, low defect density conductors, for which quantum mechanical effects are expected to play a role. Now, in a general conductor with length below the elastic mean free path (ℓ_e) and phase relaxation length (L_φ), at low temperature and low bias (quasi-equilibrium), each mode (Bloch wave) carries a current of $2e/h$. Therefore, the total source and drain current I_{sd}, can be obtained by summing the average number of modes M, going from source to drain, with energies in the range (eV_s, eV_d) centered at the Fermi level E_F. This yields $I_{sd} = (2e^2/h)MV_{sd}$ [14.41], where e, h are the usual electron charge and Planck's constant respectively, and $V_{sd} = V_s - V_d$ is the applied source-drain (low) bias. In other words, the sample conductance $G = I_{sd}/V_{sd}$, is simply MG_0, where the quantum conductance $G_0 = (2e^2/h) = (1/12.9)\,\mathrm{k\Omega}^{-1}$ was introduced.

For an m-SWNT, at any energy close to E_F (to within ± 1 eV), there are precisely two subbands (Fig. 14.1d), meaning that $M = 2$ and the predicted conductance of a metallic tube is $G = 2G_0\,(= 1/6.5\,\mathrm{k\Omega}^{-1})$. Conductance values approaching $2G_0$, have indeed been measured experimentally [14.42, 43] for m-SWNTs. However, in most situations, G is well below $2G_0$. One reason is that the metallic leads used to contact the tube differ in geometry, lattice and electronic properties (most notably work function and effective mass) from SWNTs. The heterojunction between a metal and the SWNT incorporates interface barriers that introduce scattering and reduce the electron transfer rates. Another reason for reduced conductance $G < 2G_0$ is disorder in the nanotube, caused by structural defects, adsorbed molecules, or simply the random potential profile of the underlying oxide (trapped charges, dangling bonds, etc.). Accordingly, in order to include interface and disorder, the conductance is reduced by a multiplicative factor $\mathcal{T}\,(G \to \mathcal{T}\,2G_0)$, describing the average transmission probability for an electron to propagate from source to drain. At room temperature, for long enough nanotubes, phonon scattering leads to incoherent, classically diffusive transport, respecting Ohm's law ($\mathcal{T} \approx 1/L$).

As mentioned previously, for m-SWNTs the transmission $\mathcal{T}$ can approach 1, which corresponds to thin contact barriers, easy to tunnel by electrons, and clean SWNT surfaces. For s-SWNTs, the situation is different. The physics of heterostructures predicts that at the interface between a metal and a semiconductor, Schottky barriers (SB) decaying slowly within the semiconductor may arise. Figure 14.7a depicts schematically the band diagram at the interface between a metal, of work function ϕ_m, and an intrinsic s-SWNT, of electron affinity χ_s ($\chi < \phi_m < \chi_s + E_g/2$). There are two such barriers, one at the source and the other at the drain. For simplicity, assume low V_{sd} bias (quasi thermal equilibrium), that allows defining a flat Fermi level throughout the structure. Assume as well that the conductance of the device can be written as $1/G = 1/G_s + 1/G_t + 1/G_d$, with $G_{s,t,d}$ the conductance of the source barrier, nanotube channel and drain barrier, respectively. The last assumption ignores interference effects and holds only if the length L of the nanotube segment exceeds L_φ [14.41]. Although still debated, this seems to be the case for SWNTs with $L \geq 1\,\mu\mathrm{m}$ at room temperature [14.44]. Within this picture, $G_d = G_s$ and we can focus on just one interface.

At finite temperature ($T \neq 0$), the charge flow across any metal-semiconductor junction, characterized by some interface barrier ϕ_B, has two components: tunneling through ϕ_B and thermionic emission over ϕ_B. At $T = 0$ only direct tunneling at E_F is possible. There are two such barriers, one for electrons ϕ_B^n and one for holes ϕ_B^p. In Fig. 14.7a, corresponding to $V_{gs} = 0$ and an intrinsic s-SWNT, $\phi_B^n = E_g/2$, $\phi_B^p = E_g + \chi_s - \phi_m$ and only thermionic emission is possible. In this situation I_{sd} is practically 0. A positive voltage $V_{gs} > 0$ applied on the gate (Fig. 14.7b) shifts downwards the bands in the bulk of the nanotube, but not the position of the band edges at the interface with respect to E_F. Thermionic emission of electrons increases while it decreases for holes. At some point, when the nanotube conduction band E_C becomes aligned to E_F, $\phi_B^n \equiv \phi_{SB}^n = \phi_m - \chi_s$ and $\phi_B^p = E_g$. The barrier ϕ_B^n is also a lot thinner than at $V_{gs} = 0$ because the electron density inside the nanotube is higher, screening any interface

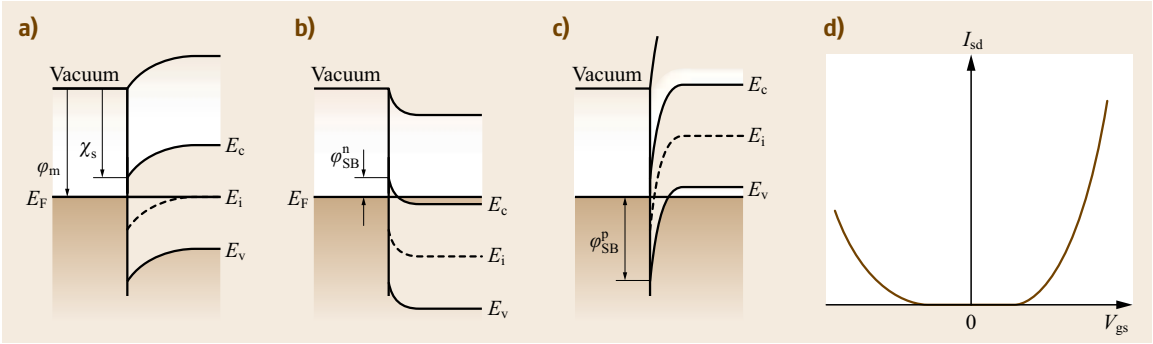

Fig. 14.7a–d Band structure diagram at the interface between a metal and an s-SWNT. **(a)** No gate bias applied $V_{gs} = 0$, **(b)** $V_{gs} > 0$ right above the threshold for electron conduction, and **(c)** $V_{gs} < 0$ right below the threshold for hole conduction. **(d)** The $I_{sd}(V_{gs})$ characteristic of the transistor, emphasizing asymmetric electron versus hole conductivity, due to $\phi^p_{SB} > \phi^n_{SB}$

potential more effectively. Tunneling of electrons increases and will eventually exceed thermionic emission (see below). Above this threshold, increasing V_{gs} further thins down the barrier, increasing I_{sd}. The barrier width depends, besides the position of E_F, on the geometry of the leads and oxide thickness [14.45]. Similarly, for negative, large enough gate voltage, the bulk valence band E_V becomes aligned to E_F (Fig. 14.7c). In this case $\phi^p_B \equiv \phi_{SB} = E_g + \chi_s - \phi_m$, $\phi^n_B = E_g$, and hole tunneling dominates. The inequality between the electron and hole barriers (in this example $\phi^p_{SB} > \phi^n_{SB}$) translates into asymmetric electron versus hole conductivity (the two branches of the $I_{sd}(V_{gs})$ characteristic), sketched qualitatively in Fig. 14.7d.

As opposed to normal, planar junctions (e.g., metal-silicon), Fermi level pinning is proposed not to exist in metal-CNT junctions, because of the particular tubular geometry of the CNTs [14.46]. As a result, different metals lead to barriers of different heights, which should also depend on the CNT diameter d_t (d_t determines the band gap E_g as discussed in Sect. 14.1.1). This fact, evidenced experimentally [14.47], is a strong confirmation of the Schottky barrier model of CNFETs. Consequently, it seems possible to completely eliminate the Schottky barrier by either choosing large work function metals such as Au, Pt, Pd ($\phi_m \approx 5.1$ eV) to cancel ϕ^p_{SB}, or low work function metals such as Al ($\phi_m \approx 4.2$ eV) to cancel ϕ^n_{SB}, knowing that the mid gap work function of SWNTs is around 4.5 eV. On the basis of this principle *Javey* et al. [14.48] have demonstrated G within 50% of the ideal $2G_0$. More experimental evidence in support of the SB-CNFET model has been brought by *Appenzeller* et al. [14.49, 50]. By measuring the temperature dependence of the $I_{sd}(V_{gs})$ characteristic [14.50], they concluded that tunneling is the main injection mechanism in SB-CNFETs and not thermionic emission. Work function alone, however, is not enough, as for example Pt ($\phi_m \approx 5.6$ eV) yields poor contacts, likely due to poor wetting or native oxide tunnel barriers [14.51].

For certain CNFET sensor devices, the Schottky barrier FET model is essential in understanding the device operation and sensing mechanism. This is the case of (bio)chemical sensors to be discussed in Sect. 14.3.1. In other devices, Schottky barriers, if present at all, contribute only to the contact resistance that is in a first approximation constant during the sensing process, and can be thus factored-out from the sensing mechanism. This is the case with piezoresistive gauges and resonators as presented in Sects. 14.3.2 and 14.3.3, respectively. For these devices, the transport picture introduced in this section, in terms of thermionic emission and tunneling, is still useful in explaining the operation. The only difference is that potential barriers for electrons and holes will be found on the nanotube and not only at the interface (Fig. 14.16c,d). Further insight into the physics of CNFETs in different regimes (large bias, low-temperature phenomena such as Luttinger liquid, Coulomb blockade, or orbital Kondo effects, etc.) may be obtained from [14.52–54].

14.1.3 Sensor Characterization

Sensor characterization refers to assessing performance metrics for a certain sensing technology. Some of the most important performance metrics are: sensitivity, signal-to-noise ratio (SNR), limit-of-detection (LoD), cross-sensitivity/selectivity, signal rise/fall time (speed), repeatability, offset/sensitivity, drift, hysteresis, and lifetime/robustness. So far, mainly *sensitivity* and *dynamic properties e.g., signal rise/fall time* have been targeted by the CNT sensor community (see results in Sect. 14.3). This is a natural situation, considering that the technology for fabricating individual

SWNT FETs is not yet scalable (Sect. 14.2). The efforts have been then focused on demonstrating that CNT nanosensors are superior to existent devices, so as to motivate and justify future investment. Conversely, the lack of batch fabrication processes has hindered gathering statistical information about characteristics of CNT sensors in operation; most publications on individual SWNT sensors (in particular FET devices) refer to data obtained from just a few fabricated samples. Therefore, *reproducibility* of sensor characteristics has been ignored, or marginally addressed.

To better illustrate matters, consider the story of chemical CNFET sensors. In 2000 *Kong* et al. [14.2] first report detecting NO_2 and NH_3 with individual SWNT FETs. In 2008, *Cho* et al. (in collaboration with Kong) published first results for a hybrid CNT chemical sensor with a CMOS interface chip [14.55]. The fabrication of CNT sensor arrays is still far from scalable, yet by this approach the interface captures signals from up to 24 CNFETs in parallel, further multiplexed and sent to analysis. The authors manage to measure 414 devices which results in a histogram of the distribution of resistance, spread over 6 orders of magnitude. This large dispersion is the result of varying number and type of CNTs in the devices, which is not controlled during fabrication. The dispersion is also visible in the recorded sensor response on the measurand. This kind of platform is a first step towards capturing device performance statistics, a prerequisite for process control and optimization.

Acquiring sensor *signal-to-noise-ratio* is currently under-progress. Electronic noise in CNFETs has received a lot of attention lately. *Collins* et al. [14.56] were the first to measure $1/f$ noise in SWNTs, both individual tubes and mats. The noise spectrum was found to agree with the classical noise power formula $S_V(f) = (A/f^{\beta})V^2$, where A is the noise amplitude, f the frequency, $\beta \approx 1$, and V the biasing voltage. Furthermore, the noise amplitude seems to obey the empirical Hooge law $A = \alpha_H/N$, with α_H the Hooge constant and N the number of carriers in the channel, because on average A decreases with the number of tubes in the sample [14.56]. Interestingly, the $S_V(f)$ formula is expected to hold for classically diffusive transport which is questionable for CNFETs. However, *Appenzeller* et al. [14.57] have calculated the average number of carriers inside SWNT ballistic FETs, for different contact metals, and found the Hooge law to be valid even in this regime, with a fitted α_H value of $\approx 2 \times 10^{-3}$ (same as for bulk silicon). Upon closer examination, it has been observed by Tersoff [14.58] that the Hooge law is not accurate in the subthreshold region of a CNFET. He proposed adding a phenomenological term to the noise power proportional to $(dI_{sd}/dV_{gs})^2$, that accounts for gating of the CNFET by fluctuating charges in the vicinity of the tube. The model has been recently confirmed experimentally in [14.59]. Overall, regardless of the model utilized, the noise in CNFETs is found to be significant, which limits the SNR of CNT sensors. The fact that noise is proposed to be mainly extrinsic [14.57], i. e., caused by external fluctuators, is however encouraging since it sets clear technical objectives in achieving better control of the CNT environment.

14.2 Sensor Fabrication: SWNT Synthesis and Integration

Fabrication of CNT devices involves many different aspects. These can roughly be grouped in two main tasks, namely *synthesis* of SWNTs and *integration* (or assembly) of nanotubes into devices. *Synthesis* is concerned with production of SWNTs with controlled properties such as diameter, length, defect densities, electrical conductivity type or even chirality. Sometimes synthesis is followed by postsynthesis methods for CNT purification, sorting, and most importantly functionalization. Conversely, *integration* refers to techniques and methods for placing SWNTs at predefined locations on a substrate with controlled number of nanotubes, orientation and slack (straightness). Postassembly, other processing steps such as nanotube electrical contacting or device encapsulation may follow. Also note that the distinction is sometimes artificial, e.g., in situ nanotube synthesis can be simultaneously both a synthesis and integration method. Complete processes for fabrication of micro- and nanosystems that integrate nanotube devices/sensors with acceptable yield, remains one of the key topics in CNT research. This section attempts to survey some of the available methods and processes aimed at controlled *diameter*, *chirality*, *location*, and *orientation*. Moreover, some consideration will be given to process *cleanliness*. In the last few years it has become increasingly clearer that sensor device performance is heavily affected by contamination of the nanotubes during processing.

As discussed in Sect. 14.1, the intrinsic properties and property modulations of SWNTs depend directly on the nanotube chiral indices. Another, more easily controllable parameter is SWNT *diameter* d_t. For example, the band gap E_g of an s-SWNT is inversely proportional to d_t, and so are Schottky barriers $\phi_{SB}^{n/p}$

in CNFETs. Other properties, most notably piezoresistance, depend as well on *chiral angle* θ. Since d_t and θ of an SWNT are determined during synthesis (production), methods for nanotube production are briefly surveyed in Sect. 14.2.1. *Location* and *orientation* control during synthesis or/and assembly, are important for building complex structures, for developing batch fabrication processes, or for large-scale device integration (sensor arrays). Section 14.2.2 will thus review processes for the assembly of SWNTs into devices, together with some general strategies in achieving location and orientation control. Section 14.2.3 will briefly discuss the importance of maintaining nanotube cleanliness throughout the process.

14.2.1 Methods for SWNT Production

Carbon nanotube production methods can be classified in two categories, namely high-temperature (*arc discharge* and *laser ablation*, $T =$ above 3000 °C) and medium temperature (*catalytic chemical vapor deposition* (CCVD), $T = 400–1100$ °C). Details about each method can be obtained from textbooks [14.21, 23] and also Chap. 8 of this book. Here, only those features that are relevant for CNT devices and integration are discussed.

Because of higher production temperature potentially annealing defects, *arc discharge* and *laser ablation* are expected to produce SWNTs with better crystallinity. However, with these methods it is not possible to produce SWNTs directly on the target substrate for device fabrication; only postsynthesis assembly is possible. Typically, as-produced nanotubes are first dispersed in a liquid that can be subsequently utilized to deposit SWNTs on the target substrate (Sect. 14.2.2). Also, the distribution of diameters is difficult to control with these methods during SWNT production. Nevertheless, after dispersing nanotubes in a liquid, different techniques can be employed to separate semiconducting from metallic and sort by diameter or even by chirality CNTs, as explained below. Sorting and purification techniques are reviewed in [14.60] and separation techniques in [14.61].

In *catalytic chemical vapor deposition*, SWNTs are synthesized on catalyst nanoparticles, particles or seeds and from a carbon-containing gas feedstock [14.62, 63]. Since CCVD is a catalytic process, patterning of a catalyst area can be utilized to grow nanotubes at selected locations directly on preprocessed (silicon) chips (more on this in Sect. 14.2.2). The key observation for CCVD is that *the size of the catalyst particle correlates with SWNT diameter* [14.64], and the *catalyst particle density determines* the final *CNT density* [14.65]. In [14.64] *Cheung* et al. have prepared Fe nanoparticles, with narrow diameter distributions centered around 3, 9 and 13 nm, on SiO_2. The grown CNT diameter distribution mirrors the initial particle size distribution, with a standard deviation roughly 30% of the average. However, 3 nm particles produce SWNTs with double-walled CNTs (DWNT), 9 nm produce D/MWNT with just a few SWNTs, and 13 nm produce only MWNTs, showing that typically a particle size < 3 nm is required for CCVD synthesis of SWNTs. However, as shown in [14.66] even larger particles can produce relatively small-diameter SWNTs by the so-called *perpendicular mode* growth mechanism. For SWNT-based FETs, a good compromise between low contact resistance (low $\phi_{SB}^{n/p}$) and high gap E_g (large ON/OFF ratio) would correspond to diameters in the range 1.5–2 nm [14.47]. Obtaining such small catalyst nanoparticles, while keeping a narrow size distribution, is challenging. *Li* et al. [14.67] have demonstrated SWNT diameter distributions of either 1.5 ± 0.4 nm or 3.0 ± 0.9 nm (again standard deviation/average $\approx$ 30%). Their method involved loading the hollow cavity of the iron-storage protein Ferritin (internal cavity diameter 8 nm) with Fe, followed by deposition on a substrate and calcination of the protein shell. Particle size was controlled by the iron loading time.

Currently, much activity is going into trying to achieve SWNTs with acceptable diameter distributions or even with one or few chiral indices. For CCVD grown tubes, the most promising approach to control nanotube diameter seems to remain improving particle size distribution. Conversely, there are few approaches to produce SWNTs with specific chiral indices via *cloning* [14.68, 69], specific seeds [14.70, 71] or catalysts with defined morphology/structure [14.72, 73].

Postsynthesis, for SWNTs dispersed in solution, regardless of their origin (arc discharge, laser ablation, or CCVD), several methods have been proposed to narrow down the diameter distribution. For example, *Tromp* et al. [14.74] have recently demonstrated diameter separation of SWNTs by noncovalent functionalization with anchor molecules optimally attaching to specific tube diameters (1.2 nm). This functionalization improves solubility of the selected tubes, which are subsequently separated from the nonsoluble bulk via sonication and centrifugation. By using DNA-wrapping and density gradient ultracentrifugation (DGU), *Arnold* et al. [14.75], have shown a good separation by diameter, for SWNTs with diameters below 1 nm. Soon after, the same group [14.76] extended the technique to surfactants, and managed to isolate narrow distributions of SWNTs with $> 97\%$ within 0.02 nm diameter range, with e.g., 84% of the tubes being of (6,5) chiral indices. Furthermore, by using mixtures of surfactants, they were able to produce predominantly

semiconducting or metallic SWNTs. Utilizing different DNA sequence motifs *Tu* et al. [14.77] obtained chirality-selected SWNTs with purity up to 90% and with the separation yield up to 0.8%. Combined with recently proposed continued or cloning growth methods [14.78–80] the DGU method might one day achieve macroquantities of essentially single-chirality SWNTs.

However, to date, achieving SWNTs with a single chirality in reasonable amounts and with simultaneously fulfilled requests for length, structural quality, and cleanliness remains the key challenge in CNT production.

14.2.2 Strategies for SWNT Assembly into Devices

Perhaps the simplest way to survey SWNT assembly strategies is to split the discussion into two parts by considering the nanotube source: *liquid suspension* (laser, arc, or CCVD SWNTs dispersed in liquid) or in situ growth (CCVD SWNTs grown directly on the target substrate). In-depth reviews of the various assembly strategies can be found elsewhere [14.81, 82]. Here, we focus only on those techniques resulting directly in CNFET device structures, or have some relevance to this topic. Regarding liquid suspension or in situ growth, there is an ongoing debate as to which one produces the best results. Table 14.2 compares the two in several aspects, showing a good balance of advantages and disadvantages. In general, each process type could be preferred depending on specific application requests.

Liquid Suspension Assembly Methods

Historically, liquid suspension assembly methods were the first to appear. The very first CNFETs, demonstrated in 1998 [14.83, 84], were built via a similar, simple process. In [14.84] laser-ablation SWNTs were dispersed by sonication in dichloroethane, and then spread over Au electrodes predefined using electron beam lithography (EBL), on a doped Si wafer substrate covered by a thick gate oxide film (SiO_2). The Si substrate, served as a back-gate to all devices. A schematic cross section of a CNFET stack, together with an AFM image of a fabricated device, is shown in Fig. 14.8 [14.83]. The same process, extended with a patterned poly(methyl methacrylate) (PMMA) top layer has been used in demonstrating one of the first CNT logic-inverters [14.85]. The only controlled parameter in this process is tube density, which can be adjusted – taking into account the electrode design – to obtain devices with only one nanotube bridging the correct electrodes, albeit at a very low yield.

It was soon realized that surface functionalization can significantly help in guiding SWNT depo-

Table 14.2 A comparison between liquid suspension and in situ growth assembly methods

SWNT source	CNT quality[c]	Average diameter control[e]	Diameter standard deviation[h]	Chirality control[i]	FET performance[j]	Alignment precision	Ease in integration
Liquid suspension[a]	+/−	−[f]	++	++	−[k]	−/+[l]	+/−[m]
In situ growth[b]	+/−[d]	++[g]	−/+	−/+	+	+	+[n]

[a] CNTs as produced by arc discharge or laser ablation
[b] In situ growth mainly by CCVD (Sect. 14.2.1)
[c] SWNT quality is attributed to crystallinity and defect density (Sect. 14.2.1)
[d] Progress in CCVD leads to constant increase in CNT quality. Measures can include postannealing, H_2 treatment
[e] SWNT diameters influence Schottky barrier heights in CNFETs (Sect. 14.1.2)
[f] The average diameter of arc discharge and laser ablation SWNTs is between 1.2 and 1.5 nm and is difficult to control
[g] The average diameter of SWNTs correlates with catalyst particle size and growth conditions and can be tuned (Sect. 14.2.1)
[h] A small diameter standard deviation should reduce performance variations in CNFET sensor devices
[i] Functionalization of SWNTs, sonication and centrifugation postsynthesis narrows diameter distribution. Individual chiralities may be selected (Sect. 14.2.1). Only applicable to SWNTs assembled from liquid suspension
[j] FET performance for sensing applications refers to low contact resistance, low noise, and high ON/OFF ratio
[k] Liquid suspension involves CNT surface treatment by (strongly binding) surfactants, sonication, and centrifugation. These steps may degrade CNFET performance
[l] Localized surface functionalization and dielectrophoresis increases the alignment precision. However, bundling of individual CNTs is still an issue in these processes
[m] Wet processing is better compatible with CMOS IC substrates, but wet processing may incorporate impurities on SWCNT and influence the SWNTs' electronic properties
[n] In situ growth is compatible with MEMS (microelectromechanical system) substrates including suspended MEMS and NEMS (nanoelectromechanical system) structures

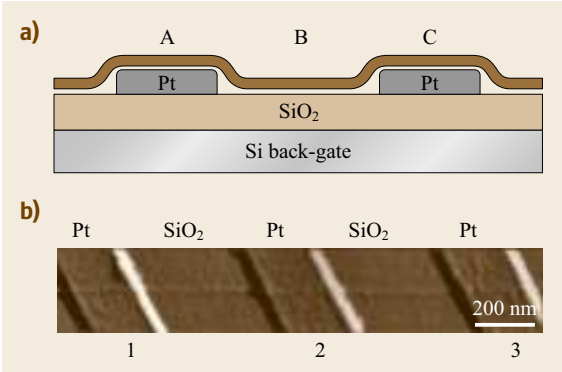

Fig. 14.8a,b First CNFET, **(a)** schematic view, and **(b)** AFM image (after [14.83])

sition. In [14.86] *Liu* et al. observed that SWNTs preferentially adsorb on amino-functionalized surfaces. Subsequently, they developed a process to define amino-functionalized regions where tubes are adsorbed, onto a tube-repelling surface (a trimethylsilyl self-assembled monolayer (SAM)). The process summarized in Fig. 14.9a, was utilized to place an SWNT between two contacts, as shown by the AFM image in Fig. 14.9b. Since then, other groups have utilized the same principle but with different nanotube-surface chemistries, for example the hydroxamic acid group-Al_2O_3 [14.87], patterned aminosilane monolayer [14.3], or polar-nonpolar interfaces [14.88]. Using an approach based on ion-exchange chemistry, *Park* et al. [14.89] recently demonstrated the first high-density integration of carbon nanotubes into transistors for logic applications.

Another important process family for SWNT assembly from solution is based on electric fields. *Krupke* et al. [14.90] used AC dielectrophoresis to place SWNT bundles from suspension, between predefined electrodes. Electrode arrays were defined using EBL, and connected to a frequency generator. On top of the electrodes a droplet of the CNT suspension was applied and evaporated. In general, $\approx 70\%$ of the electrodes were bridged by at least one bundle, and even individual SWNTs bridged occasionally. The same group [14.91], proposed that in D_2O (heavy water) with dielectric constant $\varepsilon_{D_2O} = 80$, s-SWNTs ($\varepsilon_s < 5$) will experience negative dielectrophoresis (repulsion from electrodes) and m-SWNTs ($\varepsilon_m \to \infty$) positive dielectrophoresis (attraction to electrodes). They showed that under these conditions m-SWNTs are indeed deposited on electrodes, while s-SWNTs remain in solution, thus providing a basic method to separate metallic from semiconducting tubes. Further progress in assembly processes based on dielectrophoresis are reviewed in [14.92].

In Situ Growth Assembly Methods

The second major class of assembly methods is based on *in situ growth* (via CCVD) of SWNTs directly on targeted (silicon) chips/wafers. CCVD has one major advantage over liquid suspension deposition regarding location control, namely the catalyst can be patterned [14.93]. The first process for fabricating CNFETs using CCVD was proposed by *Soh* et al. [14.94]. EBL was first used to pattern wells into which catalyst was deposited. A resist lift off left isolated islands with catalysts, from which SWNTs were grown by CCVD. Metal electrodes are defined on top of the catalyst is-

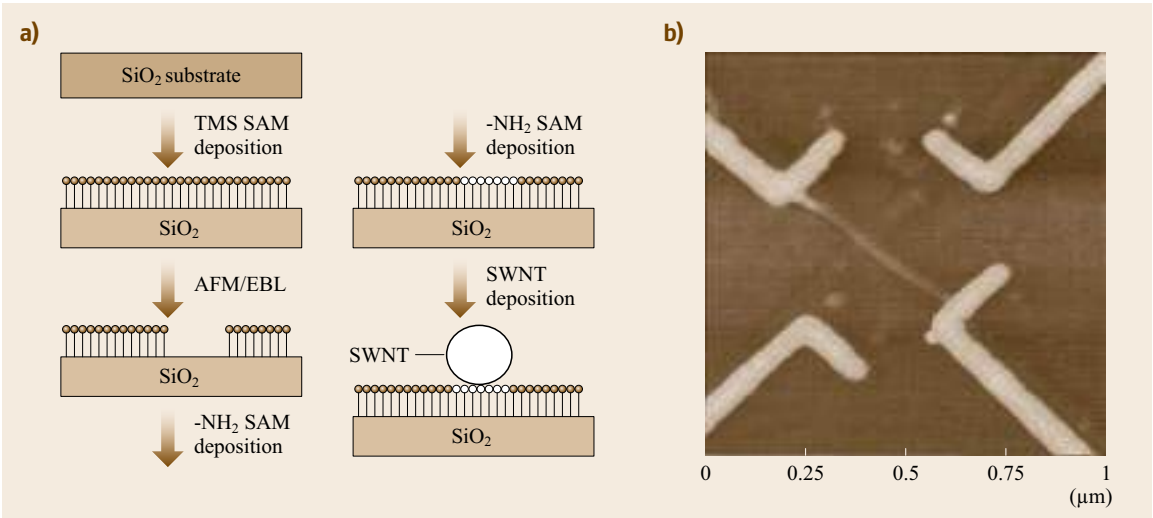

Fig. 14.9 **(a)** Schematic diagram of process for depositing SWNTs on functionalized surfaces. **(b)** AFM image of a device made on Au electrodes (after [14.86])

lands by lithography, contacting some of the grown tubes. The location of tubes is thus approximately controlled, as is the number of nanotubes between two electrodes by changing catalyst particle density and tuning growth parameters. Nevertheless, considerable progress has been made in catalyst deposition and patterning. *Javey* and *Dai* [14.95] developed a method that allows positioning of *individual* catalyst particles with EBL resolution. Furthermore, tube-to-particle number ratio approaching 1/1, i. e., close to 100% SWNT growth yield was achieved.

Since nanotube location control can be achieved by catalyst patterning, a lot of work subsequently focused on orienting the CCVD growth. Electric *field-directed growth*, has been pioneered by *Zhang* et al. [14.96], exploiting the large anisotropic polarizability of SWNTs. Polysilicon elevated structures were first defined onto a quartz substrate by optical lithography, with a catalyst layer on top, transferred by contact printing. Electric fields were applied during growth via outer poly-Si pads contacted by metal leads (electrodes). In Fig. 14.10 both the process flow and growth results are displayed, with/without applied fields. Field-directed growth was subsequently demonstrated on flat surfaces as well [14.97], and catalyst patterning and field-directed growth have been combined to build CNFETs by *Dittmer* et al. [14.98]. Another approach for orienting CNT growth was proposed in [14.99], where a strong correlation between the nanotube orientation and feedstock *gas flow direction* was observed. Finally, numerous recent studies show that *surface-directed growth* is also possible on substrates such as A- and R-planes of sapphire [14.100] or miss-cut C-plane sapphire [14.101]. The oriented SWNTs on sapphire have been contacted into FET configurations by *Liu* et al. [14.102]. These and other approaches are reviewed in [14.103].

As discussed in Sect. 14.1.1, SWNTs have interesting electromechanical properties, which often require free-standing (suspended) nanotube segments in order to manifest. Assembly of SWNTs into suspended microstructures, tends to be easier with *in situ growth* than from *liquid suspension*, because of complications arising from capillary forces. Directed growth of SWNTs from predefined silicon towers, was first shown by *Cassell* et al. [14.104] and [14.105], via a process that preceded the field-directed growth in Fig. 14.10. Basic electromechanical structures were presented later by the same group, with a process involving patterned CCVD growth directly from the surface of Mo, a refractory *metal* capable of withstanding CCVD temperatures ($\approx 900\,^{\circ}\mathrm{C}$) [14.106] and inhibiting catalyst particle diffusion. Integration of CCVD nanotube growth into a state-of-the-art fabrication process for microelectromechanical systems (MEMSs) has been demonstrated recently by *Jungen* et al. [14.107]. Both location and orientation control were achieved by confining the growth of the tubes geometrically between sharp poly-Si tips.

We end the survey of CNT assembly methods with one of the oldest processes for building SWNT devices, yet still the Swiss knife for rapid demonstration (proof of concepts) and basic investigations. The method proceeds from SWNTs already present in low density on the substrate, whether from liquid suspension or grown in situ. Location of nanotubes is recorded by AFM imaging, and electrodes are defined on nanotubes by e-beam lithography, metal evaporation and lift off. Since

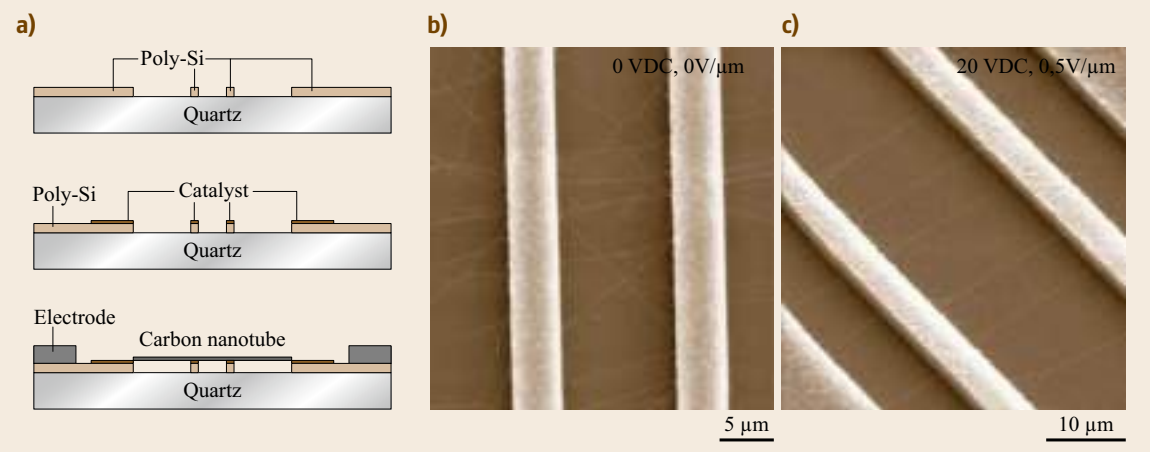

Fig. 14.10 **(a)** Schematic diagram process flow for electric-field-directed growth of SWNTs. **(b,c)** SEM images of SWNTs, grown in various fields. At zero field, tubes grow randomly **(b)**, whereas alignment is seen in 0.5 V/µm **(c)** (after [14.96])

the location and orientation of the tube is known, some basic yet precise micromachining is also possible in this approach. For example, *Witkamp* et al. [14.18] use a PMMA layer to define an etch mask over a top-contacted CNFET. The SiO_2 underneath the SWNT is etched away in HF, releasing the central part of the tube (Fig. 14.11). The resulting suspended nanotube device is an electromechanical resonator to be discussed in Sect. 14.3. The process is time-consuming (because of AFM imaging and EBL), area inefficient (because of nonaligned sparse tubes), and therefore nonscalable.

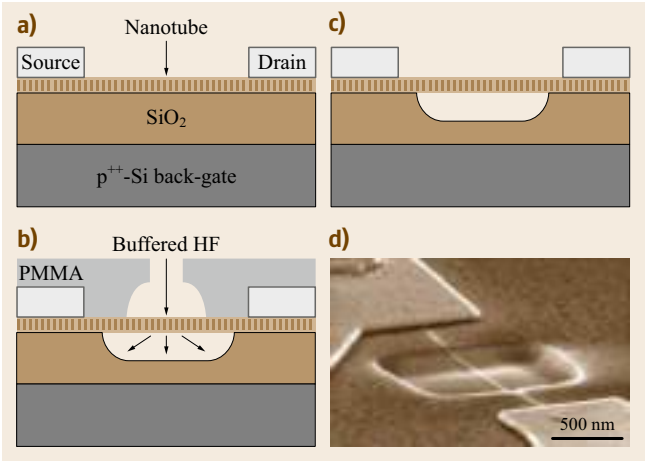

Fig. 14.11 (a–c) Schematic overview of an EBL fabrication process for SWNT resonators. (d) SEM image of a device (after [14.18])

However, currently it is the only process to guarantee individual SWNT devices with optimum alignment precision with respect to electrodes and other postdefined structures.

14.2.3 Process Contaminations and Sensor Performance

Though it was quickly established that structural defects strongly affect the properties of SWNT, the potential impact of process contaminations took more time before receiving proper attention. Indeed, the last years have produced a consistent body of evidence pointing in the same direction: integration processes are equally important to synthesis processes in regard to device quality.

A first striking example came with the work of *Muoth* et al. [14.108] who demonstrated *hysteresis-free* CNFETs in normal, humid air conditions (Fig. 14.12). This was made possible by growing individual, suspended ultraclean SWNT between two suspended tips which were subsequently metallized via shadow-masked metal deposition. This process avoids any wet chemistry or contact with lithography resists and, as such, it leaves the surface of the SWNTs, pristine, uncontaminated.

If a suspended SWNT architecture is incompatible with the application, there are some measures that can improve the quality of substrate-bound CNT devices as well. *Lee* et al. [14.109] and *Liu* et al. [14.110]

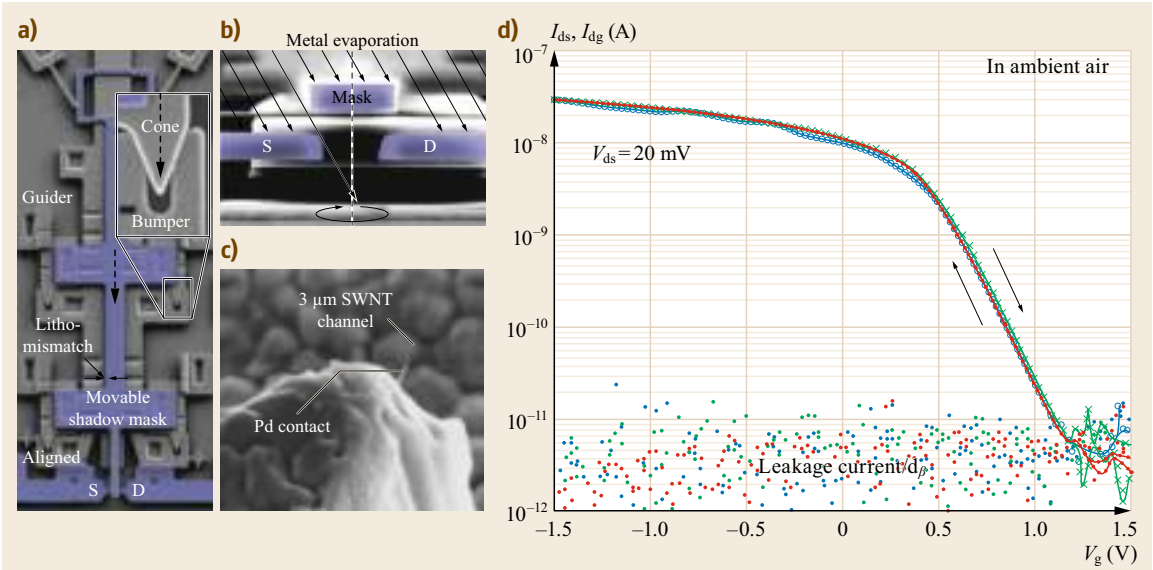

Fig. 14.12a–d Fabrication and demonstration of a hysteresis-free SWNT FET (a–c) SEM images of the movable shadow mask (a), tilted metal evaporation concept (b), and needle-like metallized nanotube contact (c). The transfer characteristic in (d), recorded under ambient conditions, shows no visible sign of hysteresis (after [14.108])

made use of a protective layer of Al_2O_3. This layer was deposited by atomic layer deposition right after the growth of SWNTs onto an SiO_2 substrate. All subsequent lithography steps – e.g., structuring of the top metal contacts – were performed on top of this protective layer. If needed the alumina layer could be stripped by H_3PO_4. This process results in reductions in hysteresis width down to 0.5 V in ambient air [14.109] and in improvements of device resistance [14.110], achieving 1.8 times reduction in the median value but also of standard deviation. The message is that if resists come into contact with CNTs, they are subsequently very hard to remove. The presence of resist residuals on the surface of SWNTs results in a significant degradation of device performance and should be avoided.

14.3 Summary of State-of-the-Art, Applications Examples

In the first section the intrinsic properties of SWNTs and the operation principle of CNFETs were introduced. Fabrication of CNFET devices, including a wide range of different SWNT production methods and various assembly strategies, was covered in the preceding Sect. 14.2. Here we finally show, by way of examples, how various properties of SWNTs assembled in CNFET configurations can be turned into sensor functions. This section will explain the concept and operation, and discuss sensing mechanisms for a few selected device demonstrators, rather than provide a thorough state-of-the-art review. References to review articles are given if available. An attempt will be made to discuss the operation of the selected SWNT sensor examples through the perspective of the CNFET model laid out in Sect. 14.1.2. In support, whenever possible, band diagrams (Schottky barriers, nanotube body bands) and their modulation by stimuli and/or bias conditions will be provided. The following subsections will cover *chemical and biochemical sensors* (Sect. 14.3.1), and *physical sensors* (strain-, pressure-, force- and mass) either piezoresistive (Sect. 14.3.2) or resonators (Sect. 14.3.3).

14.3.1 Chemical and Biochemical Sensors

Shortly after the first CNFETs were demonstrated, it was noticed that the electronic properties of these devices are very sensitive to environmental conditions. Specifically, *Collins* et al. [14.4] have shown that the resistance of SWNTs changed reversibly by up to 15% upon cycling the environment from air to vacuum, a phenomenon attributed to O_2 doping. Since then, both the number and diversity of proposed (bio)chemical SWNT sensors have grown tremendously; perhaps, this class of sensors is the largest in terms of number of publications. Excellent reviews on chemical and biochemical sensors based on carbon nanotubes are given in [14.111–113].

The first gas sensor based on an individual SWNT FET was demonstrated by *Kong* et al. [14.2]. The device is a back-gated FET, fabricated with a process as described in [14.94]. Such CNFET devices were exposed to NO_2 and NH_3 diluted in Ar or air, resulting in a significant change in their conductance. Figure 14.13a shows the response of a sensor to 200 ppm of NO_2. The conductance increased over three orders of magnitude in the time range of 2−10 s. The same device was exposed, after recovery, to 1% NH_3 (Fig. 14.13b), resulting in a 100-fold conductance decrease within 1−2 min. Upon measuring the $I_{sd}(V_{gs})$ characteristic (Fig. 14.13c) the authors conclude that NH_3 depletes the initially p-type SWNT of holes, shifting E_F away from the valence band, whereas NO_2 does the contrary, enhancing the hole concentration and pushing E_F closer to the valence band.

The exact mechanism responsible for the change in the $I_{sd}(V_{gs})$ characteristic – attributed to doping by *Kong* et al. in their original paper [14.2] – remains a controversial issue. Molecules can adsorb on the nanotube or onto the metal contacts or both, but transport in these different situations is expected to change in a qualitatively different fashion. If the molecules adsorb on the nanotube body, doping the nanotube and thus shifting its charge neutrality level E_F, the result is simply a *rigid shift* of the $I_{sd}(V_{gs})$ characteristic as sketched in Fig. 14.14b. Conversely, molecules attaching mainly to the contacts modify the metal work function ϕ_m. This modifies the relative height of the Schottky barriers $\phi_{SB}^{n/p}$, which translates into a changed polarity of the device, as illustrated by the $I_{sd}(V_{gs})$ characteristic in Fig. 14.14a. Molecules could also adsorb on the nanotube regions close to the contacts, changing the electron affinity of the SWNT χ_s or the depletion region, which also affects the electron and hole Schottky barrier heights $\phi_{SB}^{n/p}$ or widths. These two signatures were observed experimentally in [14.45] and assigned to one of the two mechanisms with the help of device simulations. Exposing a CNFET to potassium showed the *tube doping* signature, and oxygen showed the *contact adsorption* signature (Fig. 14.14c,d).

The sensing mechanism becomes further convoluted by the presence of the gate oxide. *Helbling*

et al. [14.114] showed that etching away the underlying SiO_2 from a CNFET results in chemically sensitive devices. Conversely, *Auvray* et al. [14.3] observed that SWNTs on aminosilane are 4–5 times more sensitive to triethylamine than SWNTs on SiO_2. These results suggest that, though the substrate may influence the sensitivity of the device, the substrate is not necessary for the sensor operation.

However, the debate concerning the role played by the metal contacts in gas sensing is still ongoing. In order to shed light on this issue, several groups have designed experiments in which only selected regions of the CNFET have been exposed to the molecules [14.115–121]. This was achieved via local passivation of the metal contacts, which leaves part of the nanotube surface exposed to the environment. There are mainly two opposing views on this issue. The first, most recently articulated in [14.121], holds that the dominant sensing mechanism is adsorption of the oxidizing molecules, NO_2 or NH_3, on the metal contacts leading to a change in the metal work function, whereas adsorption on the nanotube leads to smaller changes. Evidence is provided by gas measurements, Kelvin probe microscopy, and transistor modeling. The second view, summarized recently in [14.120], holds that in sensors with metal contacts passivated by gas-impermeable layers the sensor signal comes from adsorption of the molecules onto the nanotube itself. Evidence is provided by gas measurements, fully passivated control devices, and ab initio calculations [14.36]. Neither of the two views excludes the other. The debate concerns the dominant mechanism, but both admit the existence of the other mechanism. It is important to note that the interpretation of results may depend on factors such as device architecture, fabrication process, and even gas concentration range. Thus, one is advised to familiarize oneself with both views and assign the dominant mechanism based on the actual experimental conditions.

For CNFETs to work as biochemical sensors, some modifications are required. First, because of operation in aqueous solutions that contain ions, the back-gate is replaced by a reference electrode known as the liquid gate [14.122]. With this modification, CNFETs exhibit similar $I_{sd}(V_{lg})$ characteristics to devices in normal, gaseous environment ($V_{lg} \Leftrightarrow V_{gs}$). Second, to facilitate adsorption of biomolecules onto SWNTs, functionalization is often required [14.123]. The first biochemical CNFET sensor was demonstrated by *Besteman* et al. [14.7]. Glucose oxidase was attached to an SWNT, which subsequently showed response to both pH and concentration of glucose (0.1 M). In this study functionalization is an enabler; un-functionalized devices simply do not respond. More generally, functionalization is essential both in liquid and gas phase sensors for increasing sensitivity and selectivity [14.124]. For biosensors, the debate concerning the sensing mechanism follows the one for chemical sensors. Combining simulation and measurements, *Heller* et al. [14.125] found that both electrostatic gating and Schottky barriers are contributing, and that substrate also influences the response. The current understanding of the sens-

ing mechanisms as well as recent advancements in nanotube-based biosensors are reviewed in [14.126].

Concerning the sensing performance of chemical CNFET sensors, from the initial publication of *Kong* et al. [14.2], reporting concentration limits of detection of ≈ 2 ppm for NO_2 and $\approx 0.1\%$ for NH_3, there has been significant progress. Naturally, the limits of detection depend on the gas being sensed. *Chen* et al. [14.127] have measured concentrations as low as 40 ppt NO_2 and 200 ppt NH_3 with carbon nanotube mats under continuous UV illumination. With individual SWNT devices, the limit of detection was two orders of magnitude higher, but nonetheless, detecting 5 ppb of NO_2 is remarkable and well within the range that makes this technology interesting for environmental gas monitoring. Regarding CNFET biosensors, *Besteman* et al. [14.7] speculated that CNFET sensors have the potential to measure the enzymatic activity of even a single redox enzyme. Since then, single-molecule and single-charge resolution have been achieved experimentally by *Choi* et al. [14.128] and *Sharf* et al. [14.129], respectively.

Besides sensitivity, the other attractive performance metric of SWNT sensors is their energy efficiency. Biosensors are very often utilized for single measurements, diminishing the importance of recovery. But gas sensors are expected to work continuously and lots of energy is typically required to desorb attached molecules. *Chikkadi* et al. [14.119] managed to demonstrate that reproducible sensor recovery is possible with only 2.9 μW for 10 min (Fig. 14.15). Considering the power required to read out a nanotube gas sensor of around 32 μW [14.55], sensor systems operating with a few tens of μW are now possible based on this technolog1y, paving the way to tiny, ultralow power gas sensors for wireless sensor applications.

14.3.2 Piezoresistive Sensors

The electronic structure and thus the electrical conductance of all three classes of SWNTs (metallic, semiconducting, and small band gap semiconducting) depends greatly on the mechanical deformation of the SWNT structure as theoretically predicted in [14.26, 35] and briefly outlined in Sect. 14.1.1 for axial and torsional strain.

This theoretical expectation was first experimentally corroborated in pioneering work by *Tombler* et al. [14.8], for a suspended m-SWNT clamped to and contacted by two metal electrodes. Upon deforming and straining the nanotube by an AFM tip, the overall conductance of the device decreased reversibly by two orders of magnitude (strain $\varepsilon \approx 3\%$). The authors attributed this large conductance change to a mechanically induced modification of the atomic structure of the SWNT region right below the AFM tip, which could raise a tunnel barrier in the path of free carriers.

A suspended doubly clamped CNFET configuration to measure the piezoresistance (i. e., change of the band gap as a function of axial strain $dE_g/d\varepsilon$) was first proposed by *Minot* et al. [14.9]. The experimental setup was similar to that of Tombler. The CNFETs were strained by an AFM tip while the tip was simultaneously used as a local gate in the center region of the suspended SWNT (Fig. 14.16a). The overall CNFET conductance was tuned by the gate voltage at

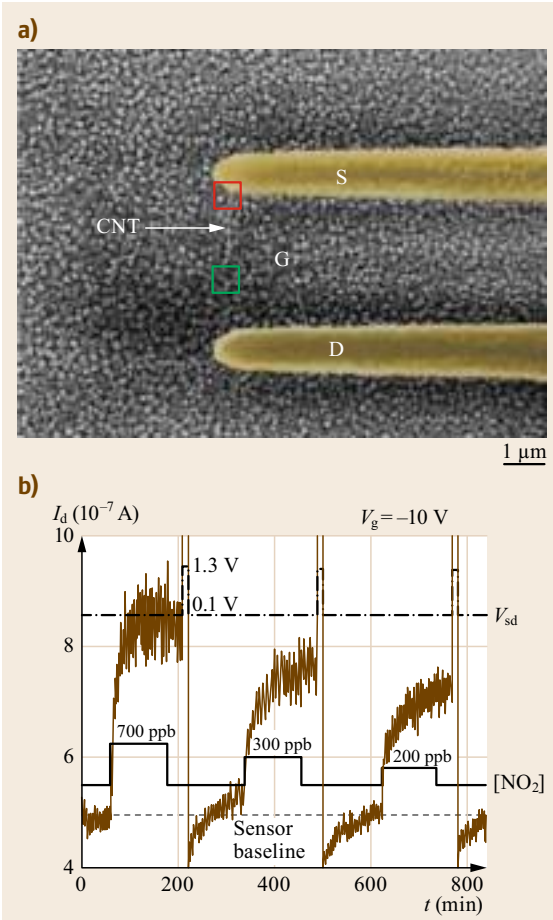

Fig. 14.15a,b Demonstration of an ultralow power NO_2 gas sensor based on SWNT FETs. **(a)** Top-view SEM image of a fabricated device consisting of suspended nanotube between source and drain contacts. **(b)** Sensor recovery by Joule self-heating. the tip (V_{tip}). Figure 14.16b shows a series of sweeps of V_{tip} on an intrinsic m-SWNT when no strain is applied. By gradually straining the suspended doubly clamped CNFET a small band gap opens ($dE_g/d\varepsilon > 0$), according to the theory of SGS-SWNTs ($p = 0$), and a conductance dip forms in the gate characteristic at $V_{tip} \approx 1$ V. In this configuration it is assumed that the tip gate is acting locally in the middle part of the SWNT, while the sections close to the contacts are p-type (this is because for $V_{tip} = 0$ V the CNFET is in the on-state hole conductance). The strained CNFET characteristic can be explained starting from this initial situation. For a small positive gate voltage ($0\,\text{V} \le V_{tip} < 1\,\text{V}$) a barrier for holes is created leading to a reduction of the total current (Fig. 14.16c). The hole current reaches its minimum (I_{min}) when the barrier formed by V_{tip} reaches E_g. Up to this point only thermionic emission is accounted for, since no tunneling is expected due to the width of the barrier formed by the tip gate (> 20 nm). For $V_{tip} > 1$ V the CNFET section of the SWNT reaches in-

version and transport increases due to tunneling through the thinned barriers ζ (Fig. 14.16d). Since the barrier height for holes at $I_{\min}$ is approximately equal to the band gap E_g of the CNFET, and since thermionic emission dominates, the overall change in the band gap of the CNFET due to strain can be extracted by employing the thermally activated conductance formula $G \approx \exp(-E_g(\varepsilon)/(K_B T))$. As a result an overall change of the band gap of $dE_g/d\varepsilon \approx 35\,\text{meV}/\%$ was extracted. This value is below the theoretical prediction of a maximum band gap change of $dE_{g\max}/d\varepsilon \approx 94\,\text{meV}/\%$ [14.35].

In contrast to doubly clamped suspended SWNTs the electromechanical properties of CNFETs adhering to thin film membranes were investigated in two studies [14.10, 11], confirming piezoresistivity also in this situation. *Grow* et al. [14.10] apply the gate voltage at the metallized backside of an SiN_x membrane. For SGS-SWNT FETs the $I_{sd}(V_{gs})$ characteristic shows that the unstrained device is p-type with no or only small Schottky barriers for the holes (small ON-state resistance). The applied strain increases the band gap ($dE_g/d\varepsilon > 0$). By increasing the back-gate voltage V_{gs} a small but wide hole barrier (zero tunneling) is formed along the length of the CNFET channel reducing the hole current, and reaching $I_{\min}$ when the barrier is close to E_g. The largest change in the channel conductance at various strain levels happens then at $I_{\min}$.

The sensitivity of the devices can be expressed as $|dE_g/d\varepsilon|$ in $\text{meV}/\%$ or alternatively by the gauge factor (GF) which is usually used for classical piezoresistors. The GF is defined by the relative change of resistance divided by the strain of the SWNT and it is only constant for small strains ($d\varepsilon$) around a working point ε_0. *Minot* et al. [14.9] reported a maximum sensitivity of $54\,\text{meV}/\%$ for the suspended CNFET while *Grow* et al. [14.10] extracted $180\,\text{meV}/\%$ for an SGS-SWNT adhering to a substrate. For a metallic SWNT a sensitivity of 340–430 $\text{meV}/\%$ was reported [14.11]. Such high sensitivities of CNFETs in contact with the substrate may be explained by additional mechanical distortions of the SWNTs due to interaction with the dielectric substrate. Some reported GF values include 856 for a membrane-based unstrained CNFET [14.10] and 2900 for a prestrained suspended metallic SWNT with $\varepsilon_0 \approx 4\%$ [14.12].

Research on the piezoresistivity of SWNTs has continued in the past few years in two directions. On the one hand, the integration of SWNTs into functional devices such as pressure sensors has been pursued [14.130, 131]. On the other hand, research into furthering understanding of the piezoresistive effect at the atomistic level has continued [14.132]. By exploiting the extraordinary gauge factors of SWNT, *Helbling* et al. [14.130] have demonstrated ultra-miniaturized pressure sensors with diaphragm diameters as small as $40\,\mu\text{m}$. *Burg* et al. [14.131] have extended this work, by using a process flow based on dielectrophoresis, to assemble the SWNT strain gauges at the high-strain locations on the membrane. At the fundamental level, *Muoth* et al. [14.132] have integrated individual, ultraclean SWNTs into MEMS tensile actuators. This approach significantly improved the control of the applied uniaxial strain in the nanotubes, while giving simultaneous access to the transport properties under strain and to the chiral indices by in situ TEM electron diffraction. Their investigations established that SWNTs withstand 4.5% strain repeatedly and confirmed the sign of the band gap modulation with strain according to the family index as predicted by the theory outlined in Sect. 14.1.1.

In general, the piezoresistive effect of SWNTs has been experimentally manifested in CNFETs by loading the tubes with axial strain. Though there are still quantitative discrepancies between theory and experiment regarding the band gap change rate with strain, this is one of the fortunate cases in which experiment exceeds theoretical expectations. From a practical point of view, piezoresistive CNFETs excel with regard to very high sensitivity already at small strain ($< 0.2\%$), nanoscale size, and ultralow power consumption (nW).

14.3.3 Resonant Sensors

Along with piezoresistive sensors, resonant sensors are useful in measuring mechanical stimuli such as strain and stress. In addition to that, resonators can be utilized to measure inertial properties (mainly mass), in which case they are known as inertial balances. The core principle, briefly explained in Sect. 14.1.1, exploits the dependence of the resonant frequency – typically the fundamental flexural mode – of an SWNT beam on quantities such as tension σ and mass density $\rho, \omega = \omega(\sigma, \rho)$.

For measuring mass, via $\omega(\rho)$, either a cantilever configuration or doubly clamped beam can be employed. Indeed, the cantilever configuration has been utilized right from the beginning to acquire CNT Young's moduli [14.133] or to demonstrate mass sensing. *Poncharal* et al. [14.14] were the first to show that with a MWNT cantilever, a mass as small as $22 \pm 6\,\text{fg}$ ($1\,\text{fg} = 10^{-15}\,\text{g}$) can be measured. *Jensen* et al. [14.15], claim to have detected only 51 Au atoms, corresponding to a mass of roughly 17 zg ($1\,\text{zg} = 10^{-21}\,\text{g}$), with a DWNT cantilever inside a field-emitting device.

Conversely, the doubly clamped beam configuration is in addition useful for measuring stress and strain, not possible with cantilevers. Moreover, for doubly clamped beams, biasing and measuring currents

through the nanotube is straightforward, which is a prerequisite for electronic readout. The first electromechanical resonator based on a doubly clamped carbon nanotube was proposed by *Sazonova* et al. [14.16]. Structurally, the device is a standard back-gate CNFET with an SWNT channel doubly clamped by top electrodes and partly or totally suspended over a trench (Fig. 14.17a and Fig. 14.11d [14.18]). The suspended region is the vibrating part of the nanotube.

The mechanical actuation of the nanotube is electrostatic. An applied gate voltage V_{gs} induces a capacitive Coulomb force F deflecting the suspended nanotube segment. V_{gs} contains a DC component to prestrain the nanotube ($\sigma \neq 0$), and a harmonic at frequency ω to excite the nanotube beam vibration. At frequencies close to the fundamental flexural mode ω_0, the nanotube behaves like a forced classical beam [14.134], oscillating with an amplitude δz that follows a classical Lorentzian centered at ω_0 (Fig. 14.2).

The readout of the nanotube displacement is done via the channel conductance. For a CNFET the conductance G depends both on the gate voltage V_{gs} and the distance of the nanotube to the gate z through the gate capacity C_{gs}. This is so because the conductance is proportional to the free-carrier concentration in the channel ($G \approx Q = C_{gs}V_{gs}$). At frequencies close to ω_0, the oscillation amplitude δz becomes important, resulting in a detectable conductance oscillation $\delta G(t)$. Theoretically $\delta G(t)$ is as easy to read as applying a source-drain voltage V_{sd} and measuring the current I_{sd}. However, because $f_0 = \omega_0/(2\pi) > 10\,\text{MHz}$, *Sazonova* et al. [14.16] have proposed using the CNFET as a mixer to downconvert $\delta G(t)$ from ω to $\Delta\omega$, conveniently chosen at around 10 kHz. In Fig. 14.17b, an intensity map of the current amplitude $\delta I_{sd}(V_{gs}, \omega)$ is shown [14.16]. As expected, ω increases with V_{gs}, since the static gate voltage changes the tension σ in the nanotube. Branches visible below the fundamental ω_0 in this map, are due to initial slack. Indeed, *Witkamp* et al. [14.18] have shown that for straight tubes (no slack) the modes below the fundamental are suppressed.

Regarding the sensing capabilities of CNT resonators, *Sazonova* et al. [14.16] have estimated the *force* resolution to be around $1\,\text{fN}/\sqrt{\text{Hz}}$ ($1\,\text{fN} = 10^{-15}\,\text{N}$), within a factor of ten of the best measured sensitivities at room temperature. At cryogenic temperatures of about 1.2 K, this resolution can be improved by 5 orders of magnitude, down to $12\,\text{zN}/\sqrt{\text{Hz}}$, as shown by *Moser* et al. in [14.135].

In [14.17], *Peng* et al. loaded a CNFET resonator with thermally evaporated Fe. Assuming a uniform coating of 2 nm of Fe ($\approx 3.5 \times 10^{-17}\,\text{g}$), they extrapolated a minimum detectable mass in the order of 1 ag ($10^{-18}\,\text{g}$). A series of improvements have followed ever since. *Lassagne* et al. [14.136] demonstrated a measurable mass limit of 25 zg at room temperature and of 1.4 zg at 5 K which corresponds roughly to the mass of only 15 Cr atoms. On the basis of measured noise power spectral densities at 20 mK, *Hüttel* et al. [14.137] estimated a mass resolution of $7\,\text{yg}/\sqrt{\text{Hz}}$ which would enable the detection of a single He atom. *Chaste* et al. [14.138] reported a mass resolution of only 1.7 yg, the mass of a single proton, at liquid helium temperatures.

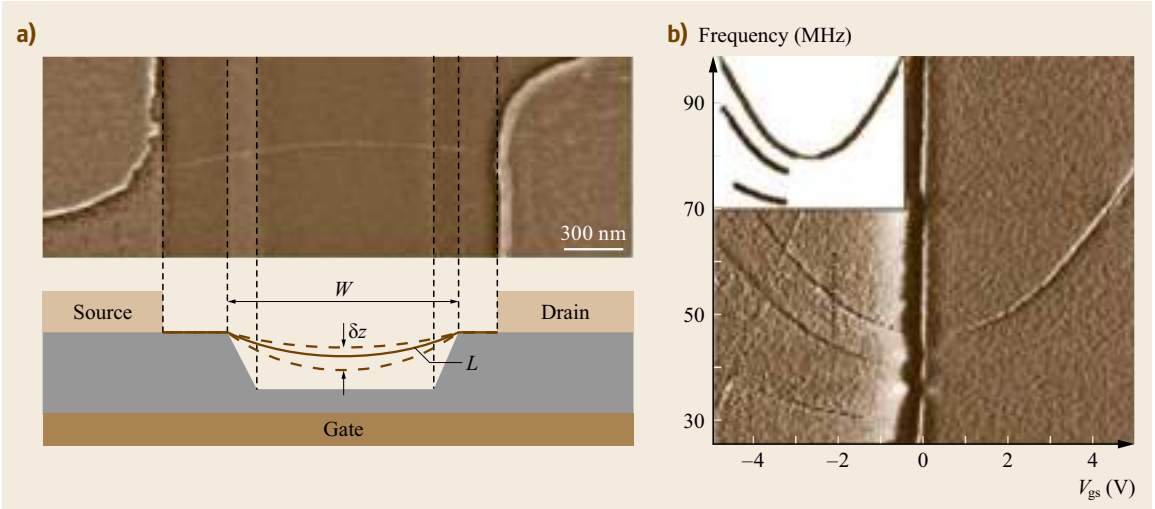

Fig. 14.17a,b Suspended SWNT resonator. **(a)** SEM image and cross-section schematic (*scale bar*, 300 nm). **(b)** Detected current as a function of gate voltage and frequency. *Inset* shows the extracted positions of the resonance frequency ω_0 (after [14.16])

Initially the limiting factor for both inertial balances and force sensors has been the quality factor Q, which in early reports was below 300 [14.16–18]. However, Q factors as high as 10^5 were demonstrated by *Hüttel* et al. [14.137], close to the intrinsic damping limit expected for SWNTs. Again, as emphasized by the authors, the key to obtaining such high quality factors, are suspended, defect-free SWNT that are not contaminated by resist residues. The measurements were performed in high-vacuum and at mK temperatures. The Q factor shows a $T^{-0.36}$ power law dependence on temperature, going from $\approx 10^5$ at 20 mK to less than 30 000 at 1 K. The authors did not continue the measurement up to room temperature, but *Lassagne* et al. [14.136] did find that the Q factor of one of their devices decreases from 865 at 5 K to 50 at 300 K. The adverse effect of pressure on Q factor has been known since the first paper on the subject, by *Sazonova* et al. [14.16], with resonance lost above pressures of 10 Torr. The scaling of the Q factor with temperature and pressure, especially the maximum achievable Q in ambient conditions is an open research question. On the practical side, devices based on carbon nanotube resonators with integrated axial MEMS actuators are well underway [14.139, 140]. Axial actuation – as opposed to electrostatic actuation – has already shown surprising capabilities, with 6 times [14.140] to 20 times [14.139] resonance frequency tuning achievable.

14.4 Concluding Remarks

Since CNTs are at the crossroad between fundamental science and engineering, transdisciplinary development in this field is highly demanded. Concerning device fabrication, synthetic chemists and process engineers still have challenges ahead of them, in trying to develop strategies for controlling nanotube electronic properties and local integration in functional systems. Even though we do not yet have chirality control, this doesn't mean that technology transfer on the midterm is not possible. In fact, the sensor concepts presented in Sect. 14.3 – with the exception of piezoresistive gauges – do not require chirality control, but band gap control (diameter and metallic versus semiconducting separation). With state-of-the-art methods for SWNT synthesis, separation and sorting, and CCVD, catalyst control and in situ growth, band gap control is almost here. Actually, one shouldn't rule out even piezoresistive gauges, since calibration, tuning and performance characterization, as usually done for sensors, may result in acceptable product yield. Still, as has become clearer in the past few years, besides controlled nanotube growth and integration, processes that do not contaminate the nanotubes after growth are of major importance and may see a surge of interest in the near future. On the application side, nanosystems technology may become the first user of SWNTs because in contrast to mainstream technologies (CMOS logic, memories) for which ultra large scale integration (ULSI) is the goal, sensors will require the integration of individual and *just a few* structures at the wafer level, only. An ideal platform for exploring new sensing devices is the CNFET sensor tool box as presented in this chapter.

15. Nanomechanical Cantilever Array Sensors

Hans Peter Lang, Martin Hegner, Christoph Gerber

In recent years, mechanics has experienced a revival, as microfabrication technologies and nanotechnology are applied to produce tiny structures. The development of ultraprecise position sensing started three decades ago with a novel imaging technique called atomic force microscopy, which provides ultrahigh topography resolution on the atomic scale by raster-scanning the surface with a microfabricated cantilever beam that has a tiny tip at its free end. The high force sensitivity can not only be used for imaging, but also allows the measurement of surface forces during molecule adsorption processes on the cantilever surface, thus enabling cantilevers to act as chemical sensors. Because of their small size, cantilevers allow fast and reliable detection of small concentrations of molecules in air and solution. In addition to artificial nose and label-free biosensing applications, they have also been employed to measure physical properties of tiny amounts of materials in miniaturized versions of conventional standard techniques such as calorimetry, thermogravimetry, weighing, photothermal spectroscopy and monitoring of chemical reactions. In the past few years, the cantilever-sensor concept has been extended to medical applications and has entered clinics for pilot studies on patients. The small size and scalability of cantilever array sensors might turn out to be advantageous for diagnostic screening applications and disease monitoring, as well as for genomics or proteomics. Using microcantilever arrays allows simultaneous detection of several analytes and solves the inherent problem of thermal drifts often present when using single microcantilever sensors, as some of the cantilevers can be used as sensor cantilevers for detection, and others as passivated reference cantilevers that do not show affinity to the molecules to be detected.

15.1 Technique

Sensors are devices that detect, or sense, changes in the environment and produce a measurable output signal. Moreover, a sensor is also a transducer, i. e., it transforms one form of energy into another. Most people will associate sensors with electrical or electronic devices that respond by a signal change when an external physical parameter is changed. Many more types of transducers exist, such as electrochemical (pH probe), electromechanical (piezoelectric actuator, quartz, strain gauge), electroacoustic (gramophone pick-up, microphone), photoelectric (photodiode, solar cell), electromagnetic (antenna), magnetic (Hall-effect sensor, hard-disk head for storage applications), electrostatic (electrometer), thermoelectric (thermocouple, thermoresistors), and electrical (capacitor, resistor). Here we focus on a further type of sensor not yet mentioned: the mechanical sensor. It responds to changes of an external parameter, such as temperature variations or molecule adsorption, by a mechanical response, e.g., by bending or deflection.

15.1.1 Cantilevers

Mechanical sensors consist of a fixed and a movable part. The movable part can be a thin membrane, a plate or a beam, fixed at one or both ends. The structures described here are called cantilevers. A cantilever is defined here as a microfabricated rectangular bar-shaped structure that is longer than it is wide and has a thickness that is much smaller than its length or width. It is a horizontal structural element supported only at one end on a chip body; the other end is free (Fig. 15.1). Most often it is used as a mechanical probe to image the topography of a sample in a technique called atomic force microscopy (AFM) or scanning force microscopy (SFM) [15.1], invented by *Binnig* et al. in the mid 1980s [15.1]. For AFM a microfabricated sharp tip is located at the apex of the cantilever that serves as a local probe to scan the sample surface. The distance between tip and surface is controlled via sensitive measurement of interatomic forces in the piconewton range.

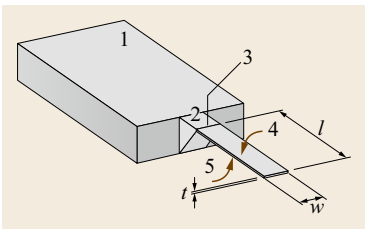

Fig. 15.1 Schematic of a cantilever: (1) rigid chip body, (2) solid cantilever support structure, (3) hinge of cantilever, (4) upper surface of the cantilever that is usually functionalized with a sensor layer for detection of molecules, (5) lower surface of the cantilever, usually passivated in order not to show affinity to the molecules to be detected. The geometrical dimensions, length l, width w and thickness t, are indicated

By scanning the tip across a conductive or nonconductive surface using an x-y-z actuator system (e.g., a piezoelectric scanner), an image of the topography is obtained by recording for all positions x and y the correction signal that has to be applied to the z-actuation drive to keep the interaction between tip and sample surface constant. SFM methods are well established in scientific research, education and, to a certain extent, also in industry. Beyond imaging of surfaces, cantilevers have been used for many other purposes, e.g., structuring of surfaces. Here, we focus on the application as mechanical sensor devices, responding by mechanical bending or change in resonance frequency.

15.1.2 History of Cantilever Sensors

The idea to use beams of silicon as sensors to measure deflections or changes in resonance frequency is actually quite old. First reports go back to 1968, when *Wilfinger* et al. [15.2] investigated silicon cantilever structures of 50 mm × 30 mm × 8 mm, i. e., quite large cantilever beams, for detecting resonances. On the one hand, they took advantage of localized thermal expansion in diffused resistors (piezoresistors) located near the cantilever support to create a temperature gradient to actuate the cantilever at its resonance frequency. On the other hand, the piezoresistors have also been used to sense mechanical deflection of the cantilever. This early report already contains essential concepts for sensing and actuation of cantilevers. In the following years only a few reports were published on the use of cantilevers as sensors, e.g., *Heng* [15.3], who fabricated in 1971 gold cantilevers capacitively coupled to microstrip lines for mechanical trimming of high-frequency oscillator circuits. In 1979, *Petersen* [15.4] constructed cantilever-type micromechanical membrane switches in silicon that should have filled the gap between silicon transistors and mechanical electromagnetic relays. *Kolesar* [15.5] suggested the use of cantilever structures as electronic nerve agent detectors in 1985.

Only with the availability of microfabricated cantilevers for AFM [15.1] did reports on the use of cantilevers as sensors become more frequent. In 1994, *Itoh* et al. [15.6] presented a cantilever coated with a thin film of zinc oxide and proposed a piezoresistive deflection readout as an alternative to the optical beam

deflection readout. *Cleveland* et al. [15.7] reported the tracking of cantilever resonance frequency to detect nanogram changes in mass loading when small particles were deposited onto AFM probe tips. *Thundat* et al. [15.8] showed that the resonance frequency as well as static bending of microcantilevers (MCs) are influenced by ambient conditions, such as moisture adsorption, and that deflection of metal-coated cantilevers can be further influenced by thermal effects (bimetallic effect). First chemical sensing applications were presented by *Gimzewski* et al. [15.9], who used static cantilever bending to detect chemical reactions with very high sensitivity. Later *Thundat* et al. [15.10] observed changes in the resonance frequency of microcantilevers due to adsorption of analyte vapor on exposed surfaces. Furthermore, frequency changes have been observed caused by mass loading or adsorption-induced changes in cantilever spring constant. By coating cantilever surfaces with hygroscopic materials, such as phosphoric acid or gelatin, the cantilever can sense water vapor with picogram mass resolution.

The deflection of individual cantilevers can easily be determined applying the optical beam deflection technique and modified AFM electronics. A single cantilever can be applied as a sensor, but its response can be prone to artifacts such as thermal drifts or unspecific adsorption. For this reason the use of cantilever arrays including passivated reference cantilevers is recommended. The first use of cantilever arrays with sensor and reference cantilevers was reported in 1998 [15.11], and represented significant progress for the understanding of true cantilever responses (calculation of difference responses of sensor and reference cantilevers).

15.2 Cantilever Array Sensors

15.2.1 Concept

For the use of a cantilever as a sensor, neither a sharp tip at the cantilever apex nor a sample surface is required. The upper or lower surface of the cantilever serves as the sensor area and allows the processes taking place on the cantilever beam to be monitored with unprecedented accuracy, in particular the adsorption of molecules. The formation of molecule layers on the cantilever surface will generate surface stress, eventually resulting in a bending of the cantilever, provided the adsorption preferentially occurs on one of the surfaces of the cantilever. Adsorption is controlled by coating one surface (typically the upper one) of a cantilever with a thin layer of a material that shows affinity to molecules in the environment (sensor surface). This surface of the cantilever is referred to as the *functionalized* surface. The other surface of the cantilever (typically the lower one) may be left uncoated or be coated with a passivation layer, i. e., a chemical surface that does not exhibit substantial affinity to the molecules from the environment we would like to detect. To create functionalized surfaces, often a metal layer is evaporated onto the area to be used as the sensor surface. Metal surfaces, e.g., gold, may be used to covalently bind a monolayer representing the chemical surface sensitive to the molecules to be detected from environment. Frequently, a monolayer of thiol molecules is used, which is covalently bound to a gold surface. The gold layer is also favorable for use as a reflection layer if the bending of the cantilever is read out via an optical beam deflection method.

15.2.2 Compressive and Tensile Stress

A cantilever coated with gold on its upper surface for adsorption of alkanethiol molecules and left uncoated on its lower surface (consisting of silicon and silicon oxide) will respond in the following way to the adsorption of thiol molecules: the molecules will covalently bind to the gold layer on the upper surface of the cantilever, resulting in a downward bending of the cantilever due to the formation of surface stress. We will call this process *development of compressive surface stress*, because the surface stress change associated with the formation of the self-assembled monolayer (SAM) produces forces stretching laterally the adsorbed layer, resulting in a downward bending of the cantilever (away from the gold coating). In the opposite situation, i. e., when the cantilever bends upwards, we would speak of tensile stress. If both upper and lower surfaces of the cantilevers are involved in the reaction, then the situation will be much more complex, as a predominant compressive stress formation on the lower cantilever surface might appear as tensile stress on the upper surface. For this reason, it is of utmost importance that the lower cantilever surface is passivated in such a way that ideally no processes will take place on the lower surface of the cantilever.

15.2.3 Disadvantages of Single Microcantilevers

Single microcantilevers are susceptible to parasitic deflections that may be caused by thermal drift or chem-

ical interaction of a cantilever with its environment, in particular if the cantilever is operated in a liquid. Often, a baseline drift is observed while measuring cantilever bending. Moreover, nonspecific physisorption of molecules on the cantilever surface or nonspecific binding to receptor molecules during measurements may contribute to the drift, as well as electrostatic effects.

15.2.4 Reference and Sensor Cantilevers in an Array

To exclude such unwanted influences, simultaneous measurement of reference cantilevers aligned in the same array as the sensing cantilevers is crucial [15.11]. As the difference in signals from the reference and sensor cantilevers represents the net cantilever response, even tiny sensor responses may be extracted from large cantilever deflections without being dominated by undesired effects. When only single microcantilevers are used, no thermal-drift compensation is possible. To obtain useful data under such circumstances, both microcantilever surfaces have to be chemically well defined. One of the surfaces, typically the lower one, has to be passivated; otherwise the cantilever response will be influenced through undesired effects originating from uncontrolled reactions taking place on the lower surface (Fig. 15.2a). However, with a pair of cantilevers, reliable measurements can be obtained. One cantilever is used as the sensor cantilever (coated typically on the upper side with a molecule layer showing substantial affinity to the molecules to be detected), whereas the other cantilever serves as the reference cantilever. Actually, it should be coated with a passivation layer on the upper surface so as not to exhibit much affinity to the molecules to be detected. In this configuration, thermal drifts are canceled out if difference responses are taken, i. e., difference in deflections of sensor and reference cantilevers. Alternatively, both cantilevers may be used as sensor cantilevers (sensor layer on the upper surfaces), provided the lower surface has been passivated (Fig. 15.2b). However, it is best to apply a cantilever array (Fig. 15.2c), in which several cantilevers are used either as sensor or as reference cantilevers so that multiple difference signals can be evaluated simultaneously. Moreover, thermal drift is canceled out if one surface of all cantilevers, typically the lower one, is left uncoated or coated with the same passivation layer.

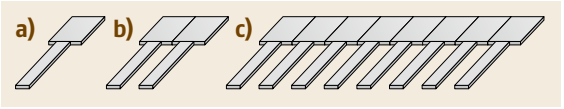

Fig. 15.2a–c Cantilever sensor arrangements. **(a)** Single cantilever; **(b)** pair of cantilevers, one to be used as the sensor cantilever, the other as the reference cantilever, and **(c)** array of cantilevers with several sensor and reference cantilevers

15.3 Modes of Operation

In analogy to AFM, various operating modes for cantilevers are described in the literature. The measurement of static deflection upon formation of surface stress during adsorption of a molecular layer is termed *static mode*. *Ibach* used cantilever-like structures to study adsorbate-induced surface stress [15.12] in 1994. Surface stress-induced bending of cantilevers during the adsorption of alkanethiols on gold was reported by *Berger* et al. in 1997 [15.13]. The mode corresponding to the technique of noncontact AFM is termed *dynamic mode*, where a cantilever is oscillated at its resonance frequency, and was described by *Cleveland* et al. [15.7]. They calculated mass changes from shifts in the cantilever resonance frequency upon the mounting of tiny tungsten particle spheres at the apex of the cantilever. Not only adsorption effects can provoke cantilever bending, but also thermal effects. The so-called *heat mode* was pioneered by *Gimzewski* et al. [15.9], who took advantage of the bimetallic effect that produces bending of a metal-coated cantilever when heat is generated on its surface. Therewith they constructed a miniaturized calorimeter with picojoule sensitivity. Further operating modes exploit other physical effects such as the production of heat from the absorption of light by materials deposited on the cantilever (photothermal spectroscopy) [15.14], or cantilever bending due to electric or magnetic forces.

15.3.1 Static mode

The continuous bending of a cantilever caused by increasing coverage with molecules is referred to as operation in the *static mode* (Fig. 15.3a). Adsorption of molecules onto the functional layer produces stress at the interface between the functional layer and the forming molecular layer. A quick estimation of the weight of the adsorbed layer of molecules clearly implies that the bending of the cantilever is not due to the mass increase by the adsorbed molecular layer. Because the forces within the functional layer try to keep the dis-

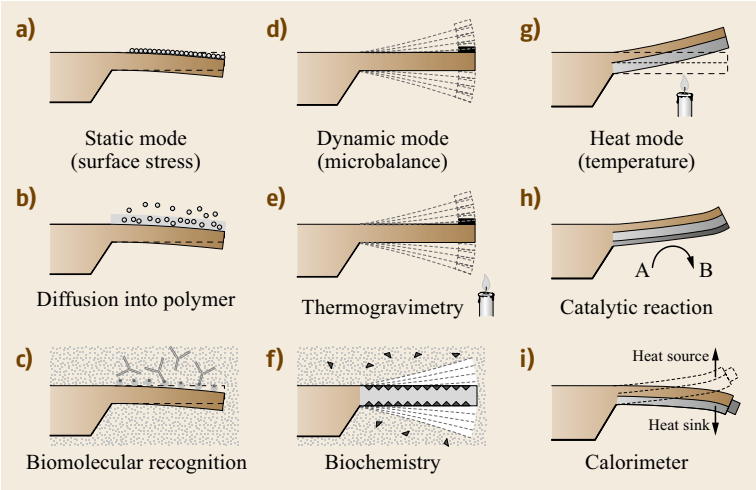

Fig. 15.3a–i Basic cantilever operation modes: **(a)** static bending of a cantilever on adsorption of a molecular layer. **(b)** Diffusion of molecules into a polymer layer leads to swelling of the polymer and eventually to a bending of the cantilever. **(c)** Highly specific molecular recognition of biomolecules by receptors changes surface stress on the upper surface of the cantilever and results in bending. **(d)** Oscillation of a cantilever at its resonance frequency (dynamic mode) allows information on mass changes taking place on the cantilever surface to be obtained (application as a microbalance). **(e)** Changing the temperature while a sample is attached to the apex of the cantilever allows information to be gathered on decomposition or oxidation processes. **(f)** Dynamic mode measurements in liquids yield details on mass changes during biochemical processes. **(g)** In heat mode, a bimetallic cantilever is employed. Here bending is due to the difference in the thermal expansion coefficients of the two materials. **(h)** Catalysic reactions produce heat, resulting in cantilever bending. **(i)** A tiny sample attached to the apex of the cantilever is investigated taking advantage of the bimetallic effect. Tracking the deflection as a function of temperature allows the observation of phase transitions in the sample in a calorimeter mode

tance between molecules constant, the cantilever beam responds by bending because of its extreme flexibility. This property is described by the spring constant k of the cantilever, which for a rectangular microcantilever of length l, thickness t, and width w is calculated as follows

$$k = \frac{Ewt^3}{4l^3} , \tag{15.1}$$

where E is the Young's modulus ($E_{Si} = 1.3 \times 10^{11}\,N/m^2$ for Si(100)).

As a response to surface stress, e.g., owing to adsorption of a molecular layer, the microcantilever bends, and its shape can be approximated as part of a circle with radius R. This radius of curvature is given by [15.15, 16]

$$\frac{1}{R} = \frac{6\,(1-\nu)}{Et^2} . \tag{15.2}$$

The resulting surface stress change is described using Stoney's formula [15.15]

$$\Delta\sigma = \frac{Et^2}{6R\,(1-\nu)} , \tag{15.3}$$

where E is Young's modulus, t the thickness of the cantilever, ν the Poisson's ratio ($\nu_{Si} = 0.24$), and R the bending radius of the cantilever.

Static mode operation has been reported in various environments. In its simplest configuration, molecules from gaseous environments adsorb on the functionalized sensing surface and form a molecular layer (Fig. 15.3a), provided the molecules exhibit at least some affinity to the surface. In case of alkanethiol covalently binding to gold, the affinity is very high, resulting in a fast bending response within minutes [15.13]. A less specific way of detection takes advantage of the penetrable network of polymer layers. Polymer sensing layers only exhibit a partial sensitivity, i. e., polymer-coated cantilevers always respond to the presence of volatile molecules, but the magnitude and temporal behavior are specific to the chemistry of the polymer. Molecules from the environment diffuse into the polymer layer at different rates, mainly depending on the size and solubility of the molecules in the polymer layer (Fig. 15.3b). A wide range of hydrophilic or hydrophobic polymers can be selected as sensing layers, differing in their affinity to polar and unpolar molecules. Thus, polymer coatings can be chosen ac-

cording to the respective requirements of the sensing application.

Static-mode operation in liquids, however, usually requires rather specific sensing layers, and is based on molecular recognition, e.g., in DNA hybridization [15.17] or antigen-antibody recognition (Fig. 15.3c). Cantilevers functionalized by coating with biochemical sensing layers respond very specifically using the biomolecular key-lock principles of molecular recognition. Whether molecular recognition will actually lead to bending of the cantilever will depend on the efficiency of transduction, as the surface stress has to be generated very close to the cantilever surface to produce substantial bending. By just scaling down standard gene chip strategies to cantilever geometry through utilization of long spacer molecules, hybridization takes place at a distance of several nanometers away from the cantilever surface. The original idea to make DNA molecules become more accessible for hybridization in a gene chip configuration, is unfavorable for cantilever-based sensing through surface stress detection, as the magnitude of bending is greatly reduced or not even observable [15.18].

15.3.2 Dynamic Mode

Since the eigenfrequency of an oscillating cantilever depends on its mass, we can determine mass changes accurately by tracking shifts in eigenfrequency. Technically, the resonance frequency of the cantilever can be measured more easily than the eigenfrequency. Often, the resonance frequency is measured by actuating the cantilever actively, e.g., by a piezoelectric actuator. The resonance frequency represents the frequency at which the oscillation amplitude is largest. The eigenfrequency is equal to the resonance frequency of an oscillating cantilever if the elastic properties of the cantilever remain unchanged and damping effects are insignificant during the molecular adsorption process. This mode of operation is called dynamic mode (e.g., the use of cantilevers as a microbalance, Fig. 15.3d). Owing to mass addition on the cantilever surface, the eigenfrequency of the cantilever will shift to a lower value. The frequency change per mass change on a rectangular cantilever is calculated [15.19] according to

$$\frac{\Delta f}{\Delta m} = \frac{1}{4\pi n_1 l^3 w}\sqrt{\frac{E}{\rho^3}}\,, \tag{15.4}$$

where $\rho = m/lwt$ is the mass density of the microcantilever and the deposited mass, and $n_1 \approx 1$ is a geometrical factor.

The mass change is calculated [15.8] from the frequency shift using

$$\Delta m = \frac{k}{4\pi^2}\left(\frac{1}{f_1^2} - \frac{1}{f_0^2}\right)\,, \tag{15.5}$$

where f_0 is the eigenfrequency before the mass change occurs, and f_1 the eigenfrequency after the mass change. Please note that this formula is only accurate for eigenfrequencies and not for resonance frequencies, if damping cannot be neglected.

Mass-change determination can be combined with varying conditions of environmental temperature (Fig. 15.3e) to obtain a method introduced in the literature as *micromechanical thermogravimetry* [15.20]. For investigation of thermal properties, a tiny piece of sample has to be mounted at the apex of the cantilever. Its mass should not exceed several hundred nanograms. Adsorption, desorption and decomposition processes, occurring while changing the temperature, produce mass changes in the picogram range that can be observed in real time by tracking the resonance-frequency shift.

Dynamic mode operation in a liquid environment is more difficult than in air, because of significant damping of the cantilever oscillation due to the high viscosity of the surrounding media (Fig. 15.3f). Significant damping results in a low quality factor Q of the oscillation, and thus the resonance frequency shift is difficult to track with high resolution. The quality factor is defined as

$$Q = 2\frac{\Delta f}{f_0}\,. \tag{15.6}$$

Whereas in air the resonance frequency can easily be determined with a resolution of below 1 Hz, only a frequency resolution of about 20 Hz is expected for measurements in liquid environments.

The damping or altered elastic properties of the cantilever during the experiment, e.g., by stiffening or softening of the spring constant caused by adsorption of a molecule layer, result in the fact that the measured resonance frequency will not be exactly equal to the eigenfrequency of the cantilever, and therewith the mass derived from the frequency shift will be inaccurate. In a medium, the vibration of a cantilever is described by the model of a driven damped harmonic oscillator

$$m^*\frac{\mathrm{d}^2x}{\mathrm{d}t^2} + \gamma\frac{\mathrm{d}x}{\mathrm{d}t} + kx = F\cos(2\pi ft)\,, \tag{15.7}$$

where $m^* = const\,(m_c + m_l)$ is the effective mass of the cantilever (for a rectangular cantilever the constant is

0.25). Especially in liquids, the mass of the co-moved liquid m_l adds significantly to the mass of the cantilever m_c. The term $\gamma dx/dt$ is the drag force due to damping, $F\cos(2\pi ft)$ is the driving force executed by the piezoelectric actuator, and k is the spring constant of the cantilever.

If no damping is present, the eigenfrequencies of the various oscillation modes of a bar-shaped cantilever are calculated according to

$$f_n = \frac{\alpha_n^2}{2\pi}\sqrt{\frac{k}{2\,(m_c + m_l)}}\,, \tag{15.8}$$

where f_n are the eigenfrequencies in n-th mode, α_n are constants depending on the mode: $\alpha_1 = 1.8751$, $\alpha_2 = 4.6941$, $\alpha_n = \pi\,(n - 0.5)$. k is the spring constant of the cantilever, m_c the mass of the cantilever, and m_l the mass of the medium surrounding the cantilever, e.g., liquid [15.21].

Addition of mass to the cantilever due to adsorption will change the effective mass as follows

$$m^* = const\,(m_c + m_l + \Delta m)\,, \tag{15.9}$$

where Δm is the additional mass adsorbed. Typically, the co-moved mass of the liquid is much larger than the adsorbed mass.

Figure 15.4 clearly shows that the resonance frequency is only equal to the eigenfrequency if no damping is present. With damping, the frequency at which the peak of the resonance curve occurs is no longer identical with the one at which the turning point of the phase curve occurs. For example, resonance curve 2 with damping γ_2 has its maximum amplitude at frequency f_2. The corresponding phase would be $\phi_{res}(\gamma_2)$, which is not equal to $\pi/2$, as would be expected in the undamped case. If direct resonance frequency tracking or a phase-locked loop is used to determine the frequency of the oscillating cantilever, then only its resonance frequency is detected, but not its eigenfrequency. Remember that the eigenfrequency, and not the resonance frequency, is required to determine mass changes.

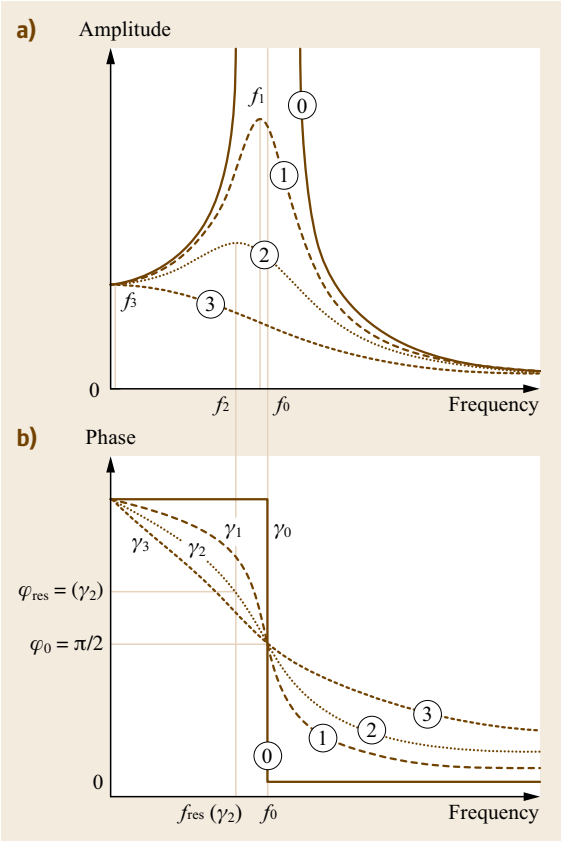

Fig. 15.4 **(a)** Resonance curve with no damping (0), and increasing damping (1)–(3). The undamped curve with resonance frequency f_0 exhibits a very high amplitude, whereas the resonance peak amplitude decreases with damping. This also involves a shift in resonance frequencies f_1 to f_3 to lower values. **(b)** Corresponding phase curves showing no damping (0), and increasing damping (1)–(3). The step-like phase jump for the undamped resonance gradually broadens with increased damping

15.3.3 Heat Mode

If a cantilever is coated with metal layers, thermal expansion differences in the cantilever and the coating layer will further influence cantilever bending as a function of temperature. This mode of operation is referred to as the *heat mode* and causes cantilever bending because of differing thermal expansion coefficients in the sensor layer and cantilever materials [15.9] (Fig. 15.3g)

$$\Delta z = 1.25\,(\alpha_1 - \alpha_2)\,\frac{(t_1 + t_2)}{t_2^2\kappa}\,\frac{l^3}{(\lambda_1 t_1 + \lambda_2 t_2)\,w}P\,. \tag{15.10}$$

Here α_1, α_2 are the thermal expansion coefficients of the cantilever and coating materials, respectively, t_1, t_2 the material thicknesses, P is the total power generated on the cantilever, and κ is a geometry parameter of the cantilever device. λ_1 and λ_2 are the thermal conductivities of layers 1 and 2.

Heat changes are either caused by external influences (change in temperature, Fig. 15.3g), occur directly on the surface by exothermal, e.g., catalytic,

reactions (Fig. 15.3h), or are due to material properties of a sample attached to the apex of the cantilever (micromechanical calorimetry, Fig. 15.3i). The sensitivity of the cantilever heat mode is orders of magnitude higher than that of traditional calorimetric methods performed on milligram samples, as it only requires nanogram amounts of sample and achieves nanojoule [15.20], picojoule [15.22], and femtojoule [15.23] sensitivity.

These three measurement modes have established cantilevers as versatile tools to perform experiments in nanoscale science with very small amounts of material.

15.3.4 Further Operation Modes

Photothermal Spectroscopy

When a material adsorbs photons, a fraction of the energy is converted into heat. This photothermal heating can be measured as a function of the light wavelength to provide optical absorption data of the material. The interaction of light with a bimetallic microcantilever creates heat on the cantilever surface, resulting in a bending of the cantilever [15.14]. Such bimetallic-cantilever devices are capable of detecting heat flows due to an optical heating power of 100 pW, being two orders of magnitude better than in conventional photothermal spectroscopy.

Electrochemistry

A cantilever coated with a metallic layer (measurement electrode) on one side is placed in an electrolytic medium, e.g., a salt solution, together with a metallic reference electrode, usually made of a noble metal. If the voltage between the measurement and the reference electrode is changed, electrochemical processes on the measurement electrode (cantilever) are induced, such as adsorption or desorption of ions from the electrolyte solution onto the measurement electrode. These processes lead to a bending of the cantilever due to changes in surface stress and in the electrostatic forces [15.24].

Detection of Electrostatic and Magnetic Forces

The detection of electrostatic and magnetic forces is possible if charged or magnetic particles are deposited on the cantilever [15.25, 26]. If the cantilever is placed in the vicinity of electrostatic charges or magnetic particles, attractive or repulsion forces occur according to the polarity of the charges or magnetic particles present on the cantilever. These forces will result in upward or downward bending of the cantilever. The magnitude of bending depends on the distribution of charged or magnetic particles on both the cantilever and in the surrounding environment according to the laws of electrostatics and magnetism.

15.4 Microfabrication

Several methods have been applied for microfabrication of cantilevers out of various materials, using either wet or dry etching techniques. The silicon cantilever sensor arrays described here have been microfabricated using a dry-etching silicon-on-insulator (SOI) fabrication technique developed in the Micro-/Nanomechanics Department at IBM's Zurich Research Laboratory. One chip comprises eight cantilevers, having a length of 500 μm, a width of 100 μm, and a thickness of 0.5 μm, and arranged at a pitch of 250 μm. For dynamic mode, the cantilever thickness may amount up to 7 μm to obtain higher resonance frequencies and better mass resolution. The resonance frequencies of the cantilevers vary by 0.5% only, demonstrating the high reproducibility and precision of cantilever fabrication. A scanning electron microscopy image of a cantilever sensor array chip is shown in Fig. 15.5.

15.5 Measurement Setup

15.5.1 Measurements in Gaseous or Liquid Environment

A measurement setup for cantilever arrays consists of four major parts:

1. The measurement chamber containing the cantilever array.
2. An optical or electrical system to detect the cantilever deflection (e.g., laser sources, collimation lenses and a position-sensitive detector (PSD), or piezoresistors and Wheatstone bridge detection electronics).
3. Electronics to amplify, process and acquire the signals from the detector.
4. A gas- or liquid-handling system to reproducibly inject samples into the measurement chamber and purge the chamber.

The following description applies to our measurement setup.

Figure 15.6 shows the schematic setup for experiments performed in (Fig. 15.6a) a gaseous and (Fig. 15.6b) a liquid (biochemical) environment for the optical beam deflection embodiment of the measurement setup. The cantilever sensor array is placed in an analysis chamber 3–90 µl in volume, which has inlet and outlet ports for gases or liquids. The cantilever deflection is determined by means of an array of eight vertical-cavity surface-emitting lasers (VCSELs) arranged at a linear pitch of 250 µm that emit at a wavelength of 760 nm into a narrow cone of 5–10°.

The light of each VCSEL is collimated and focused onto the apex of the corresponding cantilever by a pair of achromatic doublet lenses, 12.5 mm in diameter. This size has to be selected in such a way that all eight laser beams pass through the lens close to its center to minimize scattering, chromatic and spherical aberration artifacts. The light is then reflected off the gold-coated surface of the cantilever and hits the surface of a PSD. PSDs are light-sensitive photo-potentiometer-like devices that produce photocurrents at two opposing electrodes. The magnitude of the photocurrents depends linearly on the distance of the impinging light spot from the electrodes. Thus, the position of an incident light

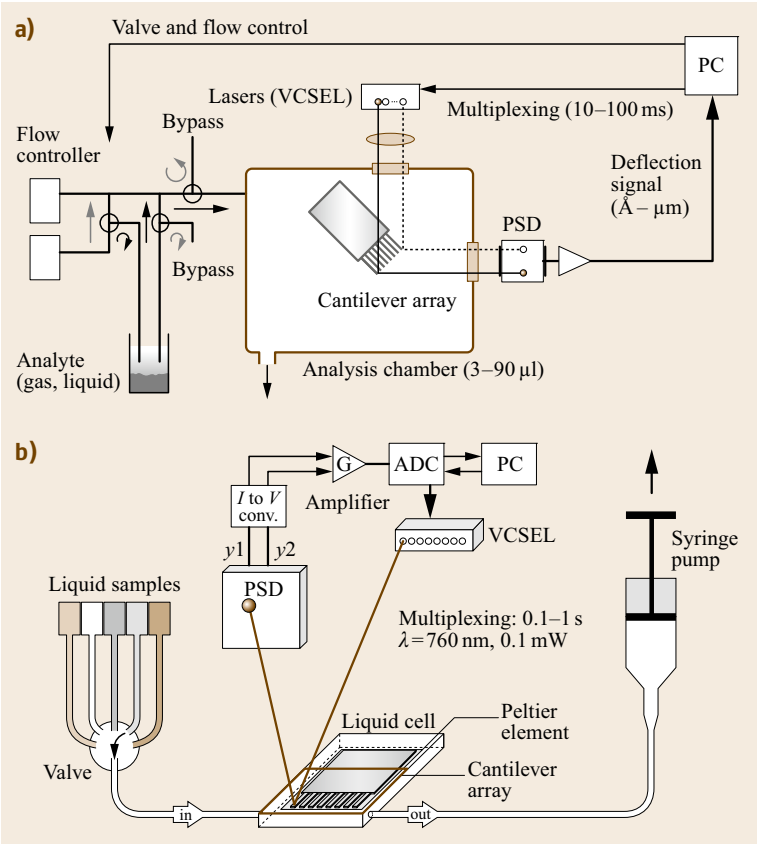

Fig. 15.6a,b Schematic of measurement setups for **(a)** a gaseous (artificial nose) and **(b)** a liquid environment (biochemical sensor)

beam can easily be determined with micrometer precision. The photocurrents are transformed into voltages and amplified in a preamplifier. As only one PSD is used, the eight laser light sources cannot be switched on simultaneously. Therefore, a time-multiplexing procedure is used to switch the lasers on and off sequentially at typical intervals of 10–100 ms. The resulting deflection signal is digitized and stored together with time information on a personal computer (PC), which also controls the multiplexing of the VCSELs as well as the switching of the valves and mass flow controllers used for setting the composition ratio of the analyte mixture.

The measurement setup for liquids (Fig. 15.6b) consists of a poly-etheretherketone (PEEK) liquid cell, which contains the cantilever array and is sealed by a Viton O-ring and a glass plate. The VCSELs and the PSD are mounted on a metal frame around the liquid cell. After preprocessing the position of the deflected light beam in a current-to-voltage converter and amplifier stage, the signal is digitized in an analog-to-digital converter and stored on a PC. The liquid cell is equipped with inlet and outlet ports for liquids. They are connected via 0.18 mm of i.d. Teflon tubing to individual thermally equilibrated glass containers, in which the biochemical liquids are stored. A six-position valve allows the inlet to the liquid chamber to be connected to each of the liquid-sample containers separately. The liquids are pulled (or pushed) through the liquid chamber by means of a syringe pump connected to the outlet of the chamber. A Peltier element is situated very close to the lumen of the chamber to allow temperature regulation within the chamber. The entire experimental setup is housed in a temperature-controlled box regulated with an accuracy of 0.01 K to the target temperature.

15.5.2 Readout Principles

This section describes various ways to determine the deflection of cantilever sensors. They differ in sensitivity, effort for alignment and setup, robustness, and ease of readout as well as in potential for miniaturization.

Piezoresistive Readout

Piezoresistive cantilevers [15.6, 20] are usually U-shaped having diffused piezoresistors in both of the legs close to the hinge (Fig. 15.7a). The resistance in the piezoresistors is measured by a Wheatstone bridge technique employing three reference resistors, one of which is adjustable. The current flowing between the two branches of the Wheatstone bridge is initially nulled by changing the resistance of the adjustable resistor. If the cantilever bends, the piezoresistor changes its value and a current will flow between the two branches of the Wheatstone bridge. This current is converted via a differential amplifier into a voltage for static mode measurement. For dynamic mode measurement, the piezoresistive cantilever is externally actuated via a frequency generator connected to a piezocrystal. The ac actuation voltage is fed as reference voltage into a lock-in amplifier and compared with the response of the Wheatstone bridge circuit. This technique allows one to sweep resonance curves and to determine shifts in resonance frequency.

Piezoelectric Readout

Piezoelectric cantilevers [15.27] are actuated by applying an electric ac voltage via the inverse piezoelectric effect (self-excitation) to the piezoelectric material (PZT or ZnO). Sensing of bending is performed by recording the piezoelectric current change due to the fact that the PZT layer may produce a sensitive field response to weak stress through the direct piezoelectric effect. Such cantilevers are multilayer structures consisting of an SiO_2 cantilever and the PZT piezoelectric layer. Two electrode layers, insulated from each other, provide electrical contact. The entire structure is protected using passivation layers (Fig. 15.7b). An identical structure is usually integrated into the rigid chip body to provide a reference for the piezoelectric signals from the cantilever.

Capacitive Readout

For capacitive readout (Fig. 15.7c), a rigid beam with an electrode mounted on the solid support and a flexible cantilever with another electrode layer are used [15.28, 29]. Both electrodes are insulated from each other. Upon bending of the flexible cantilever the capacitance between the two electrodes changes and allows the deflection of the flexible cantilever to be determined. Both static and dynamic measurement modes are possible.

Optical (Interferometric) Readout

Interferometric methods [15.30, 31] are most accurate for the determination of small movements. A laser beam passes through a polarizer plate (polarization 45°) and is partially transmitted by a nonpolarized beam splitter (Fig. 15.7d). The transmitted beam is divided in a Wollaston prism into a reference and an object beam. These mutually orthogonally polarized beams are then focused onto the cantilever. Both beams (the reference beam from the hinge region and the object beam from the apex region of the cantilever) are reflected back to the objective lens, pass the Wollaston prism, where they are re-combined into one beam, which is then reflected into the other arm of the interferometer, where after the $\lambda/4$ plate a phase shift of a quarter wavelength

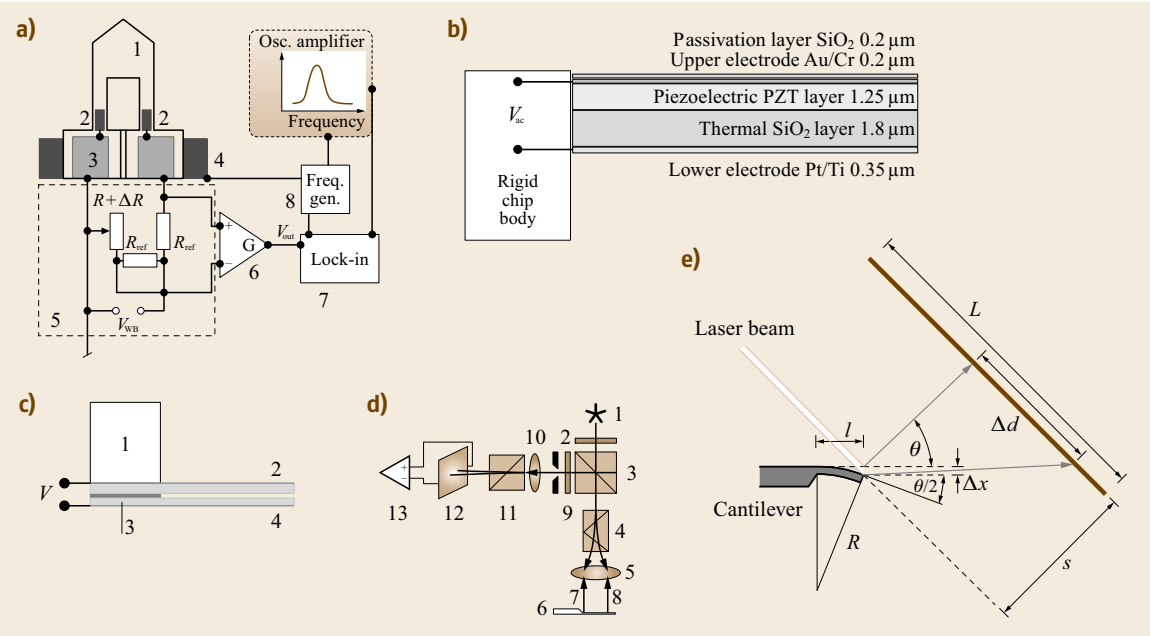

Fig. 15.7 **(a)** Piezoresistive readout: 1 cantilever, 2 piezoresistors, 3 Au contact pads, 4 external piezocrystal for actuation, 5 Wheatstone bridge circuit, 6 differential amplifier, 7 lock-in amplifier, 8 function generator. **(b)** Piezoelectric readout. **(c)** Capacitive readout: 1 solid support, 2 rigid beam with counterelectrode, 3 insulation layer (SiO_2), 4 flexible cantilever with electrode. **(d)** Interferometric readout: 1 laser diode, 2 polarizer, 3 nonpolarizing beam splitter, 4 Wollaston prism, 5 focusing lens, 6 cantilever, 7 reference beam (near cantilever hinge), 8 object beam (near cantilever apex), 9 diaphragm and $\lambda/4$ plate, 10 focusing lens, 11 Wollaston prism, 12 quadrant photodiode, 13 differential amplifier. **(e)** Beam-deflection readout

between object and reference beam is established. Another Wollaston prism separates reference and object beams again for analysis with a four-quadrant photodiode. A differential amplifier is used to obtain the cantilever deflection with high accuracy. However, the interferometry setup is quite bulky and difficult to handle.

Optical (Beam-Deflection) Readout
